**Abstract.** The chemical weathering of minerals is a primary control on atmospheric CO<sub>2</sub> levels and Earth's climate over geological timescales. As climate warming and precipitation intensify at high latitudes, glaciated terrains across the circumpolar north are poised for rapid geomorphic change and associated changes in mineral weathering dynamics. Here, we determine how the effects of permafrost thaw on mineral weathering sources and inorganic carbon cycling and export integrate across watershed scales (from ~2 to 1000 km<sup>2</sup>) in a permafrost terrain within a former glacial margin and dominated by relatively inorganic sediments (Peel Plateau, Canada). Our work was conducted along three nested transects with varying intensities of retrogressive thaw slump (RTS) thermokarst activity: a 550 m transect along a first-order thaw stream within a RTS; a 14 km transect along a stream which directly received RTS inputs; and a 70 km transect along a larger stream which received inputs from RTS-affected tributaries. In the thaw stream, rapid sulfuric acid weathering of carbonate tills appeared to amplify CO<sub>2</sub> efflux to the atmosphere and HCO<sub>3</sub><sup>-</sup> export downstream, where DIC and CO<sub>2</sub> stable isotopes revealed a shift to an abiotic-inorganic driven aquatic carbon cycle. Along the intermediate transect, DIC concentrations were ten times higher in the RTS-affected reach than in the undisturbed headwaters, and decreased downstream with decreasing RTS area. Along the largest transect, HCO<sub>3</sub><sup>-</sup> concentrations increased by two orders of magnitude in association with RTS activity, despite RTSs covering only ~0.5% of the landscape. Statistical modeling of hydrochemical measurements and geospatial landscape data showed that RTSs were a primary landscape driver of HCO<sub>3</sub><sup>-</sup> export across watershed scales. Constraining sources and rates of mineral weathering across diverse permafrost terrains will help to understand future changes in Arctic aquatic carbon cycling, as our results suggest that abiotic-inorganic processes may become prevalent.

### 1 Introduction

The chemical weathering of minerals is a fundamental control on atmospheric CO<sub>2</sub> levels over geological timescales and thus Earth's long-term climate (Berner, 1999). Rapid modern warming at northern latitudes (Serreze and Barry, 2011) is driving a suite of changes including the degradation of the cryosphere (Biskaborn et al., 2019), increasing vegetation productivity (Bjorkman et al., 2018), intensifying hydrologic cycles (Rawlins et al., 2010), and

35

strengthening land-freshwater linkages (Vonk et al., 2019; Walvoord and Kurylyk, 2016). These processes are activating large amounts of mineral substrate into biogeochemical cycles, with significant implications for the rate and magnitude of mineral weathering over modern timescales (Lacelle et al., 2019; Wadham et al., 2019). In recent decades, fluxes of carbonate alkalinity ( $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$ ) and solutes in rivers across the circumpolar north have  
40 increased and more than doubled in some regions (Drake et al., 2018a; Tank et al., 2016; Toohey et al., 2016; Zolkos et al., 2018). This intensification of dissolved inorganic carbon ( $\text{DIC} = \Sigma[\text{CO}_2, \text{HCO}_3^-, \text{CO}_3^{2-}]$ ) cycling reflects enhanced mineral weathering associated with a thickening of the active layer, deepening hydrologic flowpaths into mineral soils, and greater soil acidity associated with increasing vegetation productivity (Drake et al., 2018a; Tank et al., 2016; Toohey et al., 2016). Coupled to these processes, carbonate equilibrium reactions along the  
45 land-freshwater continuum determine the balance of DIC species and therefore its susceptibility to atmospheric exchange as  $\text{CO}_2$  versus export to the ocean as alkalinity (Stumm and Morgan, 1996).

From a geochemical perspective, three coupled factors primarily influence the magnitude and directionality of mineral weathering within climate feedbacks: the mineral composition of substrate; the acid responsible for chemical weathering; and the rate of weathering (Stumm and Morgan, 1996). First, half of riverine carbonate  
50 alkalinity exported to the ocean is returned to the atmosphere over geological timescales by precipitation reactions within the marine carbon cycle (Calmels et al., 2007). Hence, silicate weathering by atmospheric or soil respiration  $\text{CO}_2$  dissolved in water (carbonic acid,  $\text{H}_2\text{CO}_3$ ) represents a long-term  $\text{CO}_2$  sink, as this process generates alkalinity without liberating mineral carbon. In contrast, carbonate weathering by  $\text{H}_2\text{CO}_3$  is a  $\text{CO}_2$  sink only over shorter timescales, as half of the alkalinity produced is geogenic.  $\text{HCO}_3^-$  produced during carbonate weathering in the  
55 presence of strong acids, for instance sulfuric acid ( $\text{H}_2\text{SO}_4$ ) from sulfide oxidation, is thus a  $\text{CO}_2$  source. Second, these reactions demonstrate how the mineral composition of a substrate and the acids responsible for its weathering can influence the degree to which weathering is a  $\text{CO}_2$  source or sink. Lastly, rates of chemical weathering are orders of magnitude faster for carbonates and sulfides than for silicates (Stumm and Morgan, 1996). Further, weathering rates generally increase with mineral surface area, and therefore are generally fast in glacial  
60 environments owing to intense physical weathering (Anderson, 2007). Indeed, hydrochemical signatures of trace carbonate and sulfide lithologies can dominate weathering fluxes in primarily silicate glacial environments (Anderson, 2007). The disparity is so significant that, when sediment supplies are sufficient,  $\text{H}_2\text{CO}_3$  carbonate weathering in proglacial streams can consume dissolved  $\text{CO}_2$  to below atmospheric levels (Sharp et al., 1995; St. Pierre et al., 2019).

65 Glaciated permafrost terrains are poised for rapid geomorphic and associated biogeochemical change as the climate warms and precipitation intensifies at high latitudes (Kokelj et al., 2017b). Areas currently with glacial coverage are of particular interest, owing to increased understanding of their effects on atmospheric  $\text{CO}_2$  levels and long-term global climate (St. Pierre et al., 2019; Torres et al., 2017). Despite glacial retreat across much of the circumpolar north – most notably the Laurentide Ice Sheet (LIS) – lasting biogeochemical legacies remain preserved within these  
70 vast landscapes (Kokelj et al., 2017b). In North America, the comminution of carbonate and shale bedrock during the LIS expansion and the climate and vegetative protection of ice- and sediment-rich tills in the wake of its retreat

endowed former glacial margins across northwestern Canada with relatively inorganic, ice-rich permafrost (Kokelj et al., 2017b). Today, the climate-driven renewal of post-glacial landscape change is mobilizing immense stores of minerals into modern biogeochemical cycles (Kokelj et al., 2017a). On the Peel Plateau (NWT, Canada),  
75 retrogressive thaw slumps (RTSs) expose carbonate- and sulfide-bearing glaciogenic permafrost sediments that are tens of meters in thickness. The chemical weathering and fluvial transport of these sediments results in increased  $\text{HCO}_3^-$  immediately downstream and greater solute and sediment loads throughout downstream systems (Kokelj et al., 2013; Malone et al., 2013; Zolkos et al., 2018). Yet, it remains unknown how thermokarst effects on mineral weathering and DIC sources and cycling integrate across watershed scales on the Peel Plateau and in relatively  
80 inorganic-rich permafrost terrains elsewhere. These terrains, which are thought to occur within former glacial limits across the northern permafrost zone (Zolkos et al., 2018), represent a frontier with respect to current knowledge on carbon cycling and climate feedbacks.

In this study we evaluated trends in major ions, DIC concentration, and dual DIC and  $\text{CO}_2$  stable isotopes along transects within three nested watersheds in the Stony Creek watershed (1100 km<sup>2</sup>) on the Peel Plateau. The three  
85 transects spanned gradients of thermokarst disturbance: (i) a 550 m thaw stream formed by a runoff channel within an active retrogressive thaw slump (RTS FM2 runoff); (ii) a 14 km transect in a creek which originated in undisturbed headwaters, but was directly affected by RTS FM2 and additional RTSs along the studied reach (Dempster Creek); and (iii) a 70 km transect in a large stream which received inputs from multiple large RTS-affected tributaries and was itself a major tributary of the 70,000 km<sup>2</sup> Peel River watershed (Stony Creek) (Fig. 1).  
90 Our nested watershed approach and comparisons of stream chemistry between undisturbed headwaters and thermokarst-affected reaches enabled us to develop a novel conceptual model which details how RTS effects on inorganic carbon cycling integrate across watershed scales. These results help to bring abiotic-inorganic aquatic processes into our conceptualization of thermokarst effects on carbon cycling, which to-date have been driven by studies outside of former glacial limits and focused on organically-driven processes (Vonk et al., 2015).

