

# Implementation of nitrogen cycle in the CLASSIC land model

Ali Asaadi and Vivek. K. Arora

Canadian Centre for Climate Modelling and Analysis, Environment Canada, University of Victoria,  
Victoria, B.C., V8W 2Y2, Canada

1 **Abstract**

2

3 A terrestrial nitrogen (N) cycle model is coupled to carbon (C) cycle in the framework of the Canadian Land  
4 Surface Scheme Including biogeochemical Cycles (CLASSIC). CLASSIC currently models physical and  
5 biogeochemical processes and simulates fluxes of water, energy, and CO<sub>2</sub> at the land-atmosphere  
6 boundary. Similar to most models, gross primary productivity in CLASSIC increases in response to  
7 increasing atmospheric CO<sub>2</sub> concentration. In the current model version, a downregulation  
8 parameterization emulates the effect of nutrient constraints and scales down potential photosynthesis  
9 rates, using a globally constant scalar, as a function of increasing CO<sub>2</sub>. In the new model when nitrogen  
10 (N) and carbon (C) cycles are coupled, cycling of N through the coupled soil-vegetation system facilitates  
11 the simulation of leaf N content and maximum carboxylation capacity ( $V_{cmax}$ ) prognostically. An increase  
12 in atmospheric CO<sub>2</sub> decreases leaf N content, and therefore  $V_{cmax}$ , allowing the simulation of  
13 photosynthesis downregulation as a function of N supply. All primary N cycle processes, that represent  
14 the coupled soil-vegetation system, are modelled explicitly. These include biological N fixation, treatment  
15 of externally specified N deposition and fertilization application, uptake of N by plants, transfer of N to  
16 litter via litterfall, mineralization, immobilization, nitrification, denitrification, ammonia volatilization,  
17 leaching, and the gaseous fluxes of NO, N<sub>2</sub>O, and N<sub>2</sub>. The interactions between terrestrial C and N cycles  
18 are evaluated by perturbing the coupled soil-vegetation system in CLASSIC with one forcing at a time over  
19 the 1850-2017 historical period. These forcings include the increase in atmospheric CO<sub>2</sub>, change in  
20 climate, increase in N deposition, and increasing crop area and fertilizer input, over the historical period.  
21 Increase in atmospheric CO<sub>2</sub> increases the C:N ratio of vegetation; climate warming over the historical  
22 period increases N mineralization and leads to a decrease in vegetation C:N ratio; N deposition also  
23 decreases vegetation C:N ratio; and fertilizer input increases leaching, NH<sub>3</sub> volatilization, and gaseous  
24 losses of N<sub>2</sub>, N<sub>2</sub>O, and NO. These model responses are consistent with conceptual understanding of the  
25 coupled C and N cycles. The simulated terrestrial carbon sink over the 1959-2017 period, from the  
26 simulation with all forcings, is 2.0 Pg C/yr and compares reasonably well with the quasi observation-based  
27 estimate from the 2019 Global Carbon Project (2.1 Pg C/yr). The contribution of increasing CO<sub>2</sub>, climate  
28 change, and N deposition to carbon uptake by land over the historical period (1850-2017) is calculated to  
29 be 84%, 2%, and 14%, respectively.

30

31 **1. Introduction**

32           The uptake of carbon (C) by land and ocean in response to the increase in anthropogenic  
33 fossil fuel emissions of CO<sub>2</sub> has served to slow down the growth rate of atmospheric CO<sub>2</sub> since  
34 the start of the industrial revolution. At present, about 55% of total carbon emitted into the  
35 atmosphere is taken up by land and ocean (Le Quéré et al., 2018; Friedlingstein et al., 2019). It is  
36 of great policy, societal, and scientific relevance whether land and ocean will continue to provide  
37 this ecosystem service. Over land, as long as photosynthesis is not water limited, the uptake of  
38 carbon in response to increasing anthropogenic CO<sub>2</sub> emissions is driven by two primary factors,  
39 1) the CO<sub>2</sub> fertilization of the terrestrial biosphere, and 2) the increase in temperature, both of  
40 which are associated with increasing [CO<sub>2</sub>]. The CO<sub>2</sub> fertilization effect increases photosynthesis  
41 rates for about 80% of the world's vegetation that uses the C<sub>3</sub> photosynthetic pathway and is  
42 currently limited by [CO<sub>2</sub>] (Still et al., 2003; Zhu et al., 2016). The remaining 20% of vegetation  
43 uses the C<sub>4</sub> photosynthetic pathway that is much less sensitive to [CO<sub>2</sub>]. Warming increases  
44 carbon uptake by vegetation in mid-high latitude regions where growth is currently limited by  
45 low temperatures (Zeng et al., 2011).

46           Even when atmospheric CO<sub>2</sub> is not limiting for photosynthesis, and near surface air  
47 temperature is optimal, vegetation cannot photosynthesize at its maximum possible rate if  
48 available water and nutrients (most importantly nitrogen (N) and phosphorus (P)) constrain  
49 photosynthesis (Vitousek and Howarth, 1991; Reich et al., 2006b). In the absence of water and  
50 nutrients, photosynthesis simply cannot occur. N is a major component of chlorophyll (the  
51 compound through which plants photosynthesize) and amino acids (that are the building blocks  
52 of proteins). The constraint imposed by available water and nutrients implies that the carbon

53 uptake by land over the historical period in response to increasing  $[\text{CO}_2]$  is lower than what it  
54 would have been if water and nutrients were not limiting. This lower than maximum theoretically  
55 possible rate of increase of photosynthesis in response to increasing atmospheric  $\text{CO}_2$  is referred  
56 to as downregulation (Faria et al., 1996; Sanz-Sáez et al., 2010). Typically, however, the term  
57 downregulation of photosynthesis is used only in the context of nutrients and not water.  
58 Downregulation is defined as a decrease in photosynthetic capacity of plants grown at elevated  
59  $\text{CO}_2$  in comparison to plants grown at baseline  $\text{CO}_2$  (McGuire et al., 1995). However, despite the  
60 decrease in photosynthetic capacity, the photosynthesis rate for plants grown at elevated  $\text{CO}_2$  is  
61 still higher than the rate for plants grown and measured at baseline  $\text{CO}_2$  because of higher  
62 background  $\text{CO}_2$ .

