

32 between reference and experimental areas, but the dominant fish, *I. meadi*, still exhibited much  
33 lower densities in ploughed habitat, likely avoiding these areas and suggesting that the fish  
34 community remains affected after decades. At the scale of industrial mining, these results could  
35 translate to population level effects. . The scavenging community was dominated by eelpouts  
36 (*Pachycara* spp), hermit crabs (*Probeebei mirabilis*) and shrimp. The large contribution of  
37 hermit crabs appears unique amongst abyssal scavenger studies worldwide. The abyssal fish  
38 community at DISCOL was similar to that in the more northerly Clarion Clipperton Zone,  
39 though some species have only been observed at DISCOL thus far. Also, further species level  
40 identifications are required to refine this assessment. Additional studies across the polymetallic  
41 nodule provinces of the Pacific are required to further evaluate the environmental drivers of fish  
42 density, diversity and species biogeographies. This information will be important for the  
43 development of appropriate management plans aimed at minimizing human impact from deep-  
44 sea mining.

45

## 46 **1. Introduction**

47           The world's oceans are becoming increasingly exploited for their resources, and  
48 anthropogenic effects now reach the farthest corners and depths of ocean ecosystems (Ramirez-  
49 Llodra et al., 2011). New uses of our oceans are emerging. Industrial interest in deep-sea  
50 mineral extraction is at an all-time high, accelerated by global demand for minerals such as  
51 cobalt, zinc, copper, nickel, and rare-earth elements, which are enriched in seamount crusts as  
52 well as manganese nodules and deposited at hydrothermal vents. Currently, the International  
53 Seabed Authority has granted 29 exploration contracts to companies to explore for metals and  
54 rare-earth minerals in areas totaling >1,200,000 km<sup>2</sup> of seafloor in the Pacific, Atlantic, and  
55 Indian Oceans ([www.isa.org.jm](http://www.isa.org.jm)). Though the current intensity of commercial interest combined  
56 with technological innovations will soon lead to exploitation, this idea has a long history. Thus  
57 several seafloor ecosystem disturbance experiments were performed beginning in the 1970's  
58 (reviewed in Jones et al., 2017).

59           One of these, the DISturbance and reCOLonization experiment (DISCOL) was conducted  
60 in the Peru Basin in 1989. A large experimental seafloor disturbance was created by repeatedly  
61 ploughing the seafloor. Biological surveys were conducted prior to the disturbance and several  
62 times thereafter to monitor seafloor ecosystem recovery (Thiel et al., 2001). Studies of the site  
63 seven years after disturbance showed only partial recovery (Thiel et al., 2001;Bluhm, 2001).  
64 Similar studies carried out in the north Pacific have also given indications that seafloor  
65 communities have not recovered or only partially recovered in periods of 26-37 years following  
66 disturbance (Miljutin et al., 2011;Jones et al., 2017;Gollner et al., 2017). This is not surprising  
67 given low rates of recruitment and growth common in these ecosystems, and the removal of the  
68 hard substrate upon which a large portion of the fauna depends (Amon et al., 2016;Vanreusel et  
69 al., 2016;Purser et al., 2017).

70           Though a number of studies in abyssal mining regions have evaluated megafaunal  
71 biodiversity and ecosystem responses, few have included quantitative and detailed data on fishes  
72 or scavengers (Leitner et al., 2017). However, many fishes are top predators that can have  
73 important influences on communities and ecosystems (Estes et al., 2011;Drazen and Sutton,  
74 2017). Though fishes are mobile and may not suffer immediate mortality from mining, they will  
75 be affected by the large sediment plumes created (Oebius et al., 2001) and by the loss of foraging  
76 habitat or prey resources. Thus, they may suffer regionally from local mining activities. Also,

77 top predators can bioaccumulate metals and other contaminants (Chouvelon et al., 2012;Choy et  
78 al., 2009;Bonito et al., 2016) that may be released from the activities of mining. Thus, it is  
79 important to characterize the fish community in regions that will likely experience mining in the  
80 near future and to begin constructing species ranges and community biogeographies, so that  
81 scientists and managers can evaluate potential mining impacts and appropriately locate protected  
82 no-mining zones (Wedding et al., 2013).

83 In 2015 a survey was performed of the DISCOL area using photo and video transecting  
84 techniques in a similar manner to the historical surveys of the area conducted into the late 1990s.  
85 In addition, archived analogue baited camera images collected shortly after the 1989 disturbance  
86 (1989-1992) were digitized and analyzed for fishes and other mobile scavengers, some of which  
87 may avoid transecting vehicles (Trenkel et al., 2004;Colton and Swearer, 2010). Our goal was to  
88 a) describe the fish and scavenger community in the DISCOL region in detail for the first time,  
89 b) evaluate the fish community response to disturbance and potential recovery, and c) compare  
90 the fish and scavenger community to that observed to the north of the equator in the Clarion  
91 Clipperton Zone (CCZ). The majority of abyssal mining exploration licenses have been thus far  
92 granted in the CCZ, and this is where initial pilot mining activities are likely to commence.