## 95 2 Methods

### 2.1 Study Area

The Stony Creek watershed is located southwest of the hamlet of Fort McPherson, in the northern, or lower Peel River watershed (Fig. 1). Stony Creek, a tributary of the Peel River, originates in the Richardson Mountains, where the slopes are sparsely vegetated and mainly consist of colluvium from exposed marine shale and sandstone bedrock  
100 (Norris, 1985). As Stony Creek flows eastward, the main channel and its tributaries incise ice-rich glacial deposits and underlying Cretaceous bedrock, forming a stream network comprised of tundra flow tracks grading to incised gravel bed streams with increasing watershed size. The fluvially-incised valleys and increasing regional precipitation have proven conducive to thaw-driven mass wasting of ice-rich glacial deposits and formation of RTSs (Kokelj et al., 2017b). RTS growth is driven by the ablation of exposed ground ice and is perpetuated by the  
105 downslope mass wasting of thawed material via fluidized earth flows, which can accumulate large volumes of debris in stream valleys (Fig. 1). Across the Stony Creek watershed, intensifying RTS activity releases large volumes of

sediment and solutes into streams relative to undisturbed headwaters (Kokelj et al., 2017b; Segal et al., 2016). This substrate is transported to streams via rill runoff channels in the scar zone and debris tongue deposits in the stream valley. Impacts to Stony Creek are representative of numerous other major Peel River tributaries that have incised the ice-rich Peel Plateau (Kokelj et al., 2015). The ~60 km<sup>2</sup> watershed of Dempster Creek, a tributary of Stony Creek, originates in willow and open spruce taiga without RTS activity, receiving large inputs of sediments and solutes from RTSs FM2 and FM3 within several kilometers of the headwaters (Kokelj et al., 2013; Malone et al., 2013). Many small, non-RTS affected streams and several larger RTS-affected tributaries flow into Dempster Creek before its confluence with Stony Creek.

## 115 2.2 Stream Sampling

In late July, 2017, we sampled three nested transects: (i) at five locations along a 550 m-long transect within the RTS FM2 rill runoff channel (Fig. 1a); (ii) Dempster Creek in the undisturbed headwaters, along its RTS-affected reach upstream of three major tributaries, and from the tributaries near their mouths, to characterize the downstream effects of RTS FM2 on DIC; (iii) Stony Creek in the undisturbed headwaters, along the RTS-affected reach of Stony Creek upstream of seven major tributaries, and from the tributaries near their mouths, to determine RTS effects on DIC across broader scales (Fig. 1, Table A1). While the Dempster and Stony Creek headwater sites were not affected by RTSs, mainstem and tributary sampling sites were (Table A1). Minor tributaries of Dempster and Stony Creek, many of which were not affected by RTSs, were not sampled.

At all sampling sites, stream temperature and pH were measured using a pre-calibrated YSI Professional-Plus water quality meter. At most sites, water samples were collected for ions, DIC, CO<sub>2</sub>, CH<sub>4</sub>, dissolved organic carbon (DOC), UV-visible absorbance, and total suspended sediments (TSS). Along the RTS FM2 runoff transect, we sampled only for DIC and CO<sub>2</sub> concentration, and stable isotopes of dissolved CO<sub>2</sub> ( $\delta^{13}\text{C}_{\text{CO}_2}$ ). One day prior, additional parameters were sampled at runoff site five, located near the confluence of the RTS runoff with Dempster Creek, for comparison with the full suite of chemistry parameters collected along the Dempster Creek transect. At the Dempster and Stony Creek sites, we additionally sampled water for stable isotopes of DIC ( $\delta^{13}\text{C}_{\text{DIC}}$ ) and  $\delta^{13}\text{C}_{\text{CO}_2}$  and used dual DIC and CO<sub>2</sub> stable isotopes to characterize abiotic and biotic processes influencing DIC sources and cycling.

Water samples were collected from the thalweg where possible, as an integrated sample from ~15 cm below the surface to ~1 m depth. An additional sample for TSS was collected in a 1 L HDPE in the same fashion. Water samples were filtered using sample-rinsed 0.45  $\mu\text{m}$  polyethersulfone (PES, ThermoFisher) or cellulose-acetate (CA, Sartorius) membranes. Samples for DIC were collected without headspace in airtight syringes. Samples for ions, DOC, and UV-visible absorbance were collected in acid washed (24 h, 10% v/v HCl) all-plastic syringes. Syringes were triple sample-rinsed, sealed without headspace, and stored cool and dark until processing within 10 h. Water for DIC was filtered (PES) into precombusted (5 h, 500°C) glass vials without headspace and sealed with a butyl rubber septum for DIC concentration or two silicone-teflon septa for  $\delta^{13}\text{C}_{\text{DIC}}$ . Samples for cations were filtered (CA)

into acid-washed bottles and acidified with trace metal-grade  $\text{HNO}_3$ , while anions were filtered (CA) but not acidified. Samples for DOC were filtered (PES) into precombusted glass vials and acidified to  $\text{pH} < 2$  using trace metal-grade  $\text{HCl}$  (Vonk et al., 2015). Samples for UV-visible absorbance were filtered (PES) into non-acid washed 30 mL HDPE bottles. Samples were refrigerated ( $4^\circ\text{C}$ , dark) until analysis.

145 Dissolved gases were collected following the headspace equilibration method (Hesslein et al., 1991) and stored in airtight syringes (for  $\text{CO}_2$  concentration) or over-pressurized in pre-evacuated serum bottles sealed with pre-baked ( $60^\circ\text{C}$ , 12 h), gas-inert butyl rubber stoppers (for  $\delta^{13}\text{C}_{\text{CO}_2}$ ,  $\text{CH}_4$ ). At each site, atmospheric samples for  $\text{CO}_2$  and  $\text{CH}_4$  concentration and  $\delta^{13}\text{C}_{\text{CO}_2}$  were stored in the same fashion. Gas samples were stored in the dark at  $\sim 20^\circ\text{C}$  prior to analysis within 10 h ( $\text{CO}_2$ ) or two months ( $\delta^{13}\text{C}_{\text{CO}_2}$ ). Water and air temperature, atmospheric pressure, and the  
150 volumetric ratio of sample to atmospheric headspace was recorded for correcting later calculations of  $\text{CO}_2$  partial pressure ( $p\text{CO}_2$ ) and  $\delta^{13}\text{C}_{\text{CO}_2}$  (Hamilton and Ostrom, 2007).

### 2.3 Stream Flow

Discharge ( $Q$ ) in Stony Creek tributaries was estimated from a hydraulic geometry model (Gordon, 2004) that we developed using flow measurements made in Peel Plateau streams during 2015-2017 and width ( $W$ ) estimated from  
155 on-site measurements or photos from 2017 with a known scale. The model reflected measurements spanning diverse stream morphologies ( $W = 0.4\text{--}6.6$  m) and flow conditions ( $Q = 0.005\text{--}0.91$   $\text{m}^3$   $\text{s}^{-1}$ ):

$$Q = 10^{\log(W / 6.258) / 0.661} \quad (p < 0.01, R^2 = 0.89, n = 20) \quad (1)$$

Discharge values from 2015-2017 were calculated from measurements of stream flow (RedBack Model RB1, PVD100) and cross-sectional area made at increments equal to 10% of stream width (Gordon, 2004; Lurry and  
160 Kolbe, 2000), and were averaged for sites with multiple measurements.

### 2.4 Geochemical Analyses

Upon returning from the field each day,  $\text{CO}_2$  was measured using an infrared gas analyzer (PP Systems EGM-4). The EGM-4 was checked monthly for drift using a commercial standard (Scotty Gases). We calculated  $p\text{CO}_2$  using Henry's constants corrected for stream water temperature (Weiss, 1974) and accounting for the ratio of water  
165 volume to headspace during sample equilibration. DIC samples were measured by infrared  $\text{CO}_2$  detection (LiCOR 7000) following acidification within a DIC analyzer (Apollo SciTech model AS-C3). Calibration curves were made daily using certified reference material (CRM) from Scripps Institution of Oceanography. Samples with DIC concentrations  $< 400$   $\mu\text{M}$  were analyzed using solutions prepared from a 1000 ppm TIC stock (ACCUSPEC) that were calibrated with CRM. DIC species ( $\text{CO}_2$ ,  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$ ) were calculated from DIC concentration and  $p\text{CO}_2$  or  
170 pH using  $\text{CO}_2\text{sys}$  (v.2.3) (Pierrot et al., 2006), using field temperature and pressure at the time of sampling, and the freshwater equilibrium constants for K1 and K2 (Millero, 1979).