63 Earth system models (ESMs) that explicitly represent coupling of the global carbon cycle  
64 and physical climate system processes are the only tools available at present that, in a physically  
65 consistent way, are able to project how land and ocean carbon cycles will respond to future  
66 changes in  $[\text{CO}_2]$ . Such models are routinely compared to one another under the auspices of the  
67 Coupled Model Intercomparison Project (CMIP) every 6-7 years. The most recent and sixth phase  
68 of CMIP (CMIP6) is currently underway (Eyring et al., 2016). Interactions between carbon cycle  
69 and climate in ESMs have been compared under the umbrella of the Coupled Climate-Carbon  
70 Cycle Model Intercomparison Project ( $\text{C}^4\text{MIP}$ ) (Jones et al., 2016) which is an approved MIP of  
71 the CMIP. Comparison of land and ocean carbon uptake in  $\text{C}^4\text{MIP}$  studies (Friedlingstein et al.,  
72 2006; Arora et al., 2013, 2020) indicate that the inter-model uncertainty in future land carbon  
73 uptake across ESMs is more than three times than the uncertainty for the ocean carbon uptake.  
74 The reason for widely varying estimates of future land carbon uptake across models is that our

75 understanding of biological processes that determine land carbon uptake is much less advanced  
76 than the physical processes which primarily determine carbon uptake over the ocean. In the  
77 current generation of terrestrial ecosystem models, other than photosynthesis for which a  
78 theoretical framework exists, almost all of the other biological processes are represented on the  
79 basis of empirical observations and parameterized in one way or another. In addition, not all  
80 models include N and P cycles. In the absence of an explicit representation of nutrient constraints  
81 on photosynthesis, land models in ESMs parameterize downregulation of photosynthesis in other  
82 ways that reduce the rate of increase of photosynthesis to values below its theoretically  
83 maximum possible rate, as [CO<sub>2</sub>] increases (e.g., Arora et al., 2009). Comparison of models across  
84 5<sup>th</sup> and 6<sup>th</sup> phase of CMIP shows that the fraction of models with land N cycle is increasing (Arora  
85 et al., 2013, 2020).

86         The nutrient constraints on photosynthesis are well recognized (Vitousek and Howarth,  
87 1991; Arneth et al., 2010). Terrestrial carbon cycle models neglect of nutrient limitation on  
88 photosynthesis has been questioned from an ecological perspective (Reich et al., 2006a) and it  
89 has been argued that without nutrient constraints these models will overestimate future land  
90 carbon uptake (Hungate et al., 2003). Since in the real world photosynthesis downregulation does  
91 indeed occur due to nutrient constraints, it may be argued that more confidence can be placed  
92 in future projections of models that explicitly model the interactions between the terrestrial C  
93 and N cycles rather than parameterize it in some other way.

94         Here, we present the implementation of N cycle in the Canadian Land Surface Scheme  
95 Including biogeochemical Cycles (CLASSIC) model, which serves as the land component in the  
96 family of Canadian Earth System Models (Arora et al., 2009, 2011; Swart et al., 2019). Section 2

97 briefly describes existing physical and carbon cycle components and processes of the CLASSIC  
98 model. The conceptual basis of the new N cycle model and its parameterizations are described  
99 in Section 3. Section 4 outlines the methodology and data sets that we have used to perform  
100 various simulations over the 1850-2017 historical period to assess the realism of the coupled C  
101 and N cycles in CLASSIC in response to various forcings. Results from these simulations over the  
102 historical period are presented in Section 5 and finally discussion and conclusions are presented  
103 in Section 6.

## 104 **2. The CLASSIC land model**

### 105 **2.1 The physical and carbon biogeochemical processes**

106 The CLASSIC model is the successor to, and based on, the coupled Canadian Land Surface  
107 Scheme (CLASS; Verseghy, 1991; Verseghy et al., 1993) and Canadian Terrestrial Ecosystem  
108 Model (CTEM; Arora and Boer, 2005; Melton and Arora, 2016). CLASS and CTEM model physical  
109 and biogeochemical processes in CLASSIC, respectively. Both CLASS and CTEM have a long history  
110 of development as described in Melton et al. (2019) who also provide an overview of the CLASSIC  
111 land model and describe its new technical developments that launched CLASSIC as a community  
112 model. CLASSIC simulates land-atmosphere fluxes of water, energy, momentum, CO<sub>2</sub>, and CH<sub>4</sub>.  
113 The CLASSIC model can be run at a point scale, e.g. using meteorological and geophysical data  
114 from a FluxNet site, or over a spatial domain, that may be global or regional, using gridded data.  
115 We briefly summarize the primary physical and carbon biogeochemical processes of CLASSIC here  
116 that are relevant in the context of implementation of the N cycle in the model.