93

## 94 **2. Methods**

95 In 1989 a ~10.8 km<sup>2</sup> circular region of the Peru basin in the Pacific, the DISCOL  
96 experimental area (the DEA), was artificially ploughed, in an effort to simulate the effects of  
97 deep-sea mining (Thiel et al., 2001). The study site (7° 04.4' S, 88° 27.60' W) ranges in depth  
98 from 4120-4200 m. Sediments are fine grained clays overlain with heterogeneous cover of  
99 manganese nodules, sometimes in high density. The plough-harrow device was 8 m wide and  
100 when deployed, overturned the first 10-15cm of seafloor sediment, ploughing the nodules into  
101 the seafloor and removing this hard substrate from the sediment / water interface. The plough  
102 was towed in 78 radial transects through the disturbance area with ~20% of the seafloor directly  
103 disturbed by the plough. The most central region of the DEA was the most highly disturbed area  
104 crosscut by the majority of plough tows (Fig. 1; Foell et al., 1992).

105 In 2015 the DISCOL site was revisited and sampled twice (RV Sonne cruises SO242-1  
106 and 2). The initial cruise was conducted in the summer and primarily conducted detailed  
107 acoustic and image-based mapping of the plough tracks using Autonomous Underwater Vehicles

108 and ship-based sensors. This initial cruise also towed an epibenthic sled (EBS) several times  
109 across the seafloor, removing the top 20 cm of seafloor in trenches of ~2m x 500 m. These sled  
110 deployments were conducted to more accurately simulate the upper sediment removal envisioned  
111 as a likely consequence of mining. The second of these cruises focused on the detailed  
112 photographic study of the historic and recent disturbances mapped during the first cruise.

113 For investigation of megafauna, including fishes, the Alfred Wegner Institute (AWI)  
114 OFOS LAUNCHER towed camera system was used to conduct photographic transects of the  
115 seafloor. The OFOS LAUNCHER is identical to the OFOBS system described in Purser et al.  
116 (2018), with the exceptions that the OFOS was not equipped with INS, side scan or forward  
117 facing sonar systems. OFOS was flown at a height of ~1.7m above the seafloor and used a 23  
118 megapixel downward looking still camera (iSiTEC, CANON EOS 5D Mark III) to take images  
119 every 15 seconds, each of which also captured the laser points projected by a tri-laser (50 cm  
120 spacing) sizing device (iSiTEC, custom built). Ship speed was maintained at 0.2-0.4 knots.

121 Given the high heterogeneity of the seafloor area studied, each image was manually  
122 assessed to represent one of a range of disturbance categories. These were 1) 'Reference' areas,  
123 not directly within the target circle of seafloor ploughed in 1989 (DEA), 2) 'Undisturbed' areas  
124 within the central DEA circle, but not actually impacted by the plough harrow directly, 3)  
125 'Transition' images, within which both the edge of a plough track was visible as well as  
126 surrounding seafloor, 4) 'Ploughed' images within which only ploughed seafloor was visible and  
127 5) 'EBS' areas, disturbed a month prior to SO242-2 by the towed epibenthic sled deployed by  
128 SO242-1. These five disturbance categories represent increasing levels of physical disturbance.

129 Image area captured within each image was determined by measuring the spacing of the  
130 laser points in a subset of 3663 images using the PAPARA(ZZ)I software application (Marcon  
131 and Purser, 2017). The image area of all remaining images was calculated from the camera  
132 altitude (distance to seafloor) using a second order polynomial regression of the laser-based  
133 measurements. The average seafloor image area was  $5.71 \pm 3.44 \text{ m}^2$  (interquartile range 4.45-  
134  $6.25 \text{ m}^2$ ). In some instances, the camera was manually triggered to capture images of fishes that  
135 would have been missed in between timed images, or to capture a fish at a more suitable angle  
136 for identification. Images were manually annotated for fishes using a variety of published keys.  
137 For data on octopi see Purser et al., (2017) and for all invertebrates and benthic fauna see  
138 Marcon et al. submitted. Fish density was estimated by dividing the number of fish viewed in

139 regular timed images by the area photographed. Manually triggered images were not included in  
140 density estimates as these would present a positive bias towards images with fish in them.  
141 Diversity was evaluated using rarefaction curves (on all images, timed and manually triggered,  
142 because this approach only requires positive occurrences) to enable comparisons between habitat  
143 types that were not sampled at the same intensity.