Cations and trace elements were measured by optical emission spectrometry (Thermo ICAP-6300) and anions by ion chromatography (Dionex DX-600) at the University of Alberta Biogeochemical Analytical Services Laboratory (BASL, ISO/EIC accreditation #17025). DOC was measured using a total organic carbon analyzer (Shimadzu 175 5000A). DOC standard curves were made daily with a 1000 ppm KHP solution (ACCUSPEC) and an in-house caffeine standard (10 mg L<sup>-1</sup>) was run every 20 samples to monitor instrument drift. Absorbance spectra were analyzed using an Ocean Optics UV-VIS instrument with a Flame spectrometer module, following Stubbins et al. (2017) and corrected for Fe interference (Poulin et al., 2014). To evaluate organic carbon reactivity, we used specific ultraviolet absorbance at 254 nm (SUVA<sub>254</sub>) to infer DOC aromaticity (Weishaar et al., 2003).

180  $\delta^{13}\text{C}_{\text{DIC}}$  was determined using an isotope ratio mass spectrometer (Finnigan Mat DeltaPlusXP) interfaced to a total organic carbon analyzer (OI Analytical Aurora Model 1030W) at the University of Ottawa Stable Isotope Laboratory.  $\delta^{13}\text{C}_{\text{CO}_2}$  and CH<sub>4</sub> concentration were analyzed within two months using a Picarro isotope analyzer (G2201-*i*; < 0.2‰ precision, CH<sub>4</sub> operational range = 1.8–1500 ppm) equipped with an injection module for discrete samples (SSIM). Commercial  $\delta^{13}\text{C}_{\text{CO}_2}$  and CH<sub>4</sub> standards were used to check for drift during each run. We used 185 mass balance to correct  $\delta^{13}\text{C}_{\text{CO}_2}$  values for the  $\delta^{13}\text{C}$  and mass of atmospheric CO<sub>2</sub> used for equilibration (Hamilton and Ostrom, 2007). To assess  $\delta^{13}\text{C}_{\text{CO}_2}$  fractionation from calcite precipitation (Turner, 1982) and methanogenesis (Campeau et al., 2018) in RTS FM2 runoff, we calculated the saturation index (SI) and partial pressure of CH<sub>4</sub> (*p*CH<sub>4</sub>). SI was calculated using the hydrochemical software Aqion version 6.7.0 (<http://www.aqion.de>), which uses the U.S. Geological Survey software PHREEQC (Parkhurst and Appelo, 2013) as the internal numerical solver.

190 Samples for atmospheric and dissolved CH<sub>4</sub> were collected in the same fashion as  $\delta^{13}\text{C}_{\text{CO}_2}$ . *p*CH<sub>4</sub> was calculated using Bunsen solubility coefficients (Wiesenburg and Guinasso, 1979) converted to the appropriate units (Sander, 2015).

TSS samples were filtered onto muffled (450°C, 4 h) and pre-weighed glass fiber filters (Whatman GF/F; 0.7 μm nominal pore size) upon returning from the field, stored frozen, and dried (60°C, 24 h) for gravimetric analysis 195 following a modified version of U.S. Geological Survey Method I-3765.

## 2.5 Mineral Weathering and DIC Sources

We used a Piper diagram, which reflects the proportional equivalent concentrations of ions in a sample relative to mineral weathering end-members, to constrain the sources of mineral weathering and HCO<sub>3</sub><sup>-</sup>. The products of Eq. A1–A7 defined the mineral weathering end-members in the Piper diagram (Table A2). We further constrained 200 mineral weathering and DIC sources using  $\delta^{13}\text{C}_{\text{DIC}}$  and pH. End-member  $\delta^{13}\text{C}_{\text{DIC}}$  ranges for equilibrium processes (mixing with atmospheric and/or biotic CO<sub>2</sub>) and kinetic reactions (mineral weathering) were derived following Lehn et al. (2017).

To evaluate potential effects on  $\delta^{13}\text{C}_{\text{CO}_2}$  from DIC speciation along the pH continuum (Eq. A8) (Clark and Fritz, 1997), we compared theoretical and observed  $\delta^{13}\text{C}_{\text{CO}_2}$  values in the Stony Creek mainstem. Theoretical  $\delta^{13}\text{C}_{\text{CO}_2}$

205 values were calculated using mass balance to obtain  $\delta^{13}\text{C}_{\text{HCO}_3^-}$  from measurements of DIC,  $\text{CO}_2$ ,  $\text{HCO}_3^-$ ,  $\delta^{13}\text{C}_{\text{DIC}}$ , and  
 $\delta^{13}\text{C}_{\text{CO}_2}$ . We then used measurements of stream temperature ( $T$ ) to calculate the equilibrium fractionation between  
 $\text{CO}_2$  and  $\text{HCO}_3^-$  ( $\epsilon = -9.483 \times 10^3/T + 23.89\%$ ; Mook et al., 1974). Finally,  $\epsilon$  was subtracted from  $\delta^{13}\text{C}_{\text{HCO}_3^-}$  to  
obtain theoretical  $\delta^{13}\text{C}_{\text{CO}_2}$ . Similarity between observed and theoretical  $\delta^{13}\text{C}_{\text{CO}_2}$  values was interpreted as  $\delta^{13}\text{C}_{\text{CO}_2}$   
210 variability driven by carbonate equilibrium reactions, whereas dissimilarity was taken to reflect effects from  $\text{CO}_2$   
degassing (Zhang et al., 1995) and/or biotic  $\text{CO}_2$  production (Kendall et al., 2014).

## 2.6 Geospatial Analyses

Stream networks and watershed areas were delineated in ArcGIS 10.5 from the gridded (30 m) Canadian Digital  
Elevation Model (CDEM). To statistically assess landscape controls on DIC cycling (Sect. 2.7), we delineated active  
RTSs and derived terrain roughness and vegetation productivity in the major tributary watersheds of Stony Creek.  
215 RTSs were interpreted as active where exposed sediment visibly dominated the feature surface (Cray and Pollard,  
2015) in orthorectified SPOT multispectral imagery that we pan-sharpened to 1.6 m resolution using the ArcGIS  
Image Analysis tool. The satellite imagery was collected from September 9 to 25, 2016. Active RTSs that were  
connected to streams were manually delineated using ArcGIS. We used RivEx 10.25 software (Hornby, 2017) to  
quantify the number of active RTSs impacting streams in the Stony Creek watershed and to visualize RTS impact  
220 accumulation across the fluvial network. We defined RTS impact accumulation as the cumulative number of active  
RTSs impacting upstream reaches. RTSs were interpreted to impact streams based on contact or interpreted  
downslope flow based on slope direction and gradient from the CDEM (Supplementary Information). Where a  
single RTS affected multiple streams, only the upstream segment was used for the accumulation.

We used the Geomorphic and Gradients Metrics Toolbox (Evans et al., 2014) to calculate terrain roughness, which  
225 is a measure of variance across a land surface and represents topographic complexity (Riley et al., 1999). We use  
terrain roughness as a proxy for potential physical erosion, which is known to enhance sulfide oxidation by exposing  
shale regolith throughout the Peel River watershed (Calmels et al., 2007) and may therefore influence DIC. The  
enhanced vegetation index (EVI) was used to broadly evaluate vegetation productivity (Huete et al., 2002), which is  
known to influence DIC production by enhancing mineral weathering (Berner, 1999). We used the U.S. National  
230 Aeronautics and Space Administration EVI product (Didan, 2015), which is derived from gridded (250 m) moderate  
resolution imaging spectroradiometer (MODIS). The MODIS data were collected on July 28, 2017. The ArcGIS  
Zonal Statistics tool was used to calculate total RTS area, mean terrain roughness, and mean EVI in Stony Creek  
tributary watersheds.

