

35 environmental conditions. We conclude that the benthic silicon cycle is more complex than
36 previously thought and that additional Si isotope studies are needed to decipher the controls on Si
37 turnover in marine sediment and the role of sediments in the marine silicon cycle.

38

39 KEYWORDS: Si isotopes, reverse weathering, hydrothermal system, oxygen minimum zone,
40 environmental conditions

41

42 1. INTRODUCTION

43

44 Silicon (Si) is one of the key macronutrients in the ocean mainly utilized by siliceous organisms such
45 as diatoms, radiolarians or sponges (see recent review by Sutton et al., 2018). The marine Si cycle is
46 closely linked to the carbon (C) cycle by marine siliceous organisms, which transport C to the
47 sediment and thus exert a strong control on C export from the atmosphere impacting present and
48 past climate (e.g. Lewin, 1961; Tréguer and Pondaven, 2000; Tréguer and De La Rocha, 2013; and
49 recent reviews by Frings et al., 2016 and Sutton et al., 2018). Studies of Si isotopes ($\delta^{30}\text{Si}$) have
50 revealed complex uptake and dissolution processes of siliceous organisms, which have a dominant
51 control on the $\delta^{30}\text{Si}$ distribution in ocean waters (e.g. De La Rocha et al., 1997; Varela et al., 2004;
52 Cardinal et al., 2005; Beucher et al., 2008; Fripiat et al., 2011; Ehlert et al., 2012; Grasse et al., 2013;
53 Sutton et al., 2013; de Souza et al., 2014, 2015). Diatoms constitute the largest part of the Si cycling
54 fluxes in the ocean (Ragueneau et al., 2000) and discriminate between its isotopes during Si uptake,
55 whereby the light isotopes are preferentially incorporated into the diatom frustules (e.g. De La Rocha
56 et al., 1997). Si isotope fractionation during Si uptake is dependent on e.g. the diatom species, the
57 availability of Fe, and the degree of Si utilization. Fractionation factors between -0.5 and -2.1‰ have
58 been derived from regional water mass mixing and laboratory studies (De La Rocha et al., 1997;
59 Varela et al., 2004; Cardinal et al., 2005; Beucher et al., 2008; Sutton et al., 2013; Meyerink et al.,
60 2017).

61 After a planktonic bloom whereupon the nutrients are exhausted, biogenic silica (bSiO_2 , mainly
62 diatoms) sinks through the ocean, partially dissolves and accumulates on the seafloor, where its
63 preservation and recycling is controlled by dissolution and Si re-precipitation processes. The
64 dissolution of bSiO_2 mainly controls the accumulation of silicic acid (Si(OH)_4) in pore fluids, although
65 the in-situ concentration remains below the equilibrium concentration of dissolved bSiO_2 , which has
66 been explained by simultaneous formation of authigenic silicates (e.g. McManus et al., 1995; Van
67 Cappellen and Qiu, 1997a, b; Rickert et al., 2002). This process is termed reverse weathering given
68 that the authigenic precipitates are rich in seawater-derived cations, like Na, K or Mg (Mackenzie et
69 al., 1981; Michalopoulos and Aller, 1995). Experimental studies of bSiO_2 dissolution kinetics revealed

70 a dependence of the bSiO₂ reactivity on sediment depth as well as the ratio between terrigenous
71 material and bSiO₂ (Michalopoulos and Aller, 1995; Van Cappellen and Qiu, 1997a, b; Dixit et al.,
72 2001; Rickert et al., 2002). Marine weathering of terrigenous material (primary silicates like feldspars
73 and secondary silicates like clays), was found to release cations such as aluminum (Al) or iron (Fe),
74 which reduce the solubility and dissolution rate of bSiO₂ and induce aluminosilicate precipitation
75 (Michalopoulos and Aller, 1995; Van Cappellen and Qiu, 1997a, b; Michalopoulos et al., 2000; Dixit et
76 al., 2001; Rickert et al., 2002; Loucaides et al., 2010). The accumulation of Si in pore fluids and the Si
77 reflux into bottom waters are controlled by three interdependent processes, namely: opal
78 dissolution, dissolution of terrigenous solids, precipitation of authigenic minerals.

79 Early silica diagenesis has been shown to fractionate Si isotopes as a function of the crystallization
80 state, seawater Si concentration, sedimentation rate, and terrigenous mineral content (Tatzel et al.,
81 2015; Geilert et al., 2016). Since the light ²⁸Si isotope is more reactive compared to the heavier
82 isotopes (²⁹Si, ³⁰Si), processes such as reverse weathering, adsorption, and direct Si precipitation
83 from saturated solutions show low δ³⁰Si values in the reaction product and high δ³⁰Si values in its
84 substrate (i. e. fluids) (e.g. Georg et al., 2006a, 2009; Delstanche et al., 2009; Opfergelt et al., 2013;
85 Geilert et al., 2014; Roerdink et al., 2015; Ehlert et al., 2016). The few modelling and experimental
86 studies, addressing Si isotope fractionation during formation of secondary phases, report isotope
87 fractionation factors between -1.6 and -2‰ (Ziegler et al., 2005; Méheut et al., 2007; Dupuis et al.,
88 2015; Ehlert et al., 2016).

89 The δ³⁰Si data for marine pore fluids from the Peruvian margin upwelling region, which is
90 characterized by very high diatom productivity and bSiO₂-rich sediments (Abrantes et al., 2007;
91 Bruland et al., 2005), agree with these findings and clearly indicate Si isotope fractionation as a
92 consequence of authigenic aluminosilicate precipitation accompanied by a Si isotope fractionation
93 factor of -2.0‰ (Ehlert et al., 2016). Also pore fluids from the Greenland margin and Labrador Sea
94 reflect early diagenetic reactions detected by pore fluid δ³⁰Si values (between +0.76 and +2.08‰)
95 and the δ³⁰Si values were interpreted as the product of reverse weathering reactions (Ng et al.,
96 2020). In this study, the Guaymas Basin in the Gulf of California was chosen as study area, as it is
97 characterized by a relatively high diatom productivity and sediments that are predominantly
98 composed of diatomaceous muds (up to 50% diatoms; Kastner and Siever, 1983). Moreover, the
99 Guaymas Basin in the Gulf of California is influenced by hydrothermal activity (e.g. Von Damm, 1990).

100 These bSiO₂-rich sediments are thus ideal for dedicated studies of early diagenesis under the
101 influence of different thermal and redox conditions. We investigated the processes controlling Si
102 isotope fractionation during early diagenesis based on pore fluid and bSiO₂ data from three
103 fundamentally different environmental settings within the Guaymas Basin including the deep basin, a
104 hydrothermal site, and a site within the Oxygen Minimum Zone (OMZ) on the slope of the Guaymas

105 Basin (Fig. 1). In addition, the Si isotope composition of the water column, bottom waters, and
106 hydrothermal fluids was determined. A numerical transport-reaction model was applied to the OMZ
107 setting to constrain marine weathering processes and to compare the results to the Peruvian margin.
108 The aim of this study was to constrain the factors controlling Si isotope fractionation during early
109 diagenesis and to identify processes influencing bSiO_2 dissolution and authigenic silicate
110 precipitation.

111

112 2. GEOLOGICAL SETTING, SAMPLING, AND METHODS

113

114 2.1 Geological setting

115

116 The Guaymas Basin in the Gulf of California is a currently opening continental rifting environment
117 with two graben systems (northern and southern trough), which are offset by a transform fault and
118 reaches spreading rates of up to 6 cm yr^{-1} (Calvert, 1966). High biological productivity and
119 terrigenous matter input result in high sediment accumulation rates and have produced thick
120 sequences of organic-rich sediments (DeMaster, 1981). Siliceous sediments at the Guaymas Slope
121 show fine laminations within the OMZ (dissolved oxygen $<10 \mu\text{M}$ at ca. 500 – 900 m water depth;
122 Campbell and Gieskes, 1984) due to the absence of burrowing organisms (Calvert, 1964). The
123 Guaymas Basin is characterized by vigorous hydrothermal activity represented by Black Smoker type
124 vents discovered in both the northern and southern troughs (Berndt et al., 2016; Von Damm et al.,
125 1985). Hydrothermal plumes spread horizontally and mix with deep basin water up to 300 m above
126 the seafloor resulting in a fraction of hydrothermal fluids of $\sim 0.1\%$ in the deep waters of the
127 Guaymas Basin (Campbell and Gieskes, 1984). Hydrothermal sills and dikes intruding into the
128 sediments were found to accelerate early diagenetic reactions (due to the released heat) and change
129 pore fluid geochemistry significantly (Gieskes et al., 1982; Kastner and Siever, 1983; Von Damm et al.,
130 1985; Von Damm, 1990). At present, pore fluids in surface sediments show a seawater composition
131 (Geilert et al., 2018) and the absence of diagenetic high-temperature processes render these pore
132 fluids suitable for studying recent early diagenetic processes.