144 OFOS transects often crossed several habitat types, so for fish density estimates, the  
145 images from each transect were divided into habitat type transects. For some habitat transects,  
146 there were very few images collected. We eliminated those habitat transects which were so  
147 small that they were unlikely to contain at least one fish. We based this assessment on the mean  
148 density of all habitat transects (both large and small) of  $30.6 \text{ fish ha}^{-1}$ , translating to a threshold  
149 sample area of  $330 \text{ m}^2$ . If used in the analysis, these small habitat transects would either bias the  
150 results towards zero estimates if no fish were present in the small image set, or towards  
151 incorrectly high estimates if a few fish happened to be present. Fish density was compared  
152 between habitat types using a permutational ANOVA on a Euclidean distance matrix to account  
153 for uneven sample sizes and non-normal data distribution.

154 Baited cameras are now a widely used tool to census marine fishes (Bailey et al., 2007)  
155 because they can attract often sparsely distributed animals to within the census view, including  
156 some that might avoid active camera survey tools. Thus, for fully describing diversity and  
157 species abundances within a regional fish assemblage, they are indispensable. However, in  
158 contrast to transect methods, they are more difficult to use for estimations of accurate animal  
159 densities (Priede and Merrett, 1998; Yeh and Drazen, 2011).

160 During the first post disturbance cruise in 1989 and three years later in 1992 (Sonne  
161 cruises 61 and 77), free fall baited cameras (freefall baited observing systems - FBOS) were  
162 deployed (Brandt et al., 2004). These utilized a Benthos 35mm survey camera and strobe. Bait  
163 (a single 500-1000g Carangid or Lutjanid) was attached to a rod or placed in a small clear plastic  
164 tube  $\sim 1\text{m}$  from the camera, resting on the seafloor. Oblique images of  $\sim 1.7\text{m}^2$  of the seafloor  
165 were taken every 2 to 5.5 min for  $\sim 24$  to 55 hours, averaging  $725 \pm 43$  images per deployment.  
166 Animals were counted in each image. Metrics extracted from the imagery include the maximum  
167 number of each taxon visible in any one image over the camera deployment (MaxN), the time of  
168 first arrival for each taxon ( $T_{\text{arr}}$ ), and the proportion of images in which a taxon was present for a  
169 camera deployment (Yeh and Drazen, 2011; Linley et al., 2017; Leitner et al., 2017). Only

170 species that were clearly attracted to the bait were enumerated. This eliminated species that were  
171 photographed as they were simply drifting or crawling through the field of view, such as medusa  
172 and holothurians. Further, many small amphipods were often present at the bait but could not be  
173 reliably counted and so are not included. Deployments in 1989 were made within both the  
174 reference and disturbance areas, and a PERMANOVA test was used to compare community  
175 compositions on a Bray-Curtis similarity matrix based on square root transformed MaxN data.

176

### 177 **3. Results**

#### 178 3.1 Photographic transects

179 20 OFOS transects were performed resulting in 46 habitat transects (Fig. 1). From these a  
180 total of 16733 images were examined with 306 fishes observed in 300 images (Table 1). Fishes  
181 were represented by 14 taxa (not including the category “unidentified fishes”; Fig. 2). Several  
182 groups were distinct but could not be identified to species whereas others were only identifiable  
183 to genus or family. The most common species observed was the benthic *Ipnops cf meadi*  
184 representing 61% of the fish observations. The Ophidiids were the most speciose family  
185 observed with 6 operational taxonomic units (OTU), some of which were distinct but could not  
186 be identified conclusively.

187 Across the five different habitat types, sampling effort was very uneven. Within the full  
188 data set, images taken of reference area habitat and in unploughed habitat within the  
189 experimental area were most abundant (Table 1). Seafloor images showing the disturbed habitat  
190 types (transient, ploughed and epibenthic sled (EBS) tracks) were less numerous. For all the data  
191 combined, as well as for the unploughed habitat type alone, rarefaction curves suggested  
192 adequate sampling as an asymptote was beginning to be reached in both cases (Fig. 3).  
193 However, within the other habitat types, rarefaction curves suggested more sampling was  
194 required to fully capture the fish diversity. Thus, the use of estimated species richness was  
195 needed for diversity comparisons. Interestingly, the disturbed habitat types had higher rarified  
196 diversity (ES 26) than the reference area or neighboring unploughed habitat (Fig. 3).