## 2.7 Statistics

235 We tested for downstream change in  $\text{HCO}_3^-$  concentration and  $p\text{CO}_2$  along the Stony Creek mainstem using the non-  
parametric Mann-Kendall test from the R software (R Core Team, 2018) package *zyp* (Bronaugh and Werner, 2013),  
following the trend pre-whitening approach detailed by Yue et al. (2002) to account for serial autocorrelation. We  
developed a multiple linear regression model to evaluate the influence of RTS activity on  $\text{HCO}_3^-$  export in Stony

240 Creek tributary watersheds relative to hydrology, terrain roughness, and vegetation productivity. To account for  
potential effects of varying tributary watershed areas on discharge ( $Q$ ) and constituent concentration, we used  
tributary  $\text{HCO}_3^-$  yields in the model. Instantaneous discharge ( $Q$ ,  $\text{m}^3 \text{s}^{-1}$ ) was estimated from the hydraulic geometry  
relationship between  $Q$  and stream width (Eq. 1). Discharge and  $\text{HCO}_3^-$  flux (concentration\* $Q$ ) were normalized to  
the respective tributary watershed area and scaled to estimate daily water yield ( $\text{cm d}^{-1}$ ) and  $\text{HCO}_3^-$  yield ( $\mu\text{mol m}^{-2}$   
 $\text{d}^{-1}$ ). Daily  $\text{HCO}_3^-$  yields in Stony Creek tributaries were modeled as:

245 
$$\text{HCO}_3^- \text{ yield} = \text{RTS}_n + \text{RTS}_{\text{area}} + \text{Water yield} + \text{TR} + \text{EVI} \quad (2)$$

where  $\text{RTS}_n$  is the number of active RTSs;  $\text{RTS}_{\text{area}}$  is the watershed area disturbed by RTSs (%); TR is the mean  
terrain roughness (m); and EVI is the mean enhanced vegetation index (-1 to 1). The multiple linear regression was  
trimmed using the *step* function in the R package *lmerTest* (Kuznetsova et al., 2018) to eliminate covariates which  
did not improve the model. Highly collinear covariates were identified using a Variance Inflation Factor > 3 (Zuur et  
250 al., 2010) and removed from the trimmed models. Model fits were inspected visually with residual plots and  
covariates were transformed as needed to meet assumptions of independent and homoscedastic residuals (Zuur,  
2009). Statistics were performed in the R programming environment (v.3.4; R Core Team, 2018) and significance  
was interpreted at  $\alpha = 0.05$ . To understand potential effects from variable rainfall on water yields prior to and during  
the two-day sampling window of the Stony Creek tributaries, we inspected total rainfall in 24 h increments  
255 preceding the sampling of each Stony Creek tributary. Hourly rainfall data were obtained from a Government of  
Northwest Territories Total meteorological station located ~1 km from the RTS FM2 (Fig. 1).

### 3 Results and Discussion

#### 3.1 Rapid Inorganic Carbon Cycling within a Permafrost Thaw Stream

Hydrochemical trends in the FM2 runoff transect were distinct compared to the Dempster and Stony Creek and  
260 showed that RTS activity enhanced chemical weathering,  $\text{CO}_2$  production, and fluvial export of  $\text{HCO}_3^-$ .  
Concentrations of  $\text{HCO}_3^-$  were up to two orders of magnitude greater in the runoff of RTS FM2 (1510  $\mu\text{M}$ ) than in  
the Dempster and Stony Creek headwaters (1–115  $\mu\text{M}$ ), where RTSs were absent (Table 1, Fig. 2). Building on  
previous findings (Kokelj et al., 2013; Malone et al., 2013; Zolkos et al., 2018), the increase in conductivity along  
the RTS FM2 runoff transect (from 1370 to 1986  $\mu\text{S cm}^{-1}$ ) demonstrates that, upon thaw, minerals within regional  
265 permafrost tills readily weather during fluvial transport. Mineral weathering along the RTS FM2 runoff transect  
occurred in concert with a decrease in  $\text{HCO}_3^-$  from 1510 to 1386  $\mu\text{M}$  (Table 1). The high proportion of  $\text{SO}_4^{2-}$   
relative to other ions (Fig. 3) and  $^{13}\text{C}$ -enriched  $\delta^{13}\text{C}_{\text{DIC}}$  (-1.0‰) (Fig. 4) indicates that DIC was sourced from  
carbonate weathering by  $\text{H}_2\text{SO}_4$  from sulfide oxidation (Clark and Fritz, 1997) and also suggests that sulfate salt  
(e.g. gypsum) dissolution added some  $\text{SO}_4^{2-}$ . Together, these trends reflect a strong coupling between mineral  
270 weathering and DIC production following thaw and exposure of tills by thermokarst (Zolkos et al., 2018). Further,  
while  $\text{HCO}_3^-$  concentrations within the RTS FM2 runoff were high relative to undisturbed headwaters, the decrease

in  $\text{HCO}_3^-$  along the transect indicates that carbonate equilibrium reactions within RTSs on the Peel Plateau can rapidly transform  $\text{HCO}_3^-$  to  $\text{CO}_2$  during fluvial transport.

275 The trends in  $\text{HCO}_3^-$ ,  $p\text{CO}_2$ , and stable  $\text{CO}_2$  isotopes along the RTS FM2 runoff transect indicated that  $\text{H}_2\text{SO}_4$  from sulfide oxidation contributed to  $\text{CO}_2$  production in the upper reach near the RTS and that degassing along the lower reach resulted in  $\text{CO}_2$  efflux to the atmosphere. Within the first 220 m,  $p\text{CO}_2$  increased from 1046 to 1534  $\mu\text{atm}$  and relatively  $^{13}\text{C}$ -enriched  $\delta^{13}\text{C}_{\text{CO}_2}$  (range =  $-11.4$  to  $-12.1\text{‰}$ ) (Table 1, Fig. 5) aligned with values expected from  $\text{H}_2\text{SO}_4$  weathering of regional carbonate ( $-0.7$  to  $-5.6\text{‰}$ ) (Hitchon and Krouse, 1972), when accounting for isotopic fractionation of  $\sim 8\text{‰}$  between carbonate and  $\text{CO}_2$  at the temperature of FM2 runoff ( $18^\circ\text{C}$ ) (Clark and Fritz, 1997).  
280 These trends are consistent with some abiotic  $\text{CO}_2$  production via carbonate weathering and  $\text{HCO}_3^-$  conversion to  $\text{CO}_2$ . After 220 m,  $p\text{CO}_2$  decreased from 1534 to 742  $\mu\text{atm}$  and  $\delta^{13}\text{C}_{\text{CO}_2}$  values increased from  $-11.4$  to  $-10\text{‰}$ , reflecting the preferential loss of  $^{12}\text{C}$  in the  $\text{CO}_2$  phase via DIC fractionation and degassing (Doctor et al., 2008; Drake et al., 2018b; Kendall et al., 2014).  $^{13}\text{C}$  enrichment of the  $\text{CO}_2$  pool by methanogenesis (Campeau et al., 2018), photosynthesis (Descolas-Gros and Fontungne, 1990), and/or calcite precipitation (Turner, 1982) was  
285 unlikely, as  $\text{CH}_4$  in FM2 runoff was relatively low ( $p\text{CH}_4 = 3.6 \pm 1.9 \mu\text{atm}$ , mean  $\pm$  SD,  $n = 6$ ), the high turbidity of FM2 runoff likely inhibited photosynthesis, and calcite was below saturation ( $\text{SI} = -0.79$ ). These observations of rapid  $\text{CO}_2$  production along the upper reach of the transect and efflux along the lower reach align with recent estimates of high rates of  $\text{CO}_2$  efflux within RTS runoff (Zolkos et al., 2019).

290 Our observations of downstream DIC transformation coupled to mineral weathering indicate that recently thawed permafrost substrate can rapidly generate substantial  $\text{HCO}_3^-$  and some abiotic  $\text{CO}_2$  during fluvial transport within RTS rill runoff. A majority of the DIC was exported to larger streams as  $\text{HCO}_3^-$ , while a smaller proportion was converted to  $\text{CO}_2$  and degassed during fluvial transport within the RTS runoff. Similar to research on organic matter decomposition in Yedoma regions (Drake et al., 2018b), these results from a relatively inorganic-rich terrain demonstrate that thermokarst can promote rapid inorganic carbon cycling upon thaw and during fluvial transport in  
295 meltwater thaw streams.