#### 117 **2.1.1 Physical processes**

118           The physical processes of CLASSIC which simulate fluxes of water, energy and momentum,  
119 are calculated over vegetated, snow, and bare fractions at a sub-daily time step of 30 minutes.  
120 The vegetation is described in terms of four plant functional types (PFTs): needleleaf trees,  
121 broadleaf trees, crops, and grasses. The fractional coverage of these four PFTs are specified in  
122 the current study over the historical period. The structural attributes of vegetation are described  
123 by leaf area index (LAI), vegetation height, canopy mass, and rooting distribution through the soil  
124 layers and these are all simulated dynamically by the biogeochemical module of CLASSIC. In the  
125 model version used here, 20 ground layers starting with 10 layers of 0.1 m thickness are used.  
126 The thickness of layers gradually increases to 30 m for a total ground depth of over 61 m. The  
127 depth to bedrock varies geographically and is specified based on a soil depth data set. Liquid and  
128 frozen soil moisture contents, and soil temperature, are determined prognostically for  
129 permeable soil layers. CLASSIC also prognostically models the temperature, mass, albedo, and  
130 density of a single layer snow pack (when the climate permits snow to exist). Interception and  
131 throughfall of rain and snow by the canopy, and the subsequent unloading of snow, are also  
132 modelled. The energy and water balance over the land surface, and the transfer of heat and  
133 moisture through soil, affect the temperature and soil moisture content of soil layers all of which  
134 consequently affect the carbon and nitrogen cycle processes.

135

### 136 **2.1.2 Biogeochemical processes**

137           The biogeochemical processes in CLASSIC are based on CTEM, and described in detail in  
138 the appendix of Melton and Arora (2016). The biogeochemical component of CLASSIC simulates

139 the land-atmosphere exchange of CO<sub>2</sub> and while doing so simulates vegetation as a dynamic  
140 component. The biogeochemical module of CLASSIC uses information about net radiation, and  
141 liquid and frozen soil moisture contents of all the soil layers along with air temperature to  
142 simulate photosynthesis and prognostically calculates amount of carbon in the model's three live  
143 (leaves, stem, and root) and two dead (litter and soil) carbon pools for each PFT. The litter and  
144 soil carbon pools are not tracked for each soil layer. Litter is assumed to be near surface and an  
145 exponential distribution for soil carbon is assumed with values decreasing with soil depth.  
146 Photosynthesis in CLASSIC is modelled at the same sub-daily time as the physical processes. The  
147 remainder of the biogeochemical processes are modelled at a daily time step. These include: 1)  
148 autotrophic and heterotrophic respirations from all the live and dead carbon pools, respectively,  
149 2) allocation of photosynthate from leaves to stem and roots, 3) leaf phenology, 4) turnover of  
150 live vegetation components that generates litter, 5) mortality, 6) land use change (LUC), 7) fire  
151 (Arora and Melton, 2018), and 8) competition between PFTs for space (not switched on in this  
152 study).

153           Figure A1 in the appendix shows the existing structure of CLASSIC's carbon pools along  
154 with the addition of non-structural carbohydrate pools for each of the model's live vegetation  
155 components. The non-structural pools are not yet represented in the current operational version  
156 of CLASSIC (Melton et al., 2019). The addition of non-structural carbohydrate pools is explained  
157 in Asaadi et al. (2018) and helps improve leaf phenology for cold deciduous tree PFTs. The N cycle  
158 model presented here is built on the research version of CLASSIC that consists of non-structural  
159 and structural carbon pools for the leaves (L), stem (S), and root (R) components and the two  
160 dead carbon pools in litter or detritus (D) and soil or humus (H) (Figure A1). We briefly describe

161 these carbon pools and fluxes between them, since N cycle pools and fluxes are closely tied to  
162 carbon pools and fluxes. The gross primary productivity (GPP) flux enters the leaves from the  
163 atmosphere. This non-structural photosynthate is allocated between leaves, stem, and roots. The  
164 non-structural carbon then moves into the structural carbohydrates pool. Once this conversion  
165 occurs structural carbon cannot be converted back to non-structural labile carbon. The model  
166 attempts to maintain a minimum fraction of non-structural to total carbon in each component of  
167 about 0.05 (Asaadi et al., 2018). Non-structural carbon is moved from stem and root components  
168 to leaves, at the time of leaf onset for deciduous PFTs, and this is termed reallocation. The  
169 movement of non-structural carbon is indicated by red arrows. Maintenance and growth  
170 respiration (indicated by subscript *m* and *g* in Figure A1), which together constitute autotrophic  
171 respiration, occur from the non-structural components of the three live vegetation components.  
172 Litterfall from the structural and non-structural components of the vegetation components  
173 contributes to the litter pool. Leaf litterfall is generated due to normal turnover of leaves as well  
174 as cold and drought stresses, and reduction in day length. Stem and root litter is generated due  
175 to their turnover based on their specified life spans. Heterotrophic respiration occurs from the  
176 litter and soil carbon pools depending on soil moisture and temperature, and humified litter is  
177 moved from litter to the soil carbon pool.

178 All these terrestrial ecosystem processes and the amount of carbon in the live and dead  
179 carbon pools are modelled explicitly for nine PFTs that map directly onto the four base PFTs used  
180 in the physics module of CLASSIC. Needleleaf trees are divided into their deciduous and  
181 evergreen phenotypes, broadleaf trees are divided into cold deciduous, drought deciduous, and  
182 evergreen phenotypes, and crops and grasses are divided based on their photosynthetic

183 pathways into  $C_3$  and  $C_4$  versions. The sub-division of PFTs is required for modelling  
184 biogeochemical processes. For instance, simulating leaf phenology requires the distinction  
185 between evergreen and deciduous phenotypes of needleleaf and broadleaf trees. However, once  
186 LAI is known, a physical process (such as the interception of rain and snow by canopy leaves) does  
187 not need to know the underlying evergreen or deciduous nature of leaves.