197 Fish densities were highly variable. Across all habitat transects, seafloor areas imaged  
198 ranged from 355 to 7798 m<sup>2</sup> and fish density ranged from 0 to 71.4 fish ha<sup>-1</sup>. Average fish  
199 density was 30.2 ± 18.2 fish ha<sup>-1</sup> (Fig. 4). Across the habitat types, density did not vary  
200 significantly (PERMANOVA, p>0.05). The density of the most common fish, *I. meadi*, could

201 also be estimated and ranged from 0 to 68 fish ha<sup>-1</sup>, averaging 18.4 ± 17.5 fish ha<sup>-1</sup> across all  
202 habitat types (Fig. 4). Its density was significantly lower in the ploughed habitat type compared  
203 to undisturbed and reference habitats. Only a single *I. meadi* was found in the EBS habitat type  
204 (Table 1), but this individual did not occur in a habitat transect of sufficient length for density  
205 estimation. *Ipnops meadi* density in the two habitat transects available for analysis was zero.

206 Since the time of initial disturbance fish density in the DEA varied. No fish were  
207 observed 6 months post disturbance, then fish density increased at year 3 and had returned to  
208 pre-disturbance density levels after 7 years (Fig. 5; Bluhm 2001). At this time, ophiuroids,  
209 holothurians, fish and hermit crabs were observed in the plough tracks. We examined this data  
210 (1989-1996) and the 2015 data for the reference, ploughed and unploughed habitat types using a  
211 two factor PERMANOVA. Habitat type and time were significant predictors of fish density with  
212 lower fish densities in the ploughed habitat (p<0.01; Supplementary Table 1). Also, the  
213 differences in the densities of fish across the three habitat types changed significantly with time  
214 since the disturbance (habitat x time, p<0.05). Fish density in the ploughed habitat was  
215 significantly (p<0.05) lower than the other habitat types right after the disturbance, marginally  
216 lower at 6 months post disturbance (p=0.057), and significantly lower at 3 years post  
217 disturbance. At 7 years the undisturbed habitat type in the DEA had higher fish density than the  
218 reference area. At 26 years, as already mentioned, there was no difference between habitats. Fish  
219 densities were similar to levels found in the undisturbed habitats and the reference area at 3 years  
220 post disturbance but higher than other times (Fig. 5). It was not possible to evaluate the times  
221 series data for *I. meadi* as Bluhm (2001) did not publish species specific results.

222

### 223 3.2 Baited camera observations

224 Six baited camera deployments were conducted, 5 in 1989 and 1 in 1992 (Table 2). Six  
225 taxa of fishes were identified (Fig. 6). The most abundant (MaxN) taxon in the deployments was  
226 the eelpout *Pachycara nazca*. This species occurred in all 6 deployments, reached a MaxN of 9  
227 in two of the deployments and on average was present in 55% of the images. Individuals of the  
228 rattail *Coryphaenoides* sp. were either *C. armatus* or *C. yaquinae*, or both were present but, we  
229 could not differentiate them in the photographs. This taxon was present in all of the deployments  
230 but was observed on average in only 2.1% of images, and MaxN was never more than 2. Several

231 ophidiids and a synphobranchid eel were also observed. Ophidiids were generally rare and seen  
232 infrequently though *Bassozetus nasus* did generally persist at the bait when observed.

233 The baited camera also attracted 9 taxa of invertebrates (Table 2). The small shrimp  
234 *Hymenopeneus nereus* was present in all of the deployments in relatively large numbers (average  
235 MaxN = 9), with up to 15 visible at one time and was present on average in 63% of the images.  
236 The hermit crab *Probeebei mirabilis*, was also observed in every deployment but in varying  
237 numbers (from 1 to 9) and in 29% of the images. Penaeid shrimp were also observed in every  
238 deployment and were the third most abundant and common scavenging species. Two species  
239 were identified, *Cerataspis monstrosus* (identified as *Plesiopeneus armatus* in earlier papers;  
240 Leitner et al 2017) and *Benthiscymus* sp. Frequently, these could not be distinguished as they  
241 differ in the shape of the antennal scale and rostrum which were not always clearly visible.  
242 Large Munnopsid isopods were seen in all but one deployment but did not remain in the field of  
243 view for long. Ophiuroids were not abundant or common, being observed in three deployments  
244 as single individuals, but they stayed in the field of view for a long time (high persistence  
245 values).

246 Two of the camera deployments in 1989 were made in the disturbance area 6 months post  
247 event. In one of these deployments there was no obvious sign of disturbance in the limited field  
248 of view. In the other, a plough harrow track was clearly visible (FBOS006; Table 2). Low  
249 numbers of the benthic eelpout, *P. nazca*, were observed during this deployment. This  
250 deployment also had the lowest numbers of the benthic shrimp, *H. nereus*. However, the  
251 community composition did not vary significantly between the 1989 deployments inside the  
252 disturbance experiment area and reference areas (PERMANOVA,  $p > 0.05$ ). Further, the times of  
253 first arrival of the scavengers was variable between deployments and not consistently longer at  
254 the disturbance area except for *B. iris* (Supplementary Table 2).