### 3.2 Abiotic-Inorganic Carbon Cycling in a Thermokarst-Affected Intermediate Watershed

Along the Dempster Creek transect, trends in  $\text{HCO}_3^-$  concentration,  $p\text{CO}_2$ , and stable isotopes reflected a clear shift in carbon cycling driven by biotic-organic processes in the undisturbed headwaters to abiotic-inorganic processes in the RTS-affected reach (Fig. 1). In the undisturbed Dempster Creek headwaters (site one), relatively low pH (5.82)  
300 (Table 1), high  $p\text{CO}_2$  (2467  $\mu\text{atm}$ ) (Fig. 2b), and low  $\delta^{13}\text{C}_{\text{DIC}}$  and  $\delta^{13}\text{C}_{\text{CO}_2}$  values (Figs. 4, 5) reflected DIC that was primarily sourced from inputs of soil  $\text{CO}_2$  and mixing with atmospheric  $\text{CO}_2$  (Campeau et al., 2018; Kendall et al., 2014). The concentration of  $\text{HCO}_3^-$  was ten times lower in the undisturbed headwaters (115  $\mu\text{M}$ ) than at the downstream site nearest the FM2 runoff (site two, 1321  $\mu\text{M}$ ) (Table 1, Fig. 2a), where  $\delta^{13}\text{C}_{\text{DIC}}$  reflected  $\text{H}_2\text{SO}_4$  carbonate weathering and inputs from the RTS runoff described above (Fig. 4). In conjunction with the increase in  
305  $\text{HCO}_3^-$  between Dempster Creek headwaters and the first RTS-affected sampling site,  $p\text{CO}_2$  decreased (from 2467 to

686  $\mu\text{atm}$ ) and  $\delta^{13}\text{C}_{\text{CO}_2}$  increased (from  $-21.6$  to  $-16.0\%$ ) (Table 1). Although DOC from RTS runoff is known to be relatively biolabile within streams on the Peel Plateau (Littlefair et al., 2017), these trends between the undisturbed headwaters and the first RTS-affected sampling site suggest stronger effects on DIC from  $\text{CO}_2$  degassing to the atmosphere than from biotic  $\text{CO}_2$  production associated with inputs of permafrost organic carbon from RTS activity (Doctor et al., 2008; Drake et al., 2018b; Kendall et al., 2014). This may be partly due to the protection of DOC from microbial oxidation via adsorption to RTS sediments (Gentsch et al., 2015), which aligns with our observations of high TSS ( $11800 \text{ mg L}^{-1}$ ) and a decrease in DOC concentration downstream of RTS FM2 (Table 1, Fig. 6) (Littlefair et al., 2017). These trends are consistent with observations that substantial  $\text{CO}_2$  is lost in headwaters via efflux to the atmosphere (Drake et al., 2018b) and also show that abiotic-inorganic processes can dominate carbon cycling where thermokarst releases inorganic substrate into fluvial networks.

The hydrochemical trends along the RTS-affected reach of the Dempster Creek transect (sites 2–4) showed that the balance between inputs from RTS-affected and undisturbed streams moderated the magnitude of  $\text{HCO}_3^-$  export within downstream environments. The decrease in  $\text{HCO}_3^-$  ( $1321$  to  $946 \mu\text{M}$ ; Fig. 2) and conductivity ( $958$  to  $416 \mu\text{S cm}^{-1}$ ; Table 1) along the entire RTS-affected reach of the transect occurred in conjunction with inputs from dozens of small, non RTS-affected tributary streams, suggesting that these streams were partly responsible for diluting the inputs from RTS activity. Further, the area of RTS disturbance within successive downstream watersheds decreased from  $3.2$  to  $1.2\%$  (Table 1), indicating that RTS inputs diminished relative to inputs from undisturbed areas of the Dempster Creek watershed. Despite some dilution, the high concentration of  $\text{HCO}_3^-$  and  $\delta^{13}\text{C}_{\text{DIC}}$  enrichment near the mouth of Dempster Creek (Figs. 1, 4) indicate that  $\text{H}_2\text{SO}_4$  carbonate weathering associated with RTS activity enhanced  $\text{HCO}_3^-$  export far downstream.

In addition to  $\text{HCO}_3^-$ , RTSs on the Peel Plateau deliver a large amount of carbonate-bearing sediment to stream networks (Kokelj et al., 2015; Zolkos et al., 2018). We hypothesized that  $\text{H}_2\text{CO}_3$  weathering of these sediments during fluvial transport may stimulate some  $\text{CO}_2$  consumption (St. Pierre et al., 2019; Striegl et al., 2007). Along the RTS-affected reach of the Dempster Creek transect (sites 2–4, Fig. 1),  $p\text{CO}_2$  decreased from  $686$  to  $600 \mu\text{atm}$  (Fig. 2b). Yet, the coincident decreases in conductivity,  $\text{HCO}_3^-$ , and pH (Table 1, Figs. 2a, 4) suggest that dilution and degassing had stronger effects on the decreasing  $p\text{CO}_2$  than did  $\text{H}_2\text{CO}_3$  carbonate weathering. Although we observed a net decrease in  $p\text{CO}_2$ , the relatively depleted and decreasing  $\delta^{13}\text{C}_{\text{CO}_2}$  values (Table 1, Fig. 5) indicate some contribution from biotic processes to  $p\text{CO}_2$  supersaturation in the RTS-affected reach. This aligns with increasing concentrations of DOC which resembled the terrestrial-origin DOC in tributary streams (as inferred from  $\text{SUVA}_{254}$ ) (Table 1, Fig. 6), suggesting that tributary streams stimulated some microbial production of terrestrial-origin  $\text{CO}_2$ , and/or delivered  $^{13}\text{C}$ -depleted (biotic)  $\text{CO}_2$  to Dempster Creek.

Together, our observations along the RTS FM2 runoff (Sect. 3.1) and Dempster Creek (Sect. 3.2) transects suggest that rates of carbonate weathering and  $\text{CO}_2$  degassing are most pronounced following thaw and within headwaters. These effects are less pronounced in mid-order streams like Dempster Creek, which mix with inputs from

340 undisturbed tributaries, may receive and/or generate some biotic CO<sub>2</sub>, and export HCO<sub>3</sub><sup>-</sup> downstream at a magnitude  
coupled to the area of RTS disturbance.

### 3.3 Thermokarst Effects on HCO<sub>3</sub><sup>-</sup> Export and CO<sub>2</sub> Production across a Major Watershed

Hydrochemical trends along the larger Stony Creek transect resembled those in Dempster Creek and showed that  
RTS activity strengthens signals of H<sub>2</sub>SO<sub>4</sub> carbonate weathering and amplifies HCO<sub>3</sub><sup>-</sup> export across watershed  
345 scales. In the mountainous, non-RTS affected headwaters of Stony Creek, where bedrock lithologies contain limited  
carbonate, the Ca<sup>2+</sup>-Mg<sup>2+</sup>-SO<sub>4</sub><sup>2-</sup>-type waters at site one (Fig. 3a) reflected the denudation of sulfide- and gypsum-  
bearing bedrock exposed in the Richardson Mountains (Norris, 1985). In these headwaters, *p*CO<sub>2</sub> near atmospheric  
equilibrium (Fig. 2), low HCO<sub>3</sub><sup>-</sup> (33 μM) and pH (5.66), and intermediate δ<sup>13</sup>C<sub>DIC</sub> (-11.6‰) values indicated that  
mixing with atmospheric and biotic CO<sub>2</sub> were the primary sources of DIC (Fig. 4). Along the entire Stony Creek  
350 transect, the striking increase in HCO<sub>3</sub><sup>-</sup> (from 33 to 461 μM) (Tables 1, A1, Fig. 2a) together with ionic and δ<sup>13</sup>C<sub>DIC</sub>  
signals of intensified carbonate weathering (Figs. 3a, 4) reflect amplified inorganic carbon cycling associated with  
inputs from RTS-affected tributaries. Along Stony Creek, the RTS disturbance area increased from 0% in the  
undisturbed headwaters to 0.36 ± 0.03% (mean ± SD, *n* = 5) of the watersheds of sites four through eight (Table 1).  
This builds on the findings that solutes and sediments from RTSs cascade through fluvial networks (Kokelj et al.,  
355 2013; Malone et al., 2013) and shows that RTS activity, despite covering less than 0.5% of the greater Stony Creek  
watershed, greatly increases fluvial HCO<sub>3</sub><sup>-</sup> export to the Peel River.