133

134 2.2 Sampling

135

136 Sediments were sampled via multicorer (MUC) deployment during RV SONNE cruise SO241 in
137 summer 2015 as described in detail in Geilert et al. (2018). In total, 6 stations have been investigated;
138 4 within the basin (termed basin sites: MUC33-11, MUC22-04, MUC23-05, MUC15-02), one in the
139 vicinity of a hydrothermal vent field (termed hydrothermal site: MUC66-16), and one within the OMZ

140 (termed OMZ site: MUC29-09) (Fig. 1, Table 1). The coring locations within the basin were sampled in
141 water depths between 1726 and 1855 m below sea level (mbsl). The hydrothermal site (MUC66-16)
142 was sampled in 1842 mbsl and was located at a distance of ~500 m from the active hydrothermal
143 mound described by Berndt et al. (2016). The OMZ site (MUC29-09) was sampled on the Guaymas
144 Basin slope of the Mexican mainland in 665 mbsl.

145 After core retrieval, bottom water above the sediment was sampled and filtered immediately using
146 0.2 μm cellulose acetate membrane filters. Bottom water from MUC22-04 may have been
147 contaminated with surface waters during core retrieval as indicated by Si and Mn concentrations
148 (53.8 μM and 0.05 μM , respectively) lower than at the remaining sites within the deep basin, which
149 show distinct anomalies caused by mixing with hydrothermal plume fluids (e.g. MUC15-02: Si = 177.8
150 μM and Mn = 0.34 μM). Processing of sediments was conducted in a cool laboratory in an argon-
151 flushed glove bag immediately after core retrieval. Sampling intervals were 1-5 cm with the highest
152 resolution close to the sediment surface and increasing distance downcore. Pore fluids were
153 separated from sediments by centrifugation (20 min at 4500 rpm) and subsequently filtered (0.2 μm
154 cellulose acetate membrane filters) for further analyses.

155
156 Water column samples were taken using a video-guided Niskin Water sampler CTD-Rosette System.
157 Water samples were taken in the basin above MUC15-02 at 1844 mbsl (VCTD02), within the
158 hydrothermal plume between 1781 and 1800 mbsl (VCTD06 and 09) above the Black Smoker mound
159 as described in Berndt et al. (2016), and above the OMZ site (MUC29-09) at 586 mbsl (Fig. 1).

160 161 2.3 bSiO₂ separation and digestion

162
163 The bSiO₂ mass fractions of sediment samples were determined using an automated leaching
164 method following Müller and Schneider (1993) at GEOMAR Helmholtz-Centre for Ocean Research
165 Kiel. The sample material was treated with 1M NaOH at 85°C to extract the opal fraction. The
166 increase in dissolved Si was monitored and evaluated using a method described by DeMaster (1981).
167 The precision of the mass fraction determination was 5 to 10% (1SD). The bSiO₂ was separated from
168 the sediment for Si isotope analyses following the method of Morley et al. (2004). About 500 mg of a
169 freeze-dried sediment sample was transferred into a centrifuge tube. Organic matter and carbonate
170 material was removed by adding H₂O₂ (Suprapur) and HCl, respectively. Clay particles (grain size
171 <2 μm) were separated from the remaining sediment by the Atterberg method following Stoke's law
172 (Müller, 1967). The remaining sediment (bSiO₂ and heavy minerals) was sieved using a 5 μm -sieve
173 and subsequently separated from the remaining detritus using heavy liquid separation (sodium-
174 polytungstate solution). The heavy liquid purification method was repeated until clean, examined via

175 light microscopy, bSiO₂ samples (>95%) were obtained. Light microscopy revealed that the bSiO₂
176 fraction essentially consisted of diatoms and only traces of radiolarians and sponges were present
177 (<5%). The bSiO₂ samples were stored in Milli-Q water (MQ water). The bSiO₂ sample of the OMZ site
178 stems from a nearby gravity core (GC07), which is described in detail in Geilert et al. (2018). The
179 bSiO₂ samples were dissolved following a method by Reynolds et al. (2008). Aliquots of the cleaned
180 bSiO₂ samples were transferred into Teflon vials and dried on a hot plate. Drying of the samples was
181 shown by Ehlert et al. (2012) to have no effect the Si isotope composition of the samples.
182 Subsequently, 1 ml of 0.1 M NaOH was added and the samples were placed on a hot plate at 130°C
183 for 24 hours. After sample digestion, the supernatant and residue (undissolved traces of radiolarians
184 and sponges) were separated via centrifugation. The supernatant was treated with 200 µl H₂O₂
185 (Suprapur) in order to remove remaining organic matter and then dried and re-dissolved in 1 ml 0.1
186 M NaOH at 130°C for 24 hours. After the digestion procedure, the samples were diluted with MQ
187 water and neutralized with 1 M HCl.

188

189 2.4 XRD measurements

190

191 X-ray diffraction analyses of the dried clay samples were performed at the Central Laboratory for
192 Crystallography and Applied Material Science, ZEKAM, dept. of Geosciences, University Bremen,
193 using a Philips X'Pert Pro multipurpose diffractometer. The diffractometer was equipped with a Cu-
194 tube, a fixed divergent slit of $\frac{1}{4}^\circ$, a secondary Ni filter, and a X'Celerator detector system. A
195 continuous scan from 3 to 85° 2θ was applied for the measurements with a calculated step size of
196 0.016° 2θ (calculated time per step was 50 seconds). Quantification of mineral phases were based on
197 the Philips software X'Pert High Score™, the freely available X-ray diffraction software MacDiff 4.25
198 (Petschick et al., 1996), and the QUAX full-pattern method after Vogt et al. (2002). The standard
199 deviation is ±1-3% for well crystallized minerals (see also Vogt et al., 2002) and ±5% for the remaining
200 mineral phases.

201

202 2.5 Geochemical analyses of fluid and solid phases

203

204 Analyses of major and trace element concentrations of pore fluids from the basin sites and the
205 hydrothermal site as well as the water column are described in Geilert et al. (2018). OMZ site pore
206 fluids were treated in the same way. In brief, the pore fluids were analysed onboard by photometry
207 (NH₄) and on shore for dissolved anions (Cl) and cations (Si, K, Na, Mg) using ion chromatography (IC,
208 METROHM 761 Compact, conductivity mode) and inductively coupled plasma optical emission
209 spectrometry (ICP-OES, VARIAN 720-ES), respectively. Analytical precision was constrained using the

210 IAPSO seawater standard for all chemical analyses (Gieskes et al., 1991) and was found to be <1% for
211 Cl, <2% for K, Na, Mg, and <5% for Si.

212
213 Freeze dried and ground sediment samples were digested in HF (40% Suprapur), HNO₃ (Suprapur),
214 and HClO₄ (60% p.a.) for major element analyses. The accuracy of the method was tested by method
215 blanks and the reference standards SDO-1 (Devonian Ohio Shale, USGS) and MESS-3 (Marine
216 Sediment Reference Material, Canadian Research Council). The digested samples were measured for
217 their K and Al contents by ICP-OES (VARIAN 720-ES) and reproducibility was ≤5%. Total carbon (TC)
218 and total organic carbon (TOC) were measured in freeze-dried and ground sediment samples by flash
219 combustion using the Carlo Erba Element Analyzer (NA-1500). Carbonate carbon (CaCO₃) was
220 calculated by subtracting TOC from TC.