255 Overall, the diversity observed with the small number of camera deployments was fairly  
256 uniform, as evident from the plateau reached in both rarefaction and species accumulation curves  
257 (Fig. 7). This was the case for all scavengers and for the fishes alone. The baited cameras  
258 observed fewer taxa of fishes compared to the photo transects (Table 1, 2). Many of the fishes  
259 observed in the photo transects included less mobile benthic species such as members of the  
260 Ipnopidae, Bathysauridae and numerous unidentified ophidiids. However, the baited camera

261 deployments identified two fish species that were not observed in the photo transects, *Barathrites*  
262 *iris* and a Synphobranchid eel, both mobile scavengers.

263

#### 264 **4. Discussion**

##### 265 *4.1 A description of the fish and scavenging community and relationship to past DISCOL studies*

266 We present some of the first detailed fish assemblage information for the abyssal eastern  
267 Pacific. Earlier studies at the DISCOL site presented limited fish assemblage results from the  
268 first few years of the experiment and report finding 8 fish taxa with *Ipnops* sp. being the most  
269 abundant (Bluhm, 1994). All of the taxa that were observed in these initial investigations were  
270 also present in our 2015 survey results, with the exception of *Halosaurus* sp. Moreover, we  
271 observed 6 additional taxa in 2015, and together with analysis of the 1989-1992 baited camera  
272 deployments, we have observed a total of 16 taxa. Interestingly, the earlier camera transect  
273 surveys flew the camera system higher off the bottom (3-3.5m vs 1.7m) which is perhaps more  
274 appropriate for the survey of larger, mobile fishes. Advances in photographic identification of  
275 abyssal fishes across the Pacific and improvements in photographic quality have resulted in the  
276 greater detail in the present analysis.

277 The baited camera deployments provided additional information on the DISCOL fish  
278 community and also provided data on scavenging invertebrate fauna. Past taxonomic works  
279 have used trapped specimens to document the presence of the eelpouts *P. nasca* and *P. bulbiceps*  
280 (Anderson and Bluhm, 1997) and the ophiidiid *B. iris* (specimen deposited at the Senckenberg  
281 Museum). The physical specimens provide some vouchers for taxa that were identified from  
282 photographs. Two taxonomic studies used the baited camera imagery to tentatively identify the  
283 ophiidiid *Bassozetus nasus* (Nielsen and Merrett, 2000) and large Munnopsid isopods which were  
284 thought to belong to the genus *Paropsurus* (Brandt et al., 2004). Bluhm et al (1995) briefly states  
285 that *P. mirabilis* and ophiuroids were commonly seen in the baited camera photos, but these  
286 results were not given in any detail. We show the eelpouts, the shrimp *H. nereus*, and hermit  
287 crabs are indeed common and regular bait attending fauna at this site (see below for comparisons  
288 to other abyssal regions).

289

##### 290 *4.2 Evaluation of the fish community response to disturbance and potential recovery*

291 Our results, 26 years post disturbance, when compared to earlier sampling, provide some  
292 insight into the recovery potential of the fish fauna. The striking result found by Bluhm (2001)  
293 was that no fishes were observed in the disturbance area within 6 months of the disturbance;  
294 however, we show the presence of fish and scavenging invertebrates at this time from baited  
295 camera deployments. Samples sizes were low, but the community seems comparable to that in  
296 the reference areas at the same time. It seems likely that the scavengers were attracted from a  
297 larger area that could have included the proximate reference or undisturbed areas as suggested by  
298 the similar arrival times of the scavengers in reference and disturbance deployments. This could  
299 occur even if these animals were not commonly residing in the disturbance area due to habitat or  
300 prey community alteration because the DISCOL experiment created a patchwork of habitats over  
301 a scale as small as 10's of meters (Fig. 1).

302 The fish community remains affected by the DISCOL experiment even after 26 years.  
303 Total fish density in the ploughed habitat of the DEA increased over time and in relation to the  
304 reference and undisturbed habitat suggesting recovery. It should be noted that large interannual  
305 changes were evident at the reference site with fish densities peaking 3 years post disturbance  
306 and at high levels again at 26 years (Fig. 5). An increase in megafaunal density over the first 7  
307 years of the experiment was already documented and hypothesized to be the result of increased  
308 phytodetrital food flux and growing populations regionally (Bluhm, 2001). Such variation in  
309 megafaunal abundance is a regular feature of abyssal communities (Kuhnz et al., 2014; Ruhl and  
310 Smith, 2004). Comparisons between habitats at a point in time can provide a more robust means  
311 to assess recovery after plough disturbance (Miljutin et al., 2011). We found no differences in  
312 total fish density between the disturbed and undisturbed habitats at 26 years. Further, diversity  
313 (ES 26) was slightly higher in the disturbed habitat areas, although with relatively small sample  
314 sizes. However, the most common fish *I. meadi*, that makes up more than half of all the fish  
315 observations, had only a third of the density in 26-year-old plough tracks compared to  
316 undisturbed and reference areas, and only one individual was seen in the fresh EBS tracks (Fig.  
317 4). This fish is found in the undisturbed habitat which occurs in a patchwork with the disturbance  
318 tracks, hence regional reductions in population density are unlikely. Rather it seems that *I.*  
319 *meadi* actively avoids the plough tracks, showing that even the mobile fish community remains  
320 affected by the disturbance after more than two decades. This species' response likely relates to  
321 its biology as a rather sedentary, small benthic fish that, based on limited data, feeds on