While the concentration of HCO<sub>3</sub><sup>-</sup> increased downstream along the entire Stony Creek transect, *p*CO<sub>2</sub> was slightly  
above atmospheric and relatively constant (479 ± 35 μatm, mean ± SD), suggesting a greater balance between CO<sub>2</sub>  
production and degassing to the atmosphere than in the RTS FM2 runoff or undisturbed headwaters. Yet, δ<sup>13</sup>C<sub>CO<sub>2</sub></sub>  
360 values decreased downstream from -13.8 to -18.1‰ along Stony Creek (Fig. 5), indicating a shift in the processes  
influencing CO<sub>2</sub>. To evaluate the relative influence of biotic CO<sub>2</sub> production, CO<sub>2</sub> conversion to HCO<sub>3</sub><sup>-</sup>, and CO<sub>2</sub>  
degassing to the atmosphere on δ<sup>13</sup>C<sub>CO<sub>2</sub></sub> values, we compared our measurements of δ<sup>13</sup>C<sub>CO<sub>2</sub></sub> with theoretical values  
reflecting DIC controlled by speciation along the pH continuum (Eq. A8) (Sect. 2.5). From ~5 to 35 km  
downstream, the good agreement between measured and theoretical δ<sup>13</sup>C<sub>CO<sub>2</sub></sub> values reflected equilibrium  
365 fractionation (ε = 9.7‰ at 9°C; Mook et al., 1974) between CO<sub>2</sub> and HCO<sub>3</sub><sup>-</sup> (Fig. 7). This suggests that carbonate  
equilibrium reactions coupled with increasing HCO<sub>3</sub><sup>-</sup> from RTS-affected tributaries was a primary control on CO<sub>2</sub>  
along the upper reach of the Stony Creek transect. Along the lower reach of the transect, as DOC availability  
increased (Fig. 6), δ<sup>13</sup>C<sub>CO<sub>2</sub></sub> values were lower than would be expected from degassing and/or CO<sub>2</sub> conversion to  
HCO<sub>3</sub><sup>-</sup> (Fig. 7). This suggests that biotic CO<sub>2</sub> sustained the elevated *p*CO<sub>2</sub> downstream (Fig. 3b). Yet, this signal of  
370 biotic CO<sub>2</sub> production was not evident in the <sup>13</sup>C-enriched δ<sup>13</sup>C<sub>DIC</sub> along Stony Creek (Table 1, Fig. 5), which  
reflected a geogenic DIC pool dominated by inputs of HCO<sub>3</sub><sup>-</sup> from RTS-affected tributaries. These trends show that,  
in environments with abundant carbonate weathering, measuring both δ<sup>13</sup>C<sub>CO<sub>2</sub></sub> and δ<sup>13</sup>C<sub>DIC</sub> can provide a more  
complete understanding of DIC sources and cycling (Horgby et al., 2019). From a carbon cycling perspective, these

375 trends in Stony Creek show that  $\text{HCO}_3^-$  export across watershed scales is among the most striking legacies of regional thermokarst activity.

### 3.4 Landscape Controls on Inorganic Carbon Cycling in a Thermokarst-Affected Fluvial Network

In RTS-affected tributaries of Stony Creek (Fig. 1),  $\text{HCO}_3^-$  yields ( $1070 \pm 985 \mu\text{mol m}^{-2} \text{d}^{-1}$ , mean  $\pm$  SD,  $n = 6$ ) were several orders of magnitude higher than in the non-RTS affected headwaters ( $1.6 \mu\text{mol m}^{-2} \text{d}^{-1}$ ) (Table 2) and approached summertime  $\text{HCO}_3^-$  yields in watersheds with carbonate rock weathering by glacial activity ( $2700$  to  $3300 \mu\text{mol m}^{-2} \text{d}^{-1}$ ) (Lafrenière and Sharp, 2005; Striegl et al., 2007). To determine the importance of RTS activity on  $\text{HCO}_3^-$  export in Stony Creek tributary watersheds, we paired estimates of  $\text{HCO}_3^-$  and water yields with geospatial data for active RTSs, terrain roughness, and vegetation productivity in a multiple linear regression model (Sect. 2.7). Water yield, the area of RTS disturbance, and terrain roughness were retained during automated covariate selection for the final model ( $F_3 = 45$ ,  $p < 0.01$ ,  $R^2 = 0.96$ ). In addition to water yield,  $\text{HCO}_3^-$  yield was positively correlated with RTS disturbance area (Table 2). Terrain roughness was anticorrelated with  $\text{HCO}_3^-$  yield, likely owing to relatively more limited carbonate weathering in the mountainous headwaters of the Stony Creek watershed, where exposed shale bedrock predominates (Norris, 1985) (Table 1). Low  $\text{HCO}_3^-$  : water yield in the Stony Creek headwaters (Table 2) further suggested that  $\text{HCO}_3^-$  export was limited by carbonate availability rather than by water. Higher  $\text{HCO}_3^-$  : water yields in RTS-affected tributaries aligned with the model results indicating that RTS activity increases inorganic carbon availability and export across watershed scales on the Peel Plateau.

These findings align with the observation that climate warming and intensifying precipitation has rejuvenated deglaciation-phase geomorphic and associated mineral weathering dynamics across the western Canadian Arctic (Kokelj et al., 2017a). Mineral weathering will likely come to dominate biogeochemical cycles in these regions, which may bear increasing hydrochemical resemblance to landscapes with glacial coverage (Anderson, 2007; St. Pierre et al., 2019; Striegl et al., 2007; Wadham et al., 2019). Further, the considerable  $\text{HCO}_3^-$  export within the Stony Creek watershed, where RTS spanned  $< 0.5\%$  of the watershed, demonstrates that thermokarst development across a fractional proportion of ice- and sediment- rich landscapes can substantially intensify inorganic carbon cycling. Our observations, which capture the effects of mid-summertime thaw and relatively moderate rainfall within the four days prior to sampling (Fig. A1), reflect hydrochemical trends that are likely to vary during the summertime. Constraining these trends across a broader range of hydrologic and permafrost thaw conditions will help to understand variability in mineral weathering effects on inorganic carbon cycling.

### 3.5 Inorganic Carbon Cycling in Thermokarst-Affected Fluvial Networks

Our study is among the first to evaluate inorganic carbon cycling across gradients of thermokarst disturbance and nested watersheds, enabling an assessment of how catchment chemical characteristics and thermokarst effects integrate across watershed scales. In this framework, our findings support a novel conceptual model of land-freshwater linkages and carbon cycling from headwaters to intermediate scales in thermokarst terrains (Fig. 8). Broadly, these findings reveal fast DIC cycling in headwaters and substantial DIC export downstream. Thermokarst

activity increased CO<sub>2</sub> production in headwaters and fluvial HCO<sub>3</sub><sup>-</sup> export across scales by unearthing large amounts of reactive inorganic substrate previously sequestered in permafrost (see also Kokelj et al., 2013; Malone et al., 410 2013). The striking carbonate weathering and DIC production that we documented in the RTS FM2 runoff indicates that rapid carbon cycling can be expected where thermokarst releases inorganic substrate with limited prior modification (Lacelle et al., 2019). In the larger Stony Creek watershed, DIC cycling was characterized by relatively slower processes associated with HCO<sub>3</sub><sup>-</sup> export, which reached magnitudes comparable to watersheds with carbonate denudation by glacial activity (Lafrenière and Sharp, 2005; Striegl et al., 2007). Our findings directly link 415 accelerating thermokarst activity on the Peel Plateau (Segal et al., 2016) with signals of intensifying carbon weathering across the broader Peel and Mackenzie River watersheds (Tank et al., 2016; Zolkos et al., 2018) and suggest that accelerating thermokarst activity will intensify inorganic carbon cycling across broad swaths of the circumpolar north (Zolkos et al., 2018).

Permafrost terrains susceptible to hillslope thermokarst like RTSs are abundant within and outside of former glacial 420 limits across the circumpolar north (Zolkos et al., 2018). Owing to regional variability in geology, glacial activity, climate, and ecosystem history, the mineral composition of permafrost in these regions is likely heterogeneous (Lacelle et al., 2019; Zolkos et al., 2018). The degree to which carbonate weathering is coupled with sulfide oxidation in thermokarst terrains will determine if mineral weathering is a CO<sub>2</sub> sink or source, and thus the strength of abiotic components of the permafrost carbon-climate feedback (Schuur et al., 2015; Zolkos et al., 2018). Current 425 models suggest that mineral weathering across the Peel River watershed is a modest source of CO<sub>2</sub> to the atmosphere, owing to widespread sulfide oxidation coupled with carbonate weathering (Beaulieu et al., 2011). Yet these models do not account for enhanced weathering associated with RTS activity (Tank et al., 2016) and are based on relatively coarse lithologic data which under-represent the abundance of carbonate in exposed bedrock in the southern Richardson and Mackenzie Mountains (Norris, 1985). In the Eurasian north, increasing alkalinity fluxes in 430 recent decades are thought to reflect enhanced H<sub>2</sub>CO<sub>3</sub> carbonate weathering coincident with a suite of environmental changes including intensifying permafrost thaw, precipitation, and vegetation activity (Drake et al., 2018b). Integrating thermokarst activity and the mineral composition of permafrost into the next generation of dynamic-numerical biogeochemical models (Beaulieu et al., 2011) will facilitate a better understanding of the effects of permafrost thaw on carbon cycling across rapidly changing northern environments.