188         The prognostically determined biomasses in leaves, stem, and roots are used to calculate  
189 structural vegetation attributes that are required by the physics module. Leaf biomass is used to  
190 calculate LAI using PFT-dependent specific leaf area. Stem biomass is used to calculate vegetation  
191 height for tree and crop PFTs, and LAI is used to calculate vegetation height for grasses. Finally,  
192 root biomass is used to calculate rooting depth and distribution which determines the fraction of  
193 roots in each soil layer. Only total root biomass is tracked; fine and coarse root biomasses are not  
194 separately tracked. Fraction of fine roots is calculated as a function of total root biomass, as  
195 shown later.

196         The approach for calculating photosynthesis in CLASSIC is based on the standard Farquhar  
197 et al. (1980) model for  $C_3$  photosynthetic pathway, and Collatz et al. (1992) for the  $C_4$   
198 photosynthetic pathway and presented in detail in Arora (2003). The model calculates gross  
199 photosynthesis rate that is co-limited by the photosynthetic enzyme Rubisco, by the amount of  
200 available light, and by the capacity to transport photosynthetic products for  $C_3$  plants or the  $CO_2$ -  
201 limited capacity for  $C_4$  plants. In the real world, the maximum Rubisco limited rate ( $V_{cmax}$ ) depends  
202 on the leaf N content since photosynthetic capacity and leaf N are strongly correlated (Evans,  
203 1989; Field and Mooney, 1986; Garnier et al., 1999). In the current operational version of  
204 CLASSIC, the N cycle is not represented and the PFT-dependent values of  $V_{cmax}$  are therefore

205 specified based on Kattge et al. (2009) who compile  $V_{\text{cmax}}$  values using observation-based data  
 206 from more than 700 measurements. Along with available light, and the capacity to transport  
 207 photosynthetic products, the GPP in the model is determined by specified PFT-dependent values  
 208 of  $V_{\text{cmax}}$ .

209 In the current CLASSIC version a parameterization of photosynthesis downregulation is included  
 210 which, in the absence of the N cycle, implicitly attempts to simulate the effects of nutrient  
 211 constraints. This parameterization, based on approaches which express GPP as a logarithmic  
 212 function of  $[\text{CO}_2]$  (Cao et al., 2001; Alexandrov and Oikawa, 2002), is explained in detail in Arora  
 213 et al. (2009) and briefly summarized here. To parameterize photosynthesis downregulation with  
 214 increasing  $[\text{CO}_2]$  the unconstrained or potential GPP (for each time step and each PFT in a grid  
 215 cell) is multiplied by the global scalar  $\xi(c)$

$$216 \quad G = \xi(c) G_p \quad (1)$$

$$217 \quad \xi(c) = \frac{1 + \gamma_d \ln(c/c_0)}{1 + \gamma_p \ln(c/c_0)} \quad (2)$$

218 where  $c$  is  $[\text{CO}_2]$  at time  $t$  and its initial value is  $c_0$ , the parameter  $\gamma_p$  indicates the “potential” rate  
 219 of increase of GPP with  $[\text{CO}_2]$  (indicated by the subscript  $p$ ), the parameter  $\gamma_d$  represents the  
 220 downregulated rate of increase of GPP with  $[\text{CO}_2]$  (indicated by the subscript  $d$ ). When  $\gamma_d < \gamma_p$   
 221 the modelled gross primary productivity ( $G$ ) increases in response to  $[\text{CO}_2]$  at a rate determined  
 222 by the value of  $\gamma_d$ . In the absence of the N cycle, the term  $\xi(c)$  thus emulates down-regulation  
 223 of photosynthesis as  $\text{CO}_2$  increases. For example, values of  $\gamma_d=0.35$  and  $\gamma_p=0.90$ , yield a value of  
 224  $\xi(c) = 0.87$  (indicating a 13% downregulation) for  $c=390$  ppm (corresponding to year 2010) and  
 225  $c_0=285$  ppm.

226 Note that while the original model version does not include N cycle, it is capable of  
227 simulating realistic geographical distribution of GPP that partly comes from the specification of  
228 observation-based  $V_{\text{cmax}}$  values (which implicitly takes into account C and N interactions in a non-  
229 dynamic way) but more so the fact that the geographical distribution of GPP (and therefore net  
230 primary productivity, NPP), to the first order, depends on climate. The specified  $V_{\text{cmax}}$  values for  
231 the 9 PFTs in CLASSIC vary by about 2 times, from about 35 to 75  $\mu\text{-mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ . The simulated  
232 GPP in the model, however, varies from zero in the Sahara desert to about 3000  $\text{gC m}^{-2} \text{ year}^{-1}$  in  
233 the Amazonian rainforest indicating the overarching control of climate in determining the  
234 geographical distribution of GPP. This is further illustrated by the Miami NPP model, for instance,  
235 which is able to simulate the geographical distribution of NPP using only mean annual  
236 temperature and precipitation (Leith, 1975) since both the C and N cycles are governed primarily  
237 by climate. The current version of CLASSIC is also able to reasonably simulate the terrestrial C  
238 sink over the second half of the 20<sup>th</sup> century and early 21<sup>st</sup> century. CLASSIC (with its former  
239 CLASS-CTEM name) has regularly contributed to the annual Trends in Net Land–Atmosphere  
240 Carbon Exchange (TRENDY) model intercomparison since 2016 which contributes results to the  
241 Global Carbon Project’s annual assessments – the most recent one being Friedlingstein et al.  
242 (2019). What is then the purpose of coupling C and N cycles?