322 polychaetes, small bivalves, and crustaceans (Nielsen, 1966;Crabtree et al., 1991). Its prey may  
323 not have recovered in the tracks (Jones et al., 2017;Borowski, 2001). Most of the other fishes  
324 observed are benthopelagic and when swimming across a habitat mosaic might as easily be seen  
325 over an old plough track as over other habitat. Even if benthopelagic species tend to favor  
326 undisturbed habitat, this would be difficult to see in data at such a small scale. Our other benthic  
327 species include the lizardfish *B. mollis* which preys on mobile fishes and shrimps and *B. sewelli*,  
328 which is a larger member of the Ipnopidae, but was too infrequently observed to assess habitat  
329 preferences (Table 1).

330         Conclusions about fish community recovery over time must be taken with caution. With a  
331 sparsely distributed fauna and the high variability in density, there are limits on statistical power  
332 and thus our confidence. The earlier DISCOL surveys differed in methodology to the current  
333 surveys including average altitude of the camera above bottom, image quality, and attention to  
334 the fishes. Our diversity estimates may well be higher as a result. Density estimates could also  
335 be affected by these same factors. The most common fish in the surveys, *I. meadi*, is relatively  
336 small and despite reflective eyes (Fig. 2) may have been more visible in our 2015 surveys in  
337 closer proximity to the seafloor. The influence many of these parameters have had on abundance  
338 estimations of fauna in the DISCOL region has been investigated in detail for a region of the  
339 DEA which was surveyed several times during the initial 7-year period and again in 2015. In  
340 2015, the OFOS was deployed at 1.7 and 4 m in this region, and additionally an AUV was flown  
341 at 5 m to image the same region of seafloor. The results from these comparative studies (Purser  
342 et al. submitted for this special issue) show the sensitivity of density and diversity indices in the  
343 DISCOL area to changes in flight height, illumination, and camera type. Larger megafauna, such  
344 as fish, were clearly visible in images collected from higher altitudes, therefore resulting in both  
345 higher diversity and abundance estimates for a given transect length than achieved with lower  
346 flying camera systems. Certainly, methodology plays a very important role in determining the  
347 accuracy of sampling strategies in this ecosystem for determination of these parameters.

348         Our results add to a growing body of literature that generally finds little or partial  
349 recovery of faunal communities, even decades after simulated mining disturbances. Epifaunal  
350 megafauna density was considerably lower in disturbance tracks made 20 and 37 years prior to  
351 re-survey during the OMCO experiment in the CCZ (Vanreusel et al., 2016). Meta-analyses of  
352 abyssal disturbance experiments in the CCZ suggest that recovery of density and diversity is

353 faster in mobile than sedentary fauna (Gollner et al., 2017; Jones et al., 2017). For instance, the  
354 mobile holothurian community appears to have recovered from disturbance in terms of density  
355 and community composition at the DISCOL site after 26 years (Stratmann et al., 2018). Most  
356 holothurians are detrital deposit feeders and their food source settling from above may not be  
357 greatly affected by the plough disturbance, whereas some fishes, such as *I. meadi*, likely rely  
358 upon epifaunal and infaunal macrofauna for food. The meiofauna and macrofauna have not  
359 recovered completely after 26 years in the CCZ (Miljutin et al., 2011), or after 7 years at the  
360 DISCOL site (Borowski, 2001). Some of the variation in the recovery potential observed  
361 between studies is undoubtedly derived from the variation in disturbance type and intensity. The  
362 direct benthic scale of actual nodule mining activities is suggested to be from 300-600 km<sup>2</sup> y<sup>-1</sup>  
363 for a single mining license (Oebius et al., 2001; Levin et al., 2016). While it may seem that a  
364 local disruption in *I. meadi*'s distribution is a mild fish community effect 26 years post  
365 disturbance, it must be kept in mind that the DISCOL experiment did not completely disturb the  
366 DEA and that the scale of this experiment is very small in relation to industrial scale deep-sea  
367 mining. We argue that at industrial scales of seafloor disturbance, *I. meadi* could exhibit major  
368 regional reductions in population density that would last for decades and such effects could  
369 extend to other species as well. Fishes may avoid direct mining activities but experience long  
370 term habitat losses at spatial scales that seem very likely to result in regional population  
371 consequences. Plumes of sediment from collectors or from discharge of the ore dewatering  
372 plume (Rolinski et al., 2001) will greatly expand this area and magnitude of effect. Therefore, it  
373 seems unlikely that the small-scale disturbance experiments, such as DISCOL (~10.8 km<sup>2</sup>), will  
374 be adequate for evaluating the potential effects of full scale nodule mining. Further, the physical  
375 disturbance made in all experimental studies to date have not been directly reminiscent of the  
376 impacts actual mining will make in terms of volumes of surface sediment removed or displaced,  
377 subsequent sediment compaction, or generation of the high resolution topographical changes  
378 associated with the ridges and troughs likely to result from tracked mining vehicle movement  
379 (Jones et al., 2017; Doya et al., 2017; Jones et al., 2018).