#### 435 4 Conclusions

Few studies have traced the effects of thermokarst on carbon cycling across watershed scales or within a relatively inorganic-rich permafrost terrain. Here, we find that the climate-driven renewal of deglaciation-phase geomorphic and associated mineral weathering dynamics in the western Canadian Arctic is amplifying CO<sub>2</sub> release in headwaters and exporting substantial HCO<sub>3</sub><sup>-</sup> primarily from H<sub>2</sub>SO<sub>4</sub> carbonate weathering across watershed scales, 440 despite RTS disturbance across only a fractional proportion of the landscape. Mineral weathering in our study region is both a contemporary and long-term positive feedback to climate change, albeit minor at the scale of inquiry

445

(Zolkos et al., 2019). Constraining DIC sources and fluvial export across diverse permafrost terrains is critical for understanding a rapidly changing arctic carbon cycle, as our results demonstrate that accelerating thermokarst activity may cause abiotic-inorganic processes to dominate aquatic carbon cycling across broad swaths of the circumpolar north.

662

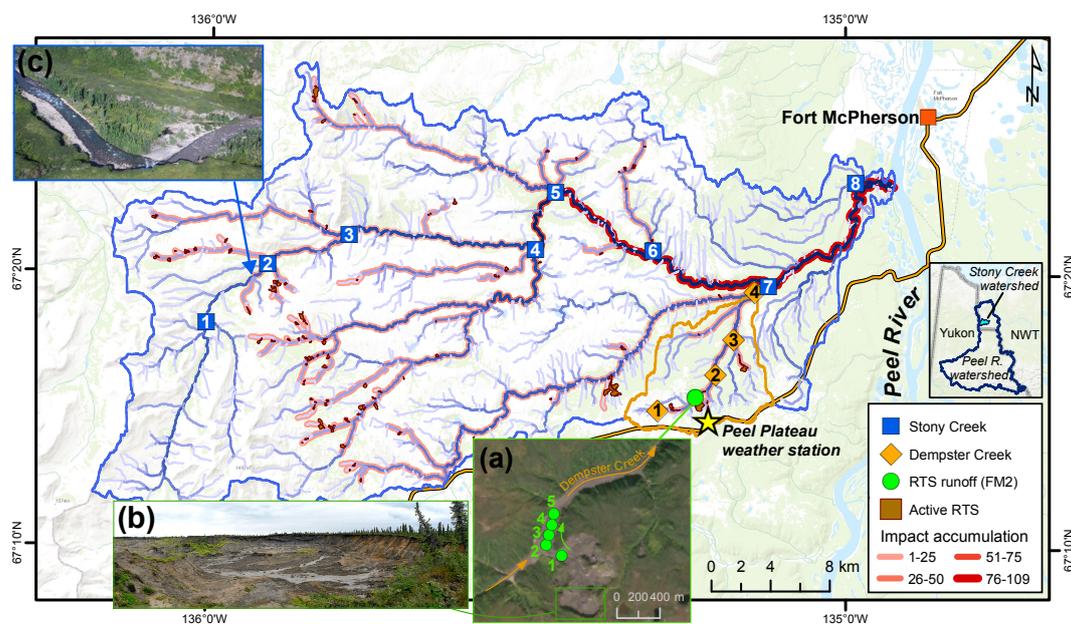

663 **Table 2.** Characteristics of Stony Creek tributary watersheds. RTS = retrogressive thaw slump. The Stony Creek  
 664 watershed contained 109 RTSs, 92 of which were in the major tributaries of the Stony Creek mainstem. TR = terrain  
 665 roughness. EVI = enhanced vegetation index. Values were used in the multiple linear regression model to determine  
 666 the drivers of  $\text{HCO}_3^-$  yields in Stony Creek tributary watersheds. Model results are shown in the lower panel.  
 667 Covariates eliminated during model selection ( $\text{RTS}_n$ , EVI) are not reflected in the lower panel or final model:  $\text{HCO}_3^-$   
 668  $\text{yield} = 2818 \ln \text{Water yield} + 183 \text{RTS}_{\text{area}} - 101 \text{TR} + 2818$ .

Tributary	$\text{HCO}_3^-$ yield ( $\mu\text{M m}^{-2} \text{d}^{-1}$ )	Water yield ( $\text{cm d}^{-1}$ )	RTS (% area)	RTS ( <i>n</i> )	Mean TR (m)	Mean EVI
1	1.6	0.20	0.00	0	16.2	0.28
2	2721	0.61	3.50	6	3.4	0.48
3	616	0.18	0.16	3	6.7	0.45
4	155	0.04	0.67	50	4.5	0.45
5	742	0.12	0.31	11	4.7	0.46
6	1791	0.28	0.20	8	2.7	0.47
7	397	0.07	0.60	14	3.6	0.45

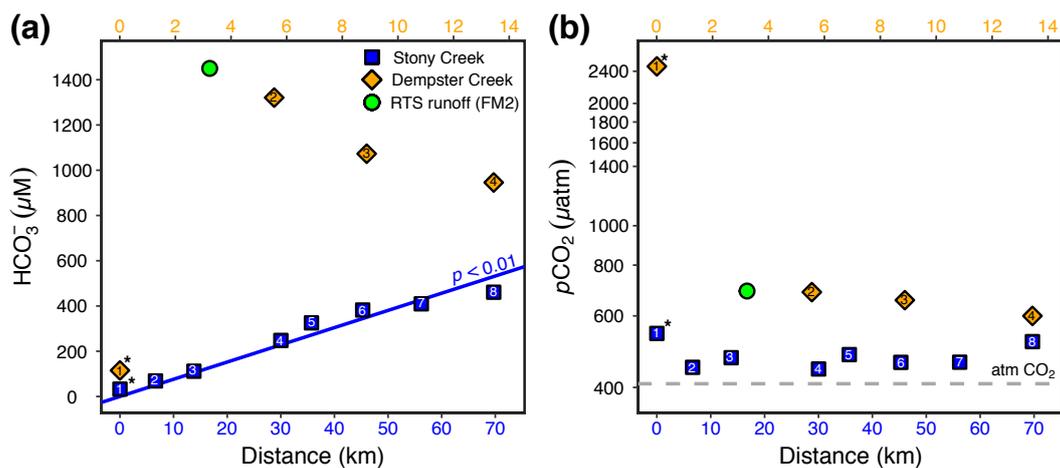

Covariate	Estimate	<i>t</i>	<i>p</i>
$\ln \text{Water yield}$	774	6.6	0.01
$\text{RTS}_{\text{area}}$	183	2.0	0.14
TR	-101	-5.0	0.02

671 **Figure 1.** Sampling sites on the Peel Plateau (NWT, Canada). Water samples were collected along the mainstem  
672 Dempster and Stony Creeks ( $n = 12$ ) and major tributaries ( $n = 10$ ), and from the rill runoff at retrogressive thaw  
673 slump (RTS) FM2. Site numbers are given within symbols (Table A1). Basemap from Esri ArcGIS Online. (a) RTS  
674 FM2 runoff transect sampling scheme. Satellite image of RTS FM2 in September 2017 obtained from Copernicus  
675 Sentinel data (European Space Agency, <https://sentinel.esa.int/>). (b) A portion of the RTS FM2 headwall (see  
676 location in (a)). RTS FM2 spans ~40 ha, its headwall reaches ~25 m in height, and the debris tongue contains ~ $10^6$   
677  $m^3$  of sediment (Kokelj et al., 2013). (c) Aerial photograph of Stony Creek where it was first impacted by RTS  
678 activity. RTS impact accumulation (see Methods Sect. 2.6) represents the number of active RTSs (total  $n = 109$ )  
679 affecting upstream reaches. Basemap: Esri ArcGIS Online © OpenStreetMap contributors, GIS User Community.