221
222 The digested bSiO₂ samples were analyzed for their Al and Si contents using the Agilent 7500 series
223 quadrupole ICPMS at GEOMAR to provide information about potential clay contamination of the
224 separated bSiO₂ fraction (Shemesh et al., 1988), whereby Al/Si ratios below 50 mM/M are considered
225 as negligible clay contamination (van Bennekom et al., 1988; Hurd, 1973). Al/Si ratios in the studied
226 bSiO₂ ranged between 15 and 39 mM/M, with three exceptions in MUC22-04, MUC15-02, and
227 MUC66-16 yielding Al/Si ratios of 71 mM/M, 57 mM/M, 50 mM/M, respectively. However, all
228 $\delta^{30}\text{Si}_{\text{bSiO}_2}$ values agreed well with surrounding $\delta^{30}\text{Si}_{\text{bSiO}_2}$ values and clay contamination is thus
229 considered unimportant. All other bSiO₂ samples are considered clay-free.

230 231 2.6 Sample purification and Si isotope measurements

232
233 Fluid and digested bSiO₂ samples were prepared for Si isotope measurements following the
234 purification method of Georg et al. (2006b). The concentration of the samples was adjusted and
235 loaded (1 ml with ~64 μM Si) onto 1 ml pre-cleaned cation-exchange resin (Biorad AG50 W-X8) and
236 subsequently eluted with 2 ml MQ water. Matrix effects originating from dissolved organic
237 compounds and anions, which cannot be separated by this purification method, have previously
238 been found to potentially influence Si isotope measurements (van den Boorn et al., 2009; Hughes et
239 al., 2011). However, no influence of the matrix effects on pore fluid Si isotope measurements has
240 been found during our measurements following several tests described in Ehlert et al. (2016). Briefly,
241 Ehlert et al. (2016) removed organic compounds by H₂O₂ and SO₄ by Ba addition yielding $\delta^{30}\text{Si}$ values
242 identical to untreated samples, within error. Therefore, our samples were not treated with H₂O₂ or
243 Ba before sample purification and Si isotope measurements.

244 Si isotope samples were measured in medium resolution on a NuPlasma MC-ICPMS (Nu
245 InstrumentsTM, Wrexham, UK) at GEOMAR using the Cetac Aridus II desolvator. Sample Si
246 concentrations of about 21 μM resulted in a ^{28}Si intensity of 3 to 4 V. The MQ blank was $\leq 3\text{mV}$,
247 resulting in a blank to signal ratio $<0.1\%$. The measurements were performed using the standard-
248 sample bracketing method to account for mass bias drifts of the instrument (Albarède et al., 2004). Si
249 isotopes are reported in the $\delta^{30}\text{Si}$ notation, representing the deviation of the sample $^{30}\text{Si}/^{28}\text{Si}$ from
250 that of the international Si standard NBS28 in permil (‰). Long-term $\delta^{30}\text{Si}$ values of the reference
251 materials Big Batch ($-10.6\pm 0.2\text{‰}$; 2SD; n=49), IRMM018 ($-1.5\pm 0.2\text{‰}$; 2SD; n=48), Diatomite
252 ($+1.3\pm 0.2\text{‰}$; 2SD; n=44), and BHVO-2 ($-0.3\pm 0.2\text{‰}$; 2SD; n=13) are in good agreement with $\delta^{30}\text{Si}$
253 values in the literature (e.g. Reynolds et al., 2007; Zambardi and Poitrasson, 2011). The seawater
254 inter-calibration standard Aloha (1000 m) resulted in $+1.3\pm 0.2\text{‰}$ (2SD; n=8) in very good agreement
255 to Grasse et al. (2017). Additionally, two in-house matrix standards have been measured. The pore
256 fluid matrix standard yielded an average $\delta^{30}\text{Si}$ value of $+1.3\pm 0.2\text{‰}$ (2SD; n=17) and the diatom matrix
257 standard (*E. rex*) $-1.0\pm 0.2\text{‰}$ (2SD; n=22), which agrees well with earlier reported values (Ehlert et al.,
258 2016). All samples were measured 2-4 times on different days and the resulting $\delta^{30}\text{Si}$ values have
259 uncertainties between 0.1 and 0.4‰ (2SD, Table 1). The $\delta^{30}\text{Si}$ values of pore fluids, bSiO_2 , and bottom
260 water are given as $\delta^{30}\text{Si}_{\text{pf}}$, $\delta^{30}\text{Si}_{\text{bSiO}_2}$, and $\delta^{30}\text{Si}_{\text{bw}}$, respectively. Error bars in the figures indicate the
261 uncertainty of the individual sample measurements (two standard deviation, 2SD).

262

263 2.7 Numerical model

264

265 A numerical reactive-transport model was applied to simulate Si turnover within OMZ site sediments.
266 The model was based on a previously published Si isotope model (Ehlert et al., 2016) and was
267 extended to consider the dissolution of additional phases. A detailed description of the model can be
268 found in the supplementary information.

269

270 2.8 Calculation of the amount of terrigenous material and mass accumulation rate

271

272 The amount of terrigenous material (%) for the Guaymas Basin was calculated as the total mass
273 subtracted by the carbonate content (CaCO_3), the organic matter content (OC), and the bSiO_2 content
274 (Sayles et al., 2001):

275

$$276 \text{Terrigenous material} = 100 - (\text{CaCO}_3 + \text{OC} + \text{bSiO}_2) \quad (1)$$

277

278 The mass accumulation rate (MAR) was calculated as

$$\text{MAR} = S \cdot d \cdot (1 - \Phi) \quad (2)$$

with S the sedimentation rate as 0.18 cm yr^{-1} (Thunell et al., 1994) and d the bulk dry density as 2.5 g cm^{-3} . The porosity (Φ) was taken at the deepest part of the core with 0.925.

3. RESULTS

3.1 Water chemistry and sediment composition

All water column, pore fluid, and hydrothermal Si concentration data, bSiO_2 weight fractions as well as Si isotope values are reported in Tables 1 and 2. A detailed description of the water column properties, pore fluids, and hydrothermal fluid chemistry can be found in Berndt et al. (2016) and Geilert et al. (2018). Pore fluids predominantly show a seawater composition at all sampling sites and are not influenced by high temperature processes related to sill intrusions or mixing with hydrothermal fluids. Pore fluid geochemistry of major elements in the OMZ resembles that of the remaining sampling sites with the exception of a strong enrichment in NH_4 (Table S1 and Geilert et al., 2018) as well as high Fe and low Mn concentrations (Scholz et al., 2019). The porosity corrected K (see supplement) and Al contents in the sediments ranged between 0.9 and 21.2 wt% and 2.9 and 66.6 wt%, respectively (Table 1). The TOC contents ranged between 0.3 and 7.8 % and are shown in Table S1.

3.2 Bottom water, water column, and hydrothermal fluid Si concentrations and $\delta^{30}\text{Si}$ values

The bottom water Si concentration ranged between 173 and 254 μM for all basin sites and the hydrothermal site (between 1726 and 1855 mbsl) with the exception of MUC22-04, where Si concentrations were as low as 54 μM (possible surface water contamination, see section 2.2 and Table 1). The bottom water $\delta^{30}\text{Si}_{\text{bw}}$ signatures ranged between +1.5‰ and +2.0‰ for all basin sites and the hydrothermal site and overlap within error (average $\delta^{30}\text{Si}_{\text{bw}}$: $+1.8 \pm 0.2\text{‰}$, 1SD; highest $\delta^{30}\text{Si}_{\text{bw}}$ for surface contaminated sample (MUC22-04)). Bottom water Si concentration for the OMZ site was 31 μM (665m water depth). The bottom water within the OMZ site had a distinctly lower $\delta^{30}\text{Si}_{\text{bw}}$ value of +0.8‰. Here, a potential contamination with surface waters can be excluded given that they are characterized by high $\delta^{30}\text{Si}$ values (from 1.7 to 4.4‰; Ehlert et al., 2012; Grasse et al., 2013), due to the preferential biological uptake of ^{28}Si (De La Rocha et al., 1997).