380

#### 381 *4.3 Comparison of the DISCOL fish and scavenger communities to those within the CCZ*

382 Nodule mining is likely to affect very large areas of the seafloor over decades (Wedding  
383 et al., 2015). Mobile fishes and other scavengers likely have the greatest ability to migrate away

384 from mining disturbances, but they may be affected regionally through the redistribution of prey  
385 resources and sublethal effects from toxic metals or sediment plumes. Consequently, the  
386 biogeographies of taxa, even mobile species, are an important input to spatial management  
387 approaches (Watling et al., 2013). The scale of species distributions will help determine where  
388 and how large reserve areas should be in order to protect species. Comparison of the present  
389 findings in the south Pacific to those in the CCZ polymetallic nodule province to the north,  
390 across the equatorial upwelling, provide some insight into the ranges of abyssal fishes and  
391 scavengers in this mining relevant region. Past studies frequently combined fish and scavenger  
392 taxa into larger functional groups such as megafauna (Jones et al., 2017), but some studies have  
393 presented lists of species, which are the focus of the comparison here.

394 A number of the fish taxa observed with camera transects in the CCZ (Pawson and Foell,  
395 1983; Radziejewska and Stoyanova, 2000; Tilot, 2006; Amon et al., 2017) have also been  
396 identified in the DISCOL area suggesting large species distributions (Table 3). 10 of the 14 taxa  
397 in the DISCOL region are shared with the CCZ. Four taxa were identified from DISCOL that  
398 were not previously identified from the CCZ region, none of which were abundant. Four fishes  
399 were observed in the various CCZ studies but not at the DISCOL site. A number of abyssal  
400 species have pan-Pacific and even global distributions (Priede, 2017). However, we are not  
401 suggesting that there is only a single community of fishes and scavengers integrated over 1000's  
402 of kilometers. Rather it is likely that there are some species from this community, such as those  
403 that occur in both the DISCOL and CCZ regions, with broad distributions that could recolonize a  
404 mining license area if extirpated by mining. The extent of such conclusions must be made with  
405 caution because the overlap between the two areas may be artificially high. Unrealistic overlap  
406 could arise due to the difficulty in identifying species from photographs, particularly those taken  
407 from high altitudes, and hence the use of genera and higher taxonomic categories. Further there  
408 are some taxa which can easily be confused depending upon image quality. For instance in the  
409 DISCOL site we identified the ophidiid, *Porogadus* sp. which has a long whip like tail and  
410 narrow body similar to Halosaurs which have been observed in the CCZ (Amon et al., 2017) and  
411 in an earlier study at the DISCOL site (Bluhm, 1994). We suspect that with increasing camera  
412 resolution and better taxonomic experience, photographic data and its analysis will improve  
413 greatly. Also, taxa are much more easily identified in oblique imagery. For instance, Halosaurs  
414 have prominent high pectoral fins and a single short dorsal whereas *Porogadus* has a long low

415 dorsal fin all of which are seen in oblique imagery. We suggest the use of both oblique and  
416 vertical cameras on the same platforms in future studies. There has been some suggestion that  
417 oblique imagery would also alleviate avoidance issues with mobile taxa, but in the one abyssal  
418 study that used both oblique and vertical cameras, greater fish density was found in the vertical  
419 imagery (Milligan et al., 2016). Finally, collecting physical specimens and genetic data would  
420 be a great complement to the camera-based approach. Trawling for fish samples in mining claim  
421 areas will be challenging due to the great depth and the abundance of nodules, which can break  
422 nets and greatly damage specimens. Baited traps are effective for some of the fauna (Leitner et  
423 al., 2017; Linley et al., 2016).