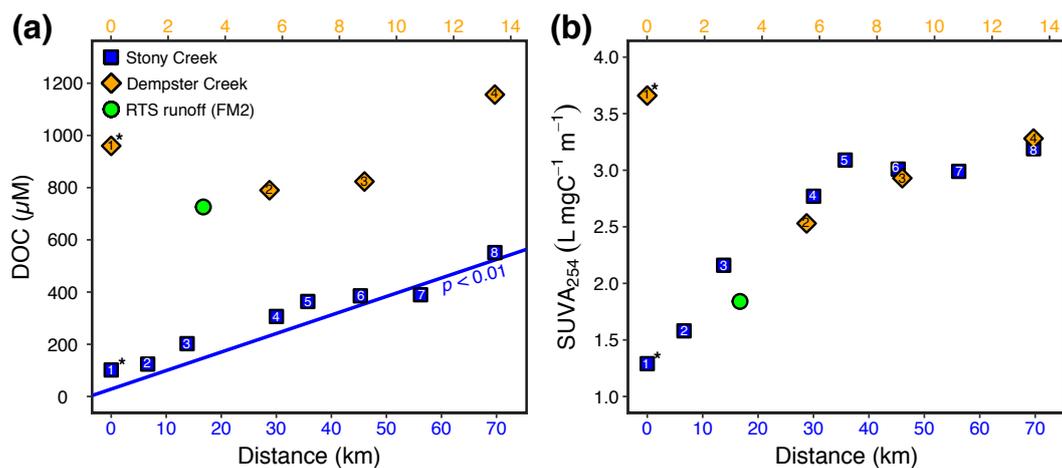

**Figure 3.** Piper diagrams (modified to show the upper half of the diamond plot) showing stream chemistry of the (a) mainstem sites and (b) tributary and retrogressive thaw slump (RTS) FM2 runoff sites. Axes and corresponding text in gray and black reflect the proportions of cations and anions, respectively. Mineral weathering end-members were derived from the proportional concentration ( $\text{meq L}^{-1}$ ) of solutes generated by  $\text{H}_2\text{CO}_3$  carbonate weathering (CACW, Eq. A1),  $\text{H}_2\text{SO}_4$  carbonate weathering (SACW, Eq. A3),  $\text{H}_2\text{SO}_4$  silicate weathering (SASW, Eq. A4), sulfate salt (gypsum) dissolution (SSD, Eq. A5), and carbonate weathering by  $\text{H}_2\text{SO}_4$  in excess ( $\text{SA}_{\text{exCW}}$ , Eq. A7). Site numbers given within symbols (Table A1). \*Site was not affected by RTSs.

694  
 695 **Figure 4.** The pH and composition of dissolved inorganic carbon stable isotopes ( $\delta^{13}\text{C}_{\text{DIC}}$ ) in streams. The upper and  
 696 lower reference lines depict theoretical end-members for equilibrium reactions (mixing with atmospheric and biotic  
 697  $\text{CO}_2$ , respectively). Gray boxes span theoretical end-member values for kinetically controlled mineral weathering  
 698 reactions (SACW =  $\text{H}_2\text{SO}_4$  carbonate weathering, CACW =  $\text{H}_2\text{CO}_3$  carbonate weathering, CASW =  $\text{H}_2\text{CO}_3$  silicate  
 699 weathering). The vertical line corresponds to the pH at which  $\geq 90\%$  of DIC is  $\text{HCO}_3^-$ , for the mean observed stream  
 700 water temperature ( $11.7^\circ\text{C}$ ). At  $\text{pH} < 7.4$ ,  $\delta^{13}\text{C}_{\text{DIC}}$  values primarily reflect equilibrium (rather than kinetic) controls  
 701 on DIC cycling. Arrows reflect increasing downstream distance from the headwaters in Stony Creek and from the  
 702 first retrogressive thaw slump (RTS) affected site in Dempster Creek. Site numbers given within symbols (Table  
 703 A1). \*Site was not affected by RTSs.  
 704

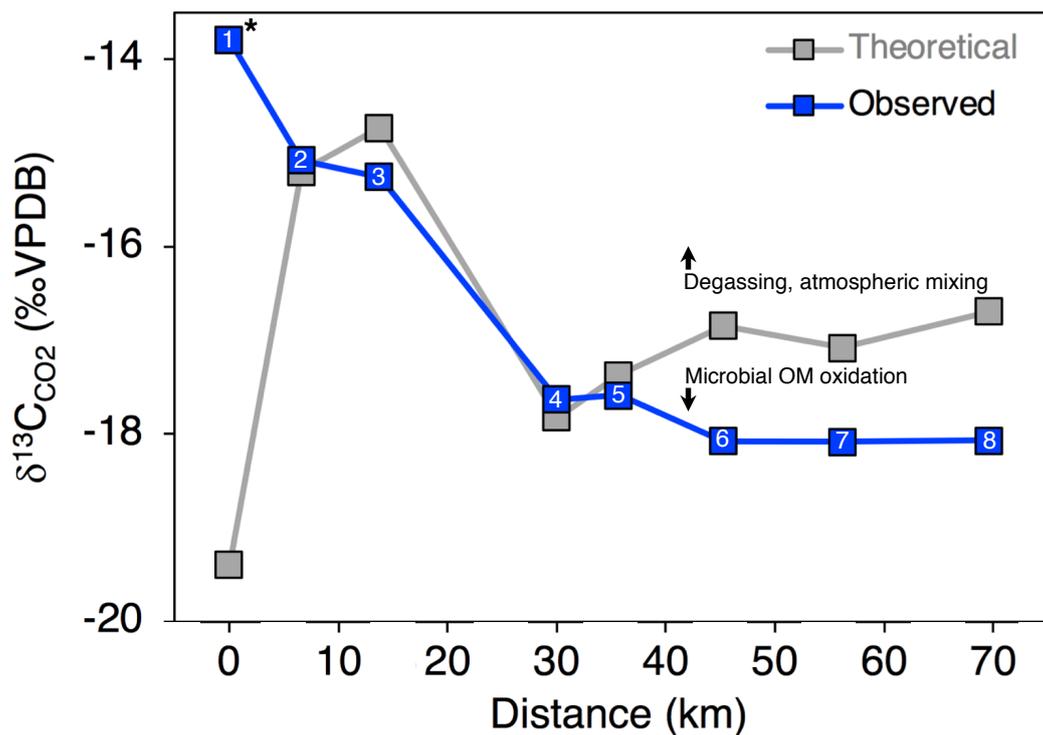

705  
706 **Figure 5.** The composition of DIC and CO<sub>2</sub> stable isotopes at varying DIC concentrations along the Dempster and  
707 Stony Creek mainstems, and in the rill runoff of retrogressive thaw slump (RTS) FM2. Arrows reflect increasing  
708 downstream distance from headwaters in Stony Creek, from the first RTS-affected site in Dempster Creek, and from  
709 the start of the FM2 runoff transect. Site numbers given within symbols (Table A1). \*Site in headwaters and not  
710 affected by RTSs.

718  
719  
720  
721  
722

**Figure 7.** Observed and expected  $\delta^{13}\text{C}_{\text{CO}_2}$  values along the Stony Creek mainstem. Theoretical  $\delta^{13}\text{C}_{\text{CO}_2}$  values were calculated as detailed in Sect. 2.6 and reflect changes in  $\text{CO}_2$  due to DIC speciation (i.e.  $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$ , Eq. A8). Deviation from theoretical  $\delta^{13}\text{C}_{\text{CO}_2}$  values by observed values thus indicates isotopic effects from degassing and/or microbial oxidation of organic matter (OM), as indicated by the arrows. Site numbers given within symbols (Table A1). \*Site was not affected by retrogressive thaw slumps.

723  
 724 **Figure 8.** Conceptual model of fluvial inorganic carbon cycling in a glaciated thermokarst terrain (Peel Plateau,  
 725 NWT). Evidence for processes in the diagram are shown as numbers and discussed in the main text: <sup>1</sup>Low CO<sub>2</sub>,  
 726 intermediate δ<sup>13</sup>C<sub>CO2</sub>; <sup>2</sup>High SO<sub>4</sub><sup>2-</sup> and <sup>13</sup>C-enriched δ<sup>13</sup>C<sub>DIC</sub>; <sup>3</sup>Low δ<sup>13</sup>C<sub>CO2</sub>; <sup>4</sup>decreasing CO<sub>2</sub>; <sup>5</sup>High HCO<sub>3</sub><sup>-</sup>, pH, and  
 727 δ<sup>13</sup>C<sub>DIC</sub>; <sup>6,7</sup>Relatively <sup>13</sup>C-enriched δ<sup>13</sup>C<sub>DIC</sub> and increasing δ<sup>13</sup>C<sub>CO2</sub>; <sup>8</sup>high but decreasing HCO<sub>3</sub><sup>-</sup> and conductivity;  
 728 <sup>9</sup>Increasing HCO<sub>3</sub><sup>-</sup>, pH, and δ<sup>13</sup>C<sub>DIC</sub>, and δ<sup>13</sup>C<sub>CO2</sub> reflective of DIC speciation; <sup>10</sup>δ<sup>13</sup>C<sub>CO2</sub> reflective of microbial  
 729 organic matter (OM) oxidation; <sup>11</sup>Saturated and stable pCO<sub>2</sub>; <sup>12</sup>Kokelj et al. (2013), Zolkos et al. (2018).