314 The basin water (VCTD02), which was sampled about 1 m above the seafloor, had a Si concentration
315 of 163 μM and a $\delta^{30}\text{Si}_{\text{deepBasin}}$ value of +1.5‰. Hydrothermal plume Si concentrations ranged between
316 253 and 690 μM and $\delta^{30}\text{Si}$ values ranged from +0.7‰ (VCTD09-06) to +1.4‰ (VCTD06-06). The water
317 column within the OMZ (586 mbsl) had a Si concentration of 78 μM and a $\delta^{30}\text{Si}_{\text{OMZ}}$ value of +1.5‰
318 (Table 2).

319

320 3.3 Pore fluid Si concentration and $\delta^{30}\text{Si}_{\text{pf}}$ values

321

322 Pore fluid Si concentrations generally increased asymptotically with depth from bottom water values
323 until reaching maximum average concentrations between 605 and 864 μM Si (Table 1, Fig. 2). For the
324 basin sites MUC33-11 and MUC15-02 as well as the OMZ site the Si concentrations asymptotically
325 increased until average values of 742 (≥ 8 cm below seafloor (cmbsf)), 729 (≥ 9 cmbsf), and 765 (≥ 9
326 cmbsf) μM were reached, respectively. Hydrothermal site Si concentrations were higher and
327 increased to 864 μM (≥ 4.5 cmbsf). MUC22-04 and MUC23-05 Si concentrations initially increased to
328 values of on average 605 μM (5.5 - 11 cmbsf) and 735 μM (3.5 - 9 cmbsf) and then decreased again to
329 364 μM (26 cmbsf) and 640 μM (22 cmbsf), respectively.

330

331 Pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values for all basin sites ranged from +0.9‰ to +1.5‰ (Table 1, Fig. 2), which is
332 lower than the respective bottom water $\delta^{30}\text{Si}_{\text{BW}}$ values ($\delta^{30}\text{Si}_{\text{BW}}$ from +1.6‰ to +2.0‰). The decrease
333 in Si concentration at MUC22-04 and MUC23-05 below 13 cmbsf and 11 cmbsf, respectively, is
334 not reflected in a significant change in $\delta^{30}\text{Si}_{\text{pf}}$. The hydrothermal site showed the highest $\delta^{30}\text{Si}_{\text{pf}}$ values
335 ranging from +1.8‰ and +2.2‰, which is higher than the bottom water $\delta^{30}\text{Si}_{\text{BW}}$ (+1.5‰). In contrast,
336 the OMZ site had the lowest $\delta^{30}\text{Si}_{\text{pf}}$ values between -0.5‰ and +0.8‰, which was also characterized
337 by very low $\delta^{30}\text{Si}_{\text{bw}}$ (+0.8‰; Table 1).

338

339 3.4 bSiO₂ content and $\delta^{30}\text{Si}_{\text{bSiO}_2}$ values

340

341 The bSiO₂ content of the sediments (Table 1, Fig. 2) varied between 4.7 wt% and 47.6 wt%. Lowest
342 contents were present at the basin site MUC22-04 (7.6 -13.1 wt%) and the hydrothermal site (4.7 -
343 14.6 wt%). The remaining sampling sites showed higher bSiO₂ contents of on average 23 \pm 7 wt%
344 (1SD). The $\delta^{30}\text{Si}_{\text{bSiO}_2}$ signatures ranged between +0.4‰ and +1.0‰ and did not vary systematically
345 with depth or sampling site within error. The small variability in $\delta^{30}\text{Si}_{\text{bSiO}_2}$ signatures most likely stems
346 from natural variability within the Guaymas Basin.

347

348 3.5 XRD results of the clay fraction

349

350 The main silicate mineral phases of all samples were phyllosilicates (16-59 wt%), primary silicates
351 (quartz, plagioclase, potassium feldspar; 15-38 wt%), and amorphous SiO₂ (4-43 wt% including
352 abiogenic and biogenic opal) (Table S2). The phyllosilicates were mainly composed of variable
353 fractions of smectite, illite, montmorillonite, and kaolinite. Apart from silicate minerals, minor
354 amounts of Fe-(hydr-)oxides (≤10 wt%, most between 2 and 3 wt%), pyroxenes (≤8 wt%), and
355 carbonates (≤6 wt%) were present. Biogenic opal fragments were identified via light microscopy to
356 be the dominating amorphous silicate phase at all sites besides the hydrothermal site and MUC23-05
357 in the basin basin. At the hydrothermal site, the abiogenic amorphous silica fraction was the
358 dominating silica phase in the uppermost and lowermost core sections with only minor occurrences
359 of biogenic opal fragments. Abiogenic amorphous silica was also found in the uppermost and
360 lowermost core sections of MUC23-05.

361

362 4. DISCUSSION

363

364 Pore fluid Si concentration and $\delta^{30}\text{Si}_{\text{pf}}$ signatures vary significantly between sampling sites and appear
365 to depend strongly on ambient conditions. The Si concentration and isotope compositions are
366 proposed to be affected by dissolution of bSiO₂, the dissolution of terrigenous phases, and the
367 formation of authigenic aluminosilicates; the latter process is defined as reverse weathering.
368 Dissolution of bSiO₂ is most effective in the reactive surface layer (≤ 10 cmbsf) where the degree of Si
369 undersaturation is highest. When Si is released into solution via bSiO₂ dissolution, certain amounts of
370 Si re-precipitate as authigenic aluminosilicates as a function of the availability of reactive metals,
371 made available by dissolution of terrigenous material (e.g. Michalopoulos and Aller, 1995; Van
372 Cappellen and Qiu, 1997a,b; Loucaides et al., 2010). In the course of this process authigenic silicate
373 precipitation induces $\delta^{30}\text{Si}$ fractionation, whereby the ²⁸Si is preferentially incorporated into the solid
374 phase, enriching the remaining fluid in ³⁰Si (Ehlert et al., 2016). In the following sections, the
375 processes during early diagenesis influencing pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ signatures under different ambient
376 conditions are discussed. For the OMZ site, we quantify these processes using a reactive transport
377 model and compare the results to the only other OMZ site where pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ data is available,
378 the Peruvian margin.

379

380 4.1. Influences on $\delta^{30}\text{Si}_{\text{pf}}$ due to source mixing

381

382 In the open ocean, a strong correlation between the inverse Si concentration (1/Si) and Si isotope
383 composition in intermediate and deep waters exists, showing low $\delta^{30}\text{Si}$ values with high Si

384 concentrations and can be used to identify water mass mixing between two endmembers with
 385 distinct Si characteristics (e.g. de Souza et al., 2012). Here, we use the two endmember mixing Eq. (3)
 386 to calculate the mixing between the deep water column and fluids originating from bSiO₂ dissolution
 387 according to

$$\delta^{30}\text{Si}_{mix} = \frac{(\delta^{30}\text{Si}_{\text{water column}} * [\text{Si}]_{\text{water column}} * f) + (\delta^{30}\text{Si}_{\text{bSiO}_2} * [\text{Si}]_{\text{bSiO}_2} * (1 - f))}{([\text{Si}]_{\text{water column}} * f) + ([\text{Si}]_{\text{bSiO}_2} * (1 - f))}$$

389 (3)

390 with $\delta^{30}\text{Si}_{\text{water column}}$ and $[\text{Si}]_{\text{water column}}$ as the respective water column Si isotope composition and
 391 concentration (Table 2) and $\delta^{30}\text{Si}_{\text{bSiO}_2}$ as the average bSiO₂ value (+0.8‰) of all sites. The equilibrium
 392 concentration in respect to bSiO₂ dissolution was derived from an experimental study by Van
 393 Cappellen and Qiu (1997a) with $[\text{Si}]_{\text{bSiO}_2} = 900\mu\text{M}$. Mixing fractions are represented by f , varied over
 394 100% water column and 0% fluids affected by bSiO₂ dissolution and vice versa.