243

### 244 **3. Implementation of the N cycle in CLASSIC**

245 The primary objective of implementation of the N cycle is to model  $V_{\text{cmax}}$  as a function of  
246 leaf N content so as to make the use of multiplier  $\xi(c)$  obsolete in the model, and allow to project

247 future carbon uptake that is constrained by available N. Modelling of leaf N content as a  
248 prognostic variable, however, requires modelling the full N cycle over land. N enters the soil in  
249 the inorganic mineral form through biological fixation of N, fertilizer application, and atmospheric  
250 N deposition in the form of ammonium and nitrate. N cycling through plants implies uptake of  
251 inorganic mineral N by plants, its return to soil through litter generation in the organic form, and  
252 its conversion back to mineral form during decomposition of organic matter in litter and soil.  
253 Finally, N leaves the coupled soil-vegetation system through leaching in runoff and through  
254 various gaseous forms to the atmosphere. This section describes how these processes are  
255 implemented and parameterized in the CLASSIC modelling framework. While the first order  
256 interactions between C and N cycles are described well by the current climate, their temporal  
257 dynamics over time require to explicitly model these processes.

258 Globally, terrestrial N cycle processes are even less constrained than the C cycle  
259 processes. As a result, the model structure and parameterizations are based on conceptual  
260 understanding and mostly empirical observations of N cycle related biological processes. We  
261 attempt to achieve balance between a parsimonious and simple model structure and the ability  
262 to represent the primary feedbacks and interactions between different model components.

### 263 **3.1 Model structure, and N pools and fluxes**

264 N is associated with each of the model's three live vegetation components and the two  
265 dead carbon pools (shown in Figure A1). In addition, separate mineral pools of ammonium ( $\text{NH}_4^+$ )  
266 and nitrate ( $\text{NO}_3^-$ ) are considered. Figure 1 shows the C and N pools together in one graphic along  
267 with the fluxes of N and C between various pools. The structural and non-structural N pools in

268 root are written as  $N_{R,S}$  and  $N_{R,NS}$ , respectively, and similarly for stem ( $N_{S,S}$  and  $N_{S,NS}$ ) and leaves  
269 ( $N_{L,S}$  and  $N_{L,NS}$ ), and together the structural and non-structural pools make up the total N pools  
270 in leaf ( $N_L = N_{L,S} + N_{L,NS}$ ), root ( $N_R = N_{R,S} + N_{R,NS}$ ), and stem ( $N_S = N_{S,S} + N_{S,NS}$ ) components.  
271 The fluxes between the pools in Figure 1 characterize the prognostic nature of the pools as  
272 defined by the rate change equations summarized in section A1 in the appendix. The model  
273 structure allows the C:N ratio of the live leaves ( $C:N_L = C_L/N_L$ ), stem ( $C:N_S = C_S/N_S$ ), and root  
274 ( $C:N_R = C_R/N_R$ ) components, and the dead litter (or debris) pool ( $C:N_D = C_D/N_D$ ) to evolve  
275 prognostically. The C:N ratio of soil organic matter ( $C:N_H = C_H/N_H$ ), however, is assumed to be  
276 constant at 13 following Wania et al. (2012) (see also references therein). The implications of this  
277 assumption are discussed later.

278 The individual terms of the rate change equations of the 10 prognostic N pools (equations  
279 A1 through A8, and equations A10 and A11 in the appendix), corresponding to Figure 1, are  
280 specified or parameterized as explained in the following sections. These parameterizations are  
281 divided into three groups and related to 1) N inputs, 2) N cycling in vegetation and soil, and 3) N  
282 cycling in mineral pools and N outputs.

283

## 284 **3.2 N inputs**

### 285 **3.2.1 Biological N fixation**

286 Biological N fixation (BNF,  $B_{NH_4}$ ) is caused by both free living bacteria in the soil and by  
287 bacteria symbiotically living within nodules of host plants' roots. Here, the bacteria convert free  
288 nitrogen from the atmosphere to ammonium, which is used by the host plants. Like any other

289 microbial activity, BNF is limited both by drier soil moisture conditions and cold temperatures.  
 290 Cleveland et al. (1999) attempt to capture this by parameterizing BNF as a function of actual  
 291 evapotranspiration (AET). AET is a function primarily of soil moisture (through precipitation and  
 292 soil water balance) and available energy. In places where vegetation exists, AET is also affected  
 293 by vegetation characteristics including LAI and rooting depth. Here, we parameterize BNF ( $B_{NH4}$ ,  
 294  $\text{gN m}^{-2} \text{day}^{-1}$ ) as a function of modelled soil moisture and temperature to depth of 0.5 m  
 295 (following the use of similar depth by Xu-Ri and Prentice (2008)) which yields a very similar  
 296 geographical distribution of BNF as the Cleveland et al. (1999) approach as seen later in Section  
 297 4.

$$\begin{aligned}
 B_{NH4} &= \left( \sum_c \alpha_c f_c + \sum_n \alpha_n f_n \right) f(T_{0.5}) f(\theta_{0.5}) \\
 f(T_{0.5}) &= 2^{(T_{0.5}-25)/10} \\
 f(\theta_{0.5}) &= \min \left( 0, \max \left( 1, \frac{\theta_{0.5}-\theta_w}{\theta_{fc}-\theta_w} \right) \right)
 \end{aligned} \tag{3}$$