424 The scavenging communities exhibit some interesting differences to those described from  
425 the eastern CCZ region and other abyssal Pacific locations. The dominant DISCOL scavengers  
426 were the shrimp *H. nereus*, eelpouts *Pachycara* spp., and the hermit crab *P. mirabilis*. The  
427 presence of large numbers of hermit crabs at the DISCOL site has been noted in earlier transect  
428 studies (Bluhm, 2001), and their large contribution to the scavenging community seems unique  
429 amongst abyssal scavenger studies. The most similar finding was a few hermit crabs  
430 (*Sympagurus birkenroadi*, MaxN= 2) attending bait from 2000 – 3000m depths off Hawaii (Yeh  
431 and Drazen, 2009). The large numbers of *H. nereus* is similar to the community in the eastern  
432 CCZ (Leitner et al., 2017). However, the eastern CCZ fishes were dominated by  
433 *Coryphaenoides* spp., which were not abundant at the DISCOL site. Overall the DISCOL  
434 scavenging community appears more similar to that observed in the western CCZ, which hosted  
435 lower numbers of *Coryphaenoides* spp. and greater numbers of ophidiids and shrimp (Leitner et  
436 al., 2017). The differences from east to west in the CCZ have been postulated to be related to the  
437 lower surface productivity in the west. Indeed, more oligotrophic regions have been shown to  
438 shift the dominance of the scavenging fishes from Macrourids to Ophidiids (Linley et al.,  
439 2017; Fleury and Drazen, 2013). However, the average long-term chlorophyll concentration at  
440 the DISCOL site estimated from the MODIS satellite (30x30km box from 2006-2016) is about  
441 1.5 times higher (0.22 mg chl-a m<sup>-3</sup>) than that reported by Leitner et al (2017) in the eastern  
442 CCZ. Whether the community differences observed between the DISCOL and CCZ regions are  
443 the result of variations in overlying productivity, species distributions, or other habitat factors  
444 cannot be discerned until a greater number of baited camera studies are conducted across the  
445 region.

465  
466  
467

In conclusion, the DISCOL site has a relatively diverse abyssal fish community dominated by *Ipnops meadi*. Fish density increased in the ploughed habitat type over time and became similar to undisturbed habitat types at 26 years post disturbance, but the density of *I. meadi* is still only a third of the undisturbed habitat types indicating that the DISCOL experiment continues to affect the fish fauna through altered distributions. At the temporal and spatial scales of industrial mining, changes in habitat availability could lead to population reductions even if fishes can avoid the direct activities of mining. The abyssal fish communities observed in the central eastern Pacific at DISCOL and the more northerly CCZ are similar with many shared taxa. However, further species level identifications are required which requires the collection of physical specimens through trawling or baited traps. The scavenging community in the DISCOL site is unique in the prevalence of the hermit crab, *P. mirabilis*, which does not appear in the CCZ in either camera transects or baited camera deployments. Not surprisingly, fishes and mobile scavengers appear generally to have large ranges but also large shifts in community composition across the CCZ (Leitner et al., 2017) and across the equator. As commercial mining of polymetallic nodule provinces rapidly progresses, with commercial field trials commencing in the Belgian and German claim areas of the CCZ in the first months of 2019, gaining a better understanding of these remote ecosystems is of paramount importance. Until key fauna, such as the various benthic fish species utilizing these habitats are better known, ensuring that appropriate management plans are developed to best minimize human impact during mining will be extremely problematic.

## 5. Data Availability

All OFOS images and data collected during the RV Sonne So242/2 cruise analyzed for this study are available with open access from the PANGAEA data repository:  
<https://doi.pangaea.de/10.1594/PANGAEA.890634>. Baited camera imagery is available through the BIIGLE data repository at <https://annotate.geomar.de>.

## 6. Author Contributions

JCD and ABL analyzed the data and wrote the manuscript. SM annotated the baited camera images and assembled the data. AP and YM designed and conducted the camera transect

477 experiments, quantified image coverage, helped write the manuscript, and generated the map  
478 figure. JG digitized and archived the original baited camera images. All authors read and  
479 commented on the manuscript.

480

#### 481 **7. Competing interests**

482 The authors declare that they have no conflict of interest.

483

#### 484 **8. Acknowledgements**

485 We thank the many DISCOL participants past and present who worked diligently to collect data  
486 over a 26-year study. We thank Kathy Dunlop and an anonymous reviewer for their careful  
487 comments on a draft of this manuscript. The Moore foundation provided funding for JCD, SM,  
488 and ABL to participate in this study. The SO242 cruises and accompanying work was funded by  
489 the German Ministry of Education and Science BMBF (grant number 03F0707A-G) through the  
490 project Mining Impact of the Joint Programming Initiative Healthy and Productive Seas and  
491 Oceans (JPIO). This is SOEST contribution #10754.