395 Pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values of all sites deviate from mixing curves between the deep water column and
 396 fluids originating from bSiO₂ dissolution and are obviously affected by additional processes (Fig. 3). Si
 397 isotope fractionation during bSiO₂ dissolution is not well constrained and ranges between -0.55‰
 398 and 0‰, while most studies argue against a significant isotope effect (Demarest et al., 2009; Egan et
 399 al., 2012; Wetzel et al., 2014). Therefore, we will also exclude Si isotope fractionation in dependence
 400 of bSiO₂ dissolution as a process affecting pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values. The $\delta^{30}\text{Si}_{\text{pf}}$ values of the basin sites
 401 and hydrothermal site are higher (+0.9‰ to +2.2‰) compared to the respective mixing curves, while
 402 $\delta^{30}\text{Si}_{\text{pf}}$ values of the OMZ site are lower (-0.5‰ to +0.8‰). While a shift to lower $\delta^{30}\text{Si}_{\text{pf}}$ values points
 403 to dissolution of an isotopically light phase, higher $\delta^{30}\text{Si}_{\text{pf}}$ values indicate that precipitation processes
 404 are important, given that the light Si isotope is preferentially incorporated in authigenic secondary
 405 phases (Georg et al., 2009). This indicates that processes governing the pore fluid Si isotope
 406 composition differ significantly between the individual sites.

407

408 4.2. Influences on $\delta^{30}\text{Si}_{\text{pf}}$ from terrigenous and biogenic material

409

410 The terrigenous/bSiO₂ ratio was found to be the main mechanism controlling asymptotic pore fluid Si
 411 concentration and the benthic Si flux (Van Cappellen and Qiu, 1997a, b). Maximum Si concentrations
 412 were reached asymptotically at four out of six sampling sites (Fig. 2). Two sites within the basin
 413 (MUC22-04 and MUC23-05) show lower Si concentrations in the deep core sections (Fig. 2), which
 414 are most likely related to the decrease of reactive silica with depth, caused by the formation of less
 415 soluble silica phases (Van Cappellen and Qiu, 1997a). At these sites, the asymptotic Si concentration

416 is defined as the maximum concentration values in the center of the core. The amount of terrigenous
417 material for the Guaymas Basin was calculated according to Eq. (1) and accounts for 75%.

418
419 Asymptotic Si concentrations plotted against the terrigenous/bSiO₂ ratio fall on the global trend
420 except for the hydrothermal site (Fig. 4a). Here, high geothermal gradients are likely responsible for
421 the higher Si concentrations with respect to the global trend (see also section 4.3.2). In contrast to
422 the asymptotic Si concentration, no strong correlation of the pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values with the
423 terrigenous/bSiO₂ ratio exists (Fig. 4b). In order to identify processes responsible for the different
424 pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values and to facilitate comparison between the three settings within the Guaymas
425 Basin, only average $\delta^{30}\text{Si}_{\text{pf}}$ values will be discussed in the following.

426
427 Average $\delta^{30}\text{Si}_{\text{pf}}$ values show distinct variations between the individual settings. The $\delta^{30}\text{Si}_{\text{pf}}$ values of
428 the OMZ site are lower ($0.0\pm 0.5\text{‰}$, 1SD, n = 6) than those of the basin sites ($+1.2\pm 0.1\text{‰}$, 1SD, n = 17)
429 and the hydrothermal site, which shows the highest $\delta^{30}\text{Si}_{\text{pf}}$ values ($+2.0\pm 0.2\text{‰}$, 1SD, n = 3). The
430 homogeneity of the individual $\delta^{30}\text{Si}_{\text{pf}}$ profiles indicates that possible effects of bioirrigation at the
431 basin sites and hydrothermal site are quickly compensated by isotopic exchange. Similarly,
432 bioturbation has also little impact on the sediment composition given the the homogeneity of the
433 bSiO₂ content profiles with depth (Fig. 2).

434

435 4.3 Influence of the ambient environmental conditions on the $\delta^{30}\text{Si}_{\text{pf}}$ values

436

437 4.3.1 Basin sites

438

439 Pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values of the basin sites deviate from the mixing curve between the deep water
440 column and fluids originating from bSiO₂ dissolution and are shifted to higher values ($+1.2\pm 0.1\text{‰}$; Fig.
441 3). This shift to higher $\delta^{30}\text{Si}_{\text{pf}}$ values can be explained by Si re-precipitation as authigenic
442 aluminosilicates, which preferentially incorporate the light ²⁸Si isotope (Fig. 5a). Alteration of
443 terrigenous material leads to mobilization and re-precipitation of Al and the uptake of K from
444 seawater in the authigenic phase (Michalopoulos and Aller, 2004). The sedimentary K/Al ratio can
445 thus be used to detect these early diagenetic reactions in addition to pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values.
446 Authigenic aluminosilicates formed during alteration of terrigenous material were found to have K/Al
447 ratios of 0.32 (Michalopoulos and Aller, 2004), which is higher than the pristine K/Al ratio of
448 terrigenous material carried by rivers (K/Al = 0.19; Viers et al., 2009). The average K/Al ratio of the
449 basin sites is 0.34 ± 0.01 (1SD), which is in the same range as K/Al ratios indicative of authigenic
450 aluminosilicate formation (Michalopoulos and Aller, 2004). Thus, at basin sites both K/Al ratios and

451 $\delta^{30}\text{Si}_{\text{pf}}$ values are in agreement to recognize bSiO_2 dissolution followed by authigenic clay formation
452 as significant processes taking place.

453

454 4.3.2 Hydrothermal site

455

456 The $\delta^{30}\text{Si}_{\text{pf}}$ values from the hydrothermal site are higher ($+2.0\pm 0.2\text{‰}$) than the mixing curve between
457 the deep water column and fluids originating from bSiO_2 dissolution and also much higher than pore
458 fluid $\delta^{30}\text{Si}_{\text{pf}}$ values from the basin (Fig. 3, 5a). The high $\delta^{30}\text{Si}_{\text{pf}}$ values indicate that precipitation plays a
459 significant role at this site. Sedimentary K/Al ratios are equivalent to basin values ($\text{K/Al} = 0.34$) and
460 thus show the formation of authigenic aluminosilicates. Consequently, the higher pore fluid $\delta^{30}\text{Si}_{\text{pf}}$
461 values compared to the basin sites can either be explained by a different Si isotope fractionation
462 factor or by the precipitation of additional silica phases. The hydrothermal site is located in close
463 proximity to a hydrothermal vent field and hydrothermal deposits are mainly composed of Fe-
464 sulfides (Berndt et al., 2016), while nearby sediments are dominated by amorphous silica, quartz, and
465 Fe-Si silicates (e.g. ferrosilite, fayalite) (Kastner, 1982; Von Damm et al., 1985). Si adsorption to iron
466 (oxyhydr)oxide and incorporation into Fe-Si gels can create substantial Si isotope fractionation with
467 ^{28}Si being preferentially enriched in the solid phase (Delstanche et al., 2009; Zheng et al., 2016). Pore
468 fluids show high Fe^{2+} concentrations (up to $190\ \mu\text{M}$; Scholz et al., 2019) and the precipitation of Fe-Si
469 silicates is thus likely, shifting pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ to the observed high values. Saturation indices
470 calculated based on the program PHREEQC (Parkhurst and Appelo, 1999) indicate that quartz is
471 supersaturated and amorphous silica is close to saturation at about $> 6\text{ cmbsf}$ (Fig. S1). Due to the
472 dynamics of hydrothermal systems, this can be subject to changes and supersaturation of amorphous
473 silica is likely to be obtained occasionally, due to the ascent of Si enriched fluids from greater depth.
474 Gieskes et al. (1988) reported on amorphous silica cement in the hydrothermally-influenced
475 sediments of the Guaymas Basin, which is supported by findings of this study and likely explains the
476 high amorphous SiO_2 contents identified by XRD ($\sim 35\ \text{wt\%}$; see Sect. 3.5; Table S2). In the Guaymas
477 Basin, high thermal gradients (up to $11\ \text{K m}^{-1}$; Geilert et al., 2018) caused by igneous sill intrusions
478 near the active spreading center significantly influence diagenetic reactions at depth and accelerate
479 Si dissolution and precipitation (Fig. 5a) (e.g. Kastner and Siever, 1983). This can also explain the high
480 pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values, given that deep Si saturated fluids ascent and Si precipitates, likely along
481 with Fe, over a large temperature range, whereby lower temperatures are associated with larger Si
482 isotope fractionation shifting pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ to the observed high values (Geilert et al., 2014; Zheng
483 et al., 2016).