299 where  $\alpha_c$  and  $\alpha_n$  ( $\text{gN m}^{-2} \text{day}^{-1}$ ) are BNF coefficients for crop ( $c$ ) and non-crop or natural ( $n$ ) PFTs,  
 300 which are area weighted using the fractional coverages  $f_c$  and  $f_n$  of crop and non-crop PFTs that  
 301 are present in a grid cell,  $f(T)$  is the dependence on soil temperature based on a  $Q_{10}$  formulation  
 302 and  $f(\theta)$  is the dependence on soil moisture which varies between 0 and 1.  $\theta_{fc}$  and  $\theta_w$  are the  
 303 soil moisture at field capacity and wilting points, respectively.  $T_{0.5}$  ( $^{\circ}\text{C}$ ) and  $\theta_{0.5}$  ( $\text{m}^3 \text{m}^{-3}$ ) in  
 304 equation (3) are averaged over the 0.5 m soil depth over which BNF is assumed to occur. We do  
 305 not make the distinction between symbiotic and non-symbiotic BNF since this requires explicit  
 306 knowledge of geographical distribution of N fixing PFTs which are not represented separately in  
 307 our base set of nine PFTs. A higher value of  $\alpha_c$  is used compared to  $\alpha_n$  to account for the use of  
 308 N fixing plants over agricultural areas. Biological nitrogen fixation has been an essential

309 component of many farming systems for considerable periods, with evidence for the agricultural  
310 use of legumes dating back more than 4,000 years (O’Hara, 1998). A higher  $\alpha_c$  than  $\alpha_n$  is also  
311 consistent with Fowler et al. (2013) who report BNF of 58 and 60 Tg N yr<sup>-1</sup> for natural and  
312 agricultural ecosystems for present day. Since the area of natural ecosystems is about five times  
313 the current cropland area, this implies BNF rate per unit land area is higher for crop ecosystems  
314 than for natural ecosystems. Values of  $\alpha_c$  than  $\alpha_n$  and other model parameters are summarized  
315 in Table A1.

316           Similar to Cleveland et al. (1999), our approach does not lead to a significant change in  
317 BNF with increasing atmospheric CO<sub>2</sub>, other than through changes in soil moisture and  
318 temperature. At least two meta-analyses, however, suggest that an increase in atmospheric CO<sub>2</sub>  
319 does lead to an increase in BNF through increased symbiotic activity associated with an increase  
320 in both nodule mass and number (McGuire et al., 1995; Liang et al., 2016). Models have  
321 attempted to capture this by simulating BNF as a function of NPP (Thornton et al., 2007; Wania  
322 et al., 2012). The caveat with this approach and the implications of our BNF approach are  
323 discussed in Section 6.

### 324 **3.2.2 Atmospheric N deposition**

325           Atmospheric N deposition is externally specified. The model reads in spatially- and  
326 temporally-varying annual deposition rates from a file. Deposition is assumed to occur at the  
327 same rate throughout the year so the same daily rate (gN m<sup>-2</sup> day<sup>-1</sup>) is used for all days of a given  
328 year. If separate information for ammonium (NH<sub>4</sub><sup>+</sup>) and nitrate (NO<sub>3</sub><sup>-</sup>) deposition rates is available

329 then it is used otherwise deposition is assumed to be split equally between  $\text{NH}_4^+$  and  $\text{NO}_3^-$   
330 (indicated as  $P_{\text{NH}_4}$  and  $P_{\text{NO}_3}$  in equations A1 and A2).

### 331 **3.2.3 Fertilizer application**

332 Geographically and temporally varying annual fertilizer application rates ( $F_{\text{NH}_4}$ ) are also  
333 specified externally and read in from a file. Fertilizer application occurs over the  $\text{C}_3$  and  $\text{C}_4$  crop  
334 fractions of grid cells. Agricultural management practices are difficult to model since they vary  
335 widely between countries and even from farmer to farmer. For simplicity, we assume fertilizer is  
336 applied at the same daily fertilizer application rate ( $\text{gN m}^{-2} \text{ day}^{-1}$ ) throughout the year in the  
337 tropics (between  $30^\circ\text{S}$  and  $30^\circ\text{N}$ ), given the possibility of multiple crop rotations in a given year.  
338 Between the  $30^\circ$  and  $90^\circ$  latitudes in both northern and southern hemispheres, we assume that  
339 fertilizer application starts on the spring equinox and ends on the fall equinox. The annual  
340 fertilizer application rate is thus distributed over around 180 days. This provides somewhat more  
341 realism, than using the same treatment as in tropical regions, since extra-tropical agricultural  
342 areas typically do not experience multiple crop rotations in a given year. The prior knowledge of  
343 start and end days for fertilizer application makes it easier to figure out how much fertilizer is to  
344 be applied each day and helps ensure that the annual amount read from the externally specified  
345 file is consistently applied.

346

### 347 **3.3 N cycling in plants and soil**

348 Plant roots take up mineral N from soil and then allocate it to leaves and stem to maintain  
349 an optimal C:N ratio of each component. Both active and passive plant uptakes of N (from both

350 the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools; explained in Sections 3.3.2 and 3.3.3) are explicitly modelled. The active  
 351 N uptake is modelled as a function of fine root biomass, and passive N uptake depends on the  
 352 transpiration flux. The modelled plant N uptake also depends on its N demand. Higher N demand  
 353 leads to higher mineral N uptake from soil as explained below. Litterfall from vegetation  
 354 contributes to the litter pool and decomposition of litter transfers humified litter to the soil  
 355 organic matter pool. Decomposition of litter and soil organic matter returns mineralized N back  
 356 to the  $\text{NH}_4^+$  pool, closing the soil-vegetation N cycle loop.