484

485 4.3.3 OMZ site

486

487 At the OMZ site, the $\delta^{30}\text{Si}_{\text{pf}}$ values are significantly lower (on average $0.0\pm 0.5\text{‰}$) than the water
488 column $\delta^{30}\text{Si}_{\text{water column}}$ value ($+1.5\pm 0.2\text{‰}$) and also lower than the $\delta^{30}\text{Si}_{\text{bSiO}_2}$ value ($+0.8\text{‰}$) (Fig. 2, 3).
489 Interestingly, the only other $\delta^{30}\text{Si}_{\text{pf}}$ values from an OMZ were obtained at the Peruvian margin (Ehlert
490 et al., 2016), where the $\delta^{30}\text{Si}_{\text{pf}}$ values in the upper 10 cmbsf are slightly higher than the water column
491 $\delta^{30}\text{Si}_{\text{bw}}$ values ($+1.8\text{‰}$ and $+1.5\text{‰}$, respectively). As Ehlert et al. (2016) concluded, the Peruvian $\delta^{30}\text{Si}_{\text{pf}}$
492 values are influenced by bSiO_2 dissolution and precipitation of authigenic aluminosilicates, the latter
493 process shifting pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ to values higher than those of the water column. Consequently, in
494 order to explain the extremely low $\delta^{30}\text{Si}_{\text{pf}}$ values at the Guaymas Basin OMZ, an additional process
495 must occur. We hypothesize that a phase enriched in ^{28}Si needs to dissolve in order to shift the pore
496 fluid $\delta^{30}\text{Si}_{\text{pf}}$ values and this phase might be 1) iron (oxyhydr)oxides with adsorbed ^{28}Si or 2) terrestrial
497 clays.

498

499 Silicon exhibits a strong affinity to iron (oxyhydr)oxides (see also section 4.3.2; Davis et al., 2002) and
500 Si isotopes fractionate significantly during Si adsorption and co-precipitation (Delstanche et al., 2009;
501 Zheng et al., 2016). Dissolved Fe^{2+} in pore fluids can be transferred across the sediment-water
502 interface via diffusion and re-precipitates as iron (oxyhydr)oxides, where it subsequently dissolves
503 again in the reducing sediment. This process can repeat, resulting in multiple cycles of Fe dissolution
504 and re-precipitation on the Guaymas Basin slope (Scholz et al., 2019). We hypothesize that the light
505 ^{28}Si adsorbs to iron (oxyhydr)oxides in the water column and that upon reductive dissolution of Fe
506 minerals in the surface sediment, the light ^{28}Si isotope is re-released into the pore fluids, adding to
507 the observed low $\delta^{30}\text{Si}_{\text{pf}}$ values. However, the quantification of this Fe-Si shuttle and the contribution
508 to the low $\delta^{30}\text{Si}_{\text{pf}}$ values in OMZ pore fluids remains difficult given that Fe undergoes multiple cycles
509 of dissolution and re-precipitation. Furthermore, the exact process of complexation, Si isotope
510 fractionation, and co-precipitation is unknown and requires further investigations (see also Fig. S3).
511 We can only speculate that the transport of ^{28}Si via the Fe-Si shuttle is only of minor importance
512 given that the MAR of bSiO_2 and terrigenous material are dominating the Si supply to Guaymas OMZ
513 sediments (Calvert, 1966; DeMaster, 1981).

514

515 The low $\delta^{30}\text{Si}_{\text{pf}}$ values can also be explained by dissolution of terrigenous clay particles, which are
516 generally enriched in ^{28}Si , showing a large range in $\delta^{30}\text{Si}$ with the majority between -3‰ to 0‰
517 (Frings et al., 2016 and references therein). Primary minerals like feldspars or olivine, which are
518 generally considered to control marine weathering reactions (e.g. Wallmann et al., 2008) have higher
519 $\delta^{30}\text{Si}$ values (e.g. feldspars with -0.15‰ ; Georg et al., 2009) and their dissolution alone cannot create
520 the low pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values (see supplement and Fig. S6). Clays are usually considered to be the

521 stable end product of silicate weathering. However, fine clay particles and highly reactive surface
522 sites of clays such as montmorillonite, smectite and illite may dissolve in natural waters (Cappelli et
523 al., 2018; Golubev et al., 2006; Köhler et al., 2005). The dissolution is promoted by organic ligands
524 and the reduction of structural iron of clay minerals under reducing conditions (Anderson and
525 Raiswell, 2004). Humic substances that are abundant in OMZ sediments enriched in organic matter
526 may catalyze the microbial reduction of structural iron in clays (Lovley et al., 1998) and their
527 dissolution (Liu et al., 2017). Clays are abundant in OMZ sediments, given that fine-grained
528 terrigenous material is transported downslope from the shelf to the basin (Scholz et al., 2019).
529 Furthermore, the microbial oxidation of ferrous Fe in these fine-grained silicate minerals and its
530 subsequent conversion to reactive iron minerals was also found to contribute to the Fe cycling at the
531 Guaymas Basin slope (Scholz et al., 2019).

532
533 In order to constrain the possibility of terrigenous clay dissolution and the related shift to low $\delta^{30}\text{Si}_{\text{pf}}$
534 values in the Guaymas OMZ a reactive transport model was applied, based on our previously
535 published $\delta^{30}\text{Si}$ model (Ehlert et al., 2016). The data obtained at the Guaymas OMZ were used to
536 model the turnover of Si in these sediments and the previously published model extended to
537 consider additional processes (Fig. 6). A full description of the model is presented in the
538 supplementary information. The model was fit to dissolved Si concentrations and $\delta^{30}\text{Si}$ values
539 measured in pore fluids and biogenic opal and K/Al ratios determined in the solid phase (Fig. 6). High
540 rates of terrigenous clay dissolution were applied at the sediment surface to reproduce the observed
541 minima in $\delta^{30}\text{Si}_{\text{pf}}$ pore fluid values and K/Al ratios in a model run best fitting our data set (Fig. 6, best
542 fit). Since the terrigenous phases deposited at the sediment surface contain potassium ($K_{\text{terr}} = 1.7$
543 wt%, K/Al = 0.19; Viers et al., 2009) and are depleted in ^{30}Si (clay $\delta^{30}\text{Si}$ (late stage weathering product)
544 = -2‰; Opfergelt et al., 2010), the dissolution of these phases induces a decline in pore fluid $\delta^{30}\text{Si}$
545 and solid phase K/Al (supplementary information). The precipitation of authigenic phases that are
546 depleted in ^{30}Si (Si isotope fractionation: $\Delta^{30}\text{Si}_{\text{au}} = -2$ ‰; Ehlert et al., 2016) and characterized by high
547 K contents (K/Al = 0.32; Michalopoulos and Aller, 2004) induces a down-core increase in pore fluid
548 $\delta^{30}\text{Si}_{\text{pf}}$ and solid phase K/Al below the surface minimum. Consequently, terrigenous clay dissolution
549 under the reducing conditions of the OMZ and subsequent authigenic aluminosilicate precipitation
550 can explain the low $\delta^{30}\text{Si}_{\text{pf}}$ values detected in Guaymas OMZ pore fluids (Fig. 5). However, our
551 model results should be regarded with caution because we applied strongly simplifying
552 assumptions (e.g. steady state, simple rate laws). Moreover, our estimates of solid phase
553 reactivity and isotopic composition are preliminary and not supported by independent data.
554