### 357 **3.3.1 Plant N demand**

358 Plant N demand is calculated based on the fraction of NPP allocated to leaves, stem, and  
 359 root components and their specified minimum PFT-dependent C:N ratios, similar to other models  
 360 (Xu-Ri and Prentice, 2008; Jiang et al., 2019). The assumption is that plants always want to  
 361 achieve their desired minimum C:N ratios if enough N is available.

$$362 \quad \Delta_{WP} = \Delta_L + \Delta_R + \Delta_S$$

$$\Delta_i = \frac{\max(0, \text{NPP} \cdot a_{i,C})}{C:N_{i,\min}}, \quad i = L, S, R \quad (4)$$

363 where the whole plant N demand ( $\Delta_{WP}$ ) is the sum of N demand for the leaves ( $\Delta_L$ ), stem ( $\Delta_S$ ),  
 364 and root ( $\Delta_R$ ) components,  $a_{i,C}$ ,  $i = L, S, R$  is the fraction of NPP (i.e., carbon as indicated by  
 365 letter C in the subscript,  $\text{gC m}^{-2} \text{day}^{-1}$ ) allocated to leaf, stem, and root components, and  
 366  $C:N_{i,\min}$ ,  $i = L, S, R$  are their specified minimum C:N ratios (see Table A1 for these and all other  
 367 model parameters). A caveat with this approach when applied at the daily time step, for  
 368 biogeochemical processes in our model, is that during periods of time when NPP is negative due  
 369 to adverse climatic conditions (e.g., during winter or drought seasons), the calculated demand is

370 negative. If positive NPP implies there is demand for N, negative NPP cannot be taken to imply  
371 that N must be lost from vegetation. As a result, from a plant’s perspective, N demand is assumed  
372 to be zero during periods of negative NPP. N demand is also set to zero when all leaves have been  
373 shed (i.e., when GPP is zero). At the global scale, this leads to about 15% higher annual N demand  
374 than would be the case if negative NPP values were taken into consideration.

375

### 376 **3.3.2 Passive N uptake**

377 N demand is weighed against passive and active N uptake. Passive N uptake depends on  
378 the concentration of mineral N in the soil and the water taken up by the plants through their  
379 roots as a result of transpiration. We assume that plants have no control over N that comes into  
380 the plant through this passive uptake. This is consistent with existing empirical evidence that too  
381 much N in soil will cause N toxicity (Goyal and Huffaker, 1984), although we do not model N  
382 toxicity in our framework. If the N demand for the current time step cannot be met by passive N  
383 uptake then a plant compensates for the deficit (i.e., the remaining demand) through active N  
384 uptake.

385 The  $\text{NH}_4^+$  concentration in the soil moisture within the rooting zone, referred to as  $[\text{NH}_4]$   
386 ( $\text{gN gH}_2\text{O}^{-1}$ ), is calculated as

387 
$$[\text{NH}_4] = \frac{N_{\text{NH}_4}}{\sum_{i=1}^{i \leq r_d} 10^6 \theta_i z_i} \quad (5)$$

388 where  $N_{\text{NH}_4}$  is ammonium pool size ( $\text{gN m}^{-2}$ ),  $\theta_i$  is the volumetric soil moisture content for soil  
389 layer  $i$  ( $\text{m}^3 \text{m}^{-3}$ ),  $z_i$  is the thickness of soil layer  $i$  (m),  $r_d$  is the soil layer in which the 99% rooting  
390 depth lies as dynamically simulated by the biogeochemical module of CLASSIC following Arora

391 and Boer (2003). The  $10^6$  term converts units of the denominator term to  $\text{gH}_2\text{O m}^{-2}$ .  $\text{NO}_3^-$   
 392 concentration ( $[\text{NO}_3]$ ,  $\text{gN gH}_2\text{O}^{-1}$ ) in the rooting zone is found in a similar fashion. The  
 393 transpiration flux  $q_t$  ( $\text{Kg H}_2\text{O m}^{-2} \text{s}^{-1}$ ) (calculated in the physics module of CLASSIC) is multiplied  
 394 by  $[\text{NH}_4]$  and  $[\text{NO}_3]$  ( $\text{gN gH}_2\text{O}^{-1}$ ) to obtain passive uptake of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  ( $\text{gN m}^{-2} \text{day}^{-1}$ ) as

$$\begin{aligned}
 395 \quad U_{p,NH4} &= 86400 \times 10^3 \beta q_t [\text{NH}_4] \\
 U_{p,NO3} &= 86400 \times 10^3 \beta q_t [\text{NO}_3]
 \end{aligned}
 \tag{6}$$

396 where the multiplier  $86400 \times 10^3$  converts  $q_t$  to units of  $\text{gH}_2\text{O m}^{-2} \text{day}^{-1}$ , and  $\beta$  (see Table A1) is  
 397 the dimensionless mineral N distribution coefficient with a value less than 1 that accounts for the  
 398 fact that  $\text{NH}_4^+$  and  $\text{NO}_3^-$  available in the soil are not well mixed in the soil moisture solution, and  
 399 not completely accessible to roots, to be taken up by plants.