555 Additional simulations were conducted to investigate how the solid phase and pore fluid composition
556 is affected by the dissolution of terrigenous clay phases and the precipitation of authigenic phases
557 (Fig. 6) and how varying $\delta^{30}\text{Si}$ values of the dissolving terrigenous phase and Si isotope fractionation
558 factors impact pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values (Fig. S6). Furthermore, varying K/Al ratios and bSiO₂ solubilities
559 are tested (see supplement). The surface minima in pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ and solid phase K/Al disappear
560 when the dissolution rate is set to zero ($R_{\text{terr}} = 0$) while the ongoing precipitation of authigenic phases
561 leads to a strong down-core increase and high values at depth that are not consistent with the data.
562 Pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ and solid phase K/Al values strongly decrease with depth when the rate of
563 authigenic phase precipitation is set to zero ($R_{\text{au}} = 0$) such that the model yields values that are
564 significantly lower than the measured values. Dissolved Si concentrations cannot be used to further
565 constrain R_{terr} and R_{au} because they are largely controlled by the dissolution of biogenic opal (R_{opal}).
566 Dissolved K concentrations show a much lower sensitivity to R_{terr} and R_{au} than solid phase K/Al ratios
567 due to the high porosity of the OMZ sediments. Changes in dissolved K are largely eliminated by
568 molecular diffusion that is favored by the high porosity while the effect of the solid phase reactions
569 R_{terr} and R_{au} on the pore fluid composition is diminished by the low solid phase contents and the high
570 background concentration of dissolved K in ambient bottom waters. However, the model runs show
571 that the more sensitive pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ and solid phase K/Al can be used to constrain the balance
572 between the dissolution of terrigenous phases and the precipitation of authigenic phases and that
573 both reactions are required to model the low $\delta^{30}\text{Si}_{\text{pf}}$ values measured in the Guaymas OMZ.
574 Additionally, $\delta^{30}\text{Si}$ values for the dissolving terrigenous material higher than -2‰ cannot reproduce
575 the measured $\delta^{30}\text{Si}$ values in the OMZ pore fluids. Only if the fractionation factor is lowered to -1‰,
576 terrigenous material with $\delta^{30}\text{Si}$ values of -1.7‰ can produce the observed values (Fig. S6). Thus, low
577 pore fluid $\delta^{30}\text{Si}$ values in the Guaymas OMZ can only be reproduced by dissolving terrigenous clay
578 particles highly depleted in ³⁰Si.

579

580 The modelled Si isotope composition of the benthic flux is -0.97‰, which is lower than the $\delta^{30}\text{Si}$
581 value of the bottom water (+0.8‰). The higher bottom water $\delta^{30}\text{Si}$ value along with the low Si
582 concentration (~30μM), which is lower than the ambient water column Si concentration (~80μM),
583 indicates that a certain amount of Si must directly re-precipitate at the sediment water interface. Still
584 the $\delta^{30}\text{Si}$ of the bottom water is lower compared to the ambient water column, showing a benthic Si
585 flux with low $\delta^{30}\text{Si}$ values at continental margin settings, which is also in excellent agreement with
586 previously modelled and calculated $\delta^{30}\text{Si}$ values (Ehlert et al., 2016; Grasse et al., 2016). These
587 findings show that benthic Si fluxes at continental margins are a source of low $\delta^{30}\text{Si}$ values to the
588 ocean and need to be taken into account in future marine Si budget models.

589

4.4 Controlling processes and the impact on the global marine Si cycle

590
591
592 Stable and radioactive Si isotope data revealed significant sedimentary import and export processes
593 influencing the marine Si cycle (Ehlert et al., 2013, 2016; Tréguer and De La Rocha, 2013; Grasse et
594 al., 2016; Rahman et al., 2017; Sutton et al., 2018). Diatom burial removes about 9.9 Tmol yr⁻¹ Si from
595 the ocean to the sediments, however, effects of terrigenous silicate dissolution and reverse silicate
596 weathering on bSiO₂ burial, preservation, and the benthic Si flux (and its Si isotope composition) are
597 not well constrained (Sutton et al., 2018). It has previously been shown that silicate minerals dissolve
598 in deep methanogenic sediments where the dissolution process is favored by high CO₂ and organic
599 ligand concentrations in ambient pore fluids (Wallmann et al., 2008). Similar to chemical weathering
600 on land, the dissolution of terrigenous silicate phases in marine sediments leads to a release of
601 cations and the conversion of CO₂ into HCO₃⁻. Moreover, this marine weathering process provides the
602 dissolved Al that is needed for reverse weathering reactions. Our OMZ data show for the first time
603 that marine silicate weathering (dissolution of terrigenous silicates) also occurs in OMZ surface
604 sediments where it can outpace reverse weathering (precipitation of authigenic silicates). Our study
605 indicates that ambient environmental conditions appear to significantly influence the balance
606 between marine weathering and reverse weathering and thereby the Si flux back to the ocean. Pore
607 fluid δ³⁰Si_{pf} values depend on a complex interplay between bSiO₂, terrigenous silicate dissolution, and
608 authigenic aluminosilicate precipitation, however, the controlling factors that determine which
609 process dominates are difficult to constrain (Fig. 5). In view of the OMZ settings (Guaymas Basin
610 versus Peruvian margin), the most pronounced difference is the MAR_{terr} which is significantly higher
611 in the Guaymas Basin (252 g m⁻² yr⁻¹; calculated by multiplying the terrigenous content derived in Eq.
612 (1) with the MAR from Eq. (2)) than at the Peruvian margin (100 g m⁻² yr⁻¹; MAR from Ehlert et al.,
613 2016; terrigenous content calculated after Eq. (1) with 6 wt% bSiO₂, 15 wt% OC, 8 wt% CaCO₃) (Fig.
614 5a, b). The high terrigenous detritus content is supplied via rivers in the Guaymas Basin (Calvert,
615 1966; DeMaster, 1981). In combination with the high MAR_{terr} in the Guaymas OMZ, high water/rock
616 ratios (high porosity) additionally promote dissolution processes (Fig. 5). Lower MAR_{terr} and
617 water/rock ratios found in the Peruvian upwelling margin appear to limit the dissolution rate of
618 terrigenous phases and promote authigenic aluminosilicate precipitation (Fig. 5b, c), shifting pore
619 fluid δ³⁰Si_{pf} to higher values compared to the corresponding δ³⁰Si_{bSiO2} and δ³⁰Si_{bw} values. This
620 illustrates that the pore fluid δ³⁰Si_{pf} values of apparently similar settings (e.g. OMZ sites) highly
621 depend on the ambient environmental conditions and are not easily transferable.

622

4.5 Hydrothermal impact on the marine Si cycle

624

625 Findings of this study show that additional Si sources like hydrothermal input appear to affect the
626 oceanic $\delta^{30}\text{Si}$ values only in close vicinity to the hydrothermal fields. The $\delta^{30}\text{Si}$ values of the
627 hydrothermal plume (+0.7 to +1.4‰) are highly diluted by seawater ($\geq 94\%$, Table 2) and thus
628 deviate from hydrothermal fluid $\delta^{30}\text{Si}$ values (-0.3‰; De La Rocha et al., 2000). However, the
629 currently available data set regarding $\delta^{30}\text{Si}$ values of hydrothermal fluids is limited (two data points;
630 De La Rocha et al., 2000), even though they are in excellent agreement with oceanic crust $\delta^{30}\text{Si}$
631 values (-0.29‰; Savage et al., 2010), the rock through which hydrothermal fluids circulate and gain
632 their Si isotopic signature. In our data set, no correlation exists between the $\delta^{30}\text{Si}$ values and the Si
633 concentration of the hydrothermal plume (Fig. S2) and instead the $\delta^{30}\text{Si}$ values are predominantly
634 controlled by Si precipitation, likely in the hydrothermal conduit during ascent or after discharge in
635 contact with colder seawater. Temperature variations and interlinked precipitation rates were found
636 in addition to co-precipitation with Al or Fe to cause large Si fractionation such that precipitates are
637 enriched in ^{28}Si (Geilert et al., 2014, 2015; Oelze et al., 2015; Roerdink et al., 2015; Zheng et al.,
638 2016). The varying impacts of these factors can also explain why the diluted hydrothermal plume
639 $\delta^{30}\text{Si}$ values with the highest hydrothermal share (Table 2) does not show the lowest $\delta^{30}\text{Si}$ values,
640 indicative of hydrothermal fluids, given that Si is more reactive compared to Mg, the element on
641 which the hydrothermal share calculations are based (see supplement from Berndt et al., 2016). The
642 large range in hydrothermal plume $\delta^{30}\text{Si}$ values, which clearly show high degrees of seawater
643 dilution, illustrates the complexity of precipitation processes when hydrothermal fluids get in contact
644 with cold seawater and which requires further investigations especially with respect to the impact on
645 the global marine Si cycle.

646

647 5. CONCLUSIONS

648

649 Marine silicate weathering and reverse weathering impact the pore fluid isotopic composition of
650 sediments and are key processes of the marine Si cycle. In the Guaymas Basin, these processes have
651 been studied under markedly differing thermal and redox conditions. Si isotope compositions of pore
652 fluids combined with those of biogenic silica and ambient bottom waters helped to decipher marine
653 weathering and reverse weathering reactions, which would have remained undetected by elemental
654 concentrations alone and highlight the importance of Si isotope studies to constrain early diagenetic
655 reactions. Si concentrations and $\delta^{30}\text{Si}_{\text{pf}}$ signatures are the result of the interplay between silica
656 dissolution and Si precipitation, however, the involved phases differ significantly between the study
657 sites. Large differences in $\delta^{30}\text{Si}_{\text{pf}}$ values in a regionally constrained basin show that oxic/anoxic
658 conditions, hydrothermal fluids, water/rock ratios and the input of terrigenous material strongly
659 affect the pathways and turnover rates of Si in marine sediments. The light $\delta^{30}\text{Si}_{\text{pf}}$ and $\delta^{30}\text{Si}_{\text{BW}}$ values

660 from the Guaymas OMZ confirm earlier studies suggesting a light Si isotope value of the benthic Si
661 flux (Ehlert et al., 2016; Grasse et al., 2016), which need to be taken into account in future oceanic
662 mass balances of Si and in modelling studies concerning the isotopic Si cycle. Environmental settings,
663 in particular the MARs of terrigenous material, water/rock ratios, and redox conditions appear to be
664 the major factors controlling the balance between marine silicate weathering and reverse
665 weathering and the Si isotope fractionation in pore fluids of marine sedimentary settings and need to
666 be considered particularly in marine Si isotope studies.

667

668 AUTHOR CONTRIBUTION

669

670 SG, CH, MS, and FS helped sampling and processing of the samples onboard. SG, PG, and KD
671 conducted the Si isotope measurements. SG, CE, PG, KD, FS, and MF helped interpreting the data.
672 KW designed the reactive transport model. SG prepared the manuscript with the contribution of all
673 authors.

674

675 COMPETING INTEREST

676

677 The authors declare that they have no conflict of interest.

678

679 ACKNOWLEDGEMENTS

680

681 This work was part of the MAKS project funded by the German Ministry of Science and Education
682 (BMBF). We appreciate the support of the master and crew of the R/V Sonne during the SO241
683 cruise. We thank Regina Surberg, Bettina Domeyer, and Anke Bleyer for analytical support during the
684 cruise and on shore. Further thanks go to Tabitha Riff, Jutta Heinze, and Tyler Goepfert. Additional
685 support of this work was provided by EU-COST Action ES1301 "FLOWS" (www.flows-cost.eu) and the
686 German Collaborative Research Centre (SFB) 754: Climate – Biogeochemistry Interactions in the
687 Tropical Ocean funded by the German Science Foundation. We would also like to thank an
688 anonymous reviewer, Jill Sutton, and Damien Cardinal for their comments and constructive reviews.

1010 **Tables**

1011

1012 Table 1: Pore fluid Si concentration (μM), $\delta^{30}\text{Si}_{\text{pf}}$ values (‰) as well as biogenic silica weight fraction
1013 (bSiO_2 in wt%), Al/Si ratio (mM/M), $\delta^{30}\text{Si}_{\text{bSiO}_2}$ values (‰), porosity (\emptyset), Al and K contents (wt%) for the
1014 basin sites, hydrothermal site, and OMZ site.

1015

1016 Table 2: Water column and hydrothermal plume Si concentration (μM) and Si isotope values (‰).
1017 Additionally, the share of hydrothermal fluids within the hydrothermal plume is given based on the
1018 calculation provided by Berndt et al. (2016) in their supplementary materials.

1019

1020 **Figures**

1021

1022 Fig. 1. A) Location map of the sampling stations in the Guaymas Basin, Gulf of California. Black square
1023 in the overview map indicates the sampling area. B) Sedimentary bSiO_2 content at each sampling
1024 station. Water column stations were above MUC15-02 (VCTD02) in the basin, the hydrothermal site
1025 (VCTD06, 09), and at the OMZ site (VCTD07).

1026

1027 Fig 2: Depth (cmbsf) profiles for all stations for pore fluid Si concentration ($\text{Si}(\text{OH})_4$) in μM (grey
1028 symbols) and $\delta^{30}\text{Si}_{\text{pf}}$ values (colored symbols) and biogenic opal weight fraction (bSiO_2) in wt% (grey
1029 symbols) and $\delta^{30}\text{Si}_{\text{bSiO}_2}$ values (colored symbols). The dashed line is the $\delta^{30}\text{Si}$ value of the deep basin
1030 (VCTD02) and the dotted line represents the $\delta^{30}\text{Si}$ value of the water column in the OMZ (VCTD07).
1031 The uppermost Si isotope data point in the pore fluid diagrams refers to the bottom water (labelled
1032 BW). Note the different depth scale for the OMZ site. The brackets around the MUC22-04 bottom
1033 water Si concentration value indicate possible surface water contamination. Error bars not indicated
1034 are within symbol size. The long-term error (2SD) of international standards is indicated in the upper
1035 right $\delta^{30}\text{Si}_{\text{pf}}$ -depth profile.

1036

1037 Fig. 3. Pore fluid $\delta^{30}\text{Si}$ values are displayed versus the inverse Si concentration ($1/\text{Si}$) for the basin
1038 sites, the hydrothermal site, and the OMZ site. Error bars not indicated are within symbol size. Mixing
1039 curves are calculated after Eq. (3) between the respective water column and the average bSiO_2 $\delta^{30}\text{Si}$
1040 value for all sites (see text for details). The grey shaded area indicates the uncertainty on the
1041 equilibrium solubility of bSiO_2 assuming $900\pm 150\mu\text{M}$ following Van Cappellen and Qiu(1997a).

1042

1043 Fig. 4. Asymptotic Si concentration (a) and the pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values (b) as a function of the
1044 terrigenous/ bSiO_2 ratio for the basin sites, the hydrothermal site, and the OMZ site in the Guaymas

1045 Basin. An exponential increase in Si concentrations with decreasing terrigenous/bSiO₂ ratio is
1046 observed, which is not reflected by corresponding systematic changes in $\delta^{30}\text{Si}_{\text{pf}}$. The values for the
1047 terrigenous/bSiO₂ ratio defining the global trend (grey dots) are from the Southern Ocean, Scotia
1048 Sea, Norwegian Sea, NE Atlantic, Juan de Fuca Ridge, Arabian Sea, and the Peru Basin (Van Cappellen
1049 and Qiu, 1997a; Rabouille et al., 1997; Rickert, 2000).

1050

1051 Fig. 5. Conceptual model of the processes influencing pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values in the Guaymas Basin
1052 (a) and the Peruvian margin after Ehlert et al. (2016) (b). Bold values in the sediment show the
1053 average pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values. Arrow length indicates the dominating process (dissolution versus
1054 precipitation). The $\delta^{30}\text{Si}$ values in the hydrothermal plume indicate dilution with seawater (see
1055 section 4.5). (c) The average pore fluid $\delta^{30}\text{Si}_{\text{pf}}$ values are shown, indicating the dominance of
1056 precipitation or dissolution processes for the three settings in the Guaymas Basin and the Peruvian
1057 OMZ.

1058

1059 Fig. 6. Data and model results for OMZ core. a: Porosity. b: Biogenic opal concentration in solid
1060 phase. c: K/Al ratio in solid phase. d: Dissolved Si concentration in pore fluids. e: Dissolved potassium
1061 in pore fluids. f: Isotopic composition of dissolved Si. g: rate of biogenic opal dissolution. h: Rate of
1062 authigenic phase precipitation. i: Rate of terrigenous phase dissolution. Sensitivity tests of the model
1063 are indicated by setting the dissolution of terrigenous clay phases to zero (red dashed line) and
1064 setting the precipitation of authigenic phases to zero (black dashed line). The model values agree
1065 best to the measured data when both processes take place (blue line, best fit).

Table 1

Station/MUC#/ Station name	Latitude (N) / Longitude (W)	Water depth (m)	Depth (cmbsf)	Pore fluid			Sediment