### 400 3.3.3 Active N uptake

401 The active plant N uptake is parameterized as a function of fine root biomass and the size  
 402 of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools in a manner similar to Gerber et al. (2010) and Wania et al. (2012). The  
 403 distribution of fine roots across the soil layers is ignored. CLASSIC does not explicitly model fine  
 404 root biomass. We therefore calculate the fraction of fine root biomass using an empirical  
 405 relationship that is very similar to the relationship developed by Kurz et al. (1996) (their equation  
 406 5) but also works below total root biomass of  $0.33 \text{ Kg C m}^{-2}$  (the Kurz et al. (1996) relationship  
 407 yields a fraction of fine root more than 1.0 below this threshold). The fraction of fine root biomass  
 408 ( $f_r$ ) is given by

$$409 \quad f_r = 1 - \frac{C_R}{C_R + 0.6}
 \tag{7}$$

410 where  $C_R$  is the root biomass ( $\text{KgC m}^{-2}$ ) simulated by the biogeochemical module of CLASSIC.  
 411 Equation (7) yields fine root fraction approaching 1.0 as  $C_R$  approaches 0, so at very low root  
 412 biomass values all roots are considered fine roots. For grasses the fraction of fine root biomass is  
 413 set to 1. The maximum or potential active N uptake for  $\text{NH}_4^+$  and  $\text{NO}_3^-$  is given by

$$\begin{aligned}
 414 \quad U_{a,pot,\text{NH}_4} &= \frac{\varepsilon f_r C_R N_{\text{NH}_4}}{k_{p,1/2} r_d + N_{\text{NH}_4} + N_{\text{NO}_3}} \\
 U_{a,pot,\text{NO}_3} &= \frac{\varepsilon f_r C_R N_{\text{NO}_3}}{k_{p,1/2} r_d + N_{\text{NH}_4} + N_{\text{NO}_3}}
 \end{aligned}
 \tag{8}$$

415 where  $\varepsilon$  (see Table A1) is the efficiency of fine roots to take up N per unit fine root mass per day  
 416 ( $\text{gN gC}^{-1} \text{day}^{-1}$ ),  $k_{p,1/2}$  (see Table A1) is the half saturation constant ( $\text{gN m}^{-3}$ ), and  $N_{\text{NH}_4}$  and  $N_{\text{NO}_3}$   
 417 are the ammonium and nitrate pool sizes ( $\text{gN m}^{-2}$ ) as mentioned earlier. Depending on the  
 418 geographical location and the time of the year, if passive uptake alone can satisfy plant N demand  
 419 the actual active N uptake of  $\text{NH}_4^+$  ( $U_{a,actual,\text{NH}_4}$ ) and  $\text{NO}_3^-$  ( $U_{a,actual,\text{NO}_3}$ ) is set to zero.  
 420 Conversely, during other times both passive and potential active N uptakes may not be able to  
 421 satisfy the demand and in this case actual active N uptake is equal to its potential rate. At times  
 422 other than these, the actual active uptake is lower than its potential value. This adjustment of  
 423 actual active uptake is illustrated in equation (9).

$$\begin{aligned} \text{if } (\Delta_{WP} \leq U_{p,NH_4} + U_{p,NO_3}) \\ U_{a,actual,NH_4} &= 0 \\ U_{a,actual,NO_3} &= 0 \end{aligned}$$

$$\begin{aligned} \text{if } (\Delta_{WP} > U_{p,NH_4} + U_{p,NO_3}) \wedge (\Delta_{WP} < U_{p,NH_4} + U_{p,NO_3} + U_{a,pot,NH_4} + U_{a,pot,NO_3}) \\ U_{a,actual,NH_4} &= (\Delta_{WP} - U_{p,NH_4} - U_{p,NO_3}) \frac{U_{a,pot,NH_4}}{U_{a,pot,NH_4} + U_{a,pot,NO_3}} \\ U_{a,actual,NO_3} &= (\Delta_{WP} - U_{p,NH_4} - U_{p,NO_3}) \frac{U_{a,pot,NO_3}}{U_{a,pot,NH_4} + U_{a,pot,NO_3}} \end{aligned} \quad (9)$$

$$\begin{aligned} \text{if } (\Delta_{WP} \geq U_{p,NH_4} + U_{p,NO_3} + U_{a,pot,NH_4} + U_{a,pot,NO_3}) \\ U_{a,actual,NH_4} &= U_{a,pot,NH_4} \\ U_{a,actual,NO_3} &= U_{a,pot,NO_3} \end{aligned}$$

425 Finally, the total N uptake ( $U$ ), uptake of  $NH_4^+$  ( $U_{NH_4}$ ) and  $NO_3^-$  ( $U_{NO_3}$ ), are calculated as

$$\begin{aligned} U &= U_{p,NH_4} + U_{p,NO_3} + U_{a,actual,NH_4} + U_{a,actual,NO_3} \\ U_{NH_4} &= U_{p,NH_4} + U_{a,actual,NH_4} \\ U_{NO_3} &= U_{p,NO_3} + U_{a,actual,NO_3} \end{aligned} \quad (10)$$

427

### 428 3.3.4 Litterfall

429 Nitrogen litterfall from the vegetation components is directly tied to the carbon litterfall  
430 calculated by the phenology module of CLASSIC through their current C:N ratios.

$$431 \quad LF_i = \frac{(1-r_L) LF_{i,C}}{C:N_i}, i = L, S, R \quad (11)$$

432 where  $LF_{i,C}$  is the carbon litterfall rate ( $gC \text{ day}^{-1}$ ) for component  $i$ , calculated by the phenology  
433 module of CLASSIC, and division by its current C:N ratio yields the nitrogen litterfall rate,  $r_L$  (see  
434 Table A1) is the leaf resorption coefficient that simulates the resorption of N from leaves of  
435 deciduous tree PFTs before they are shed and  $r_i = 0, i = R, S$ . Litter from each vegetation

436 component is proportioned between structural and non-structural components according to  
 437 their pool sizes.

### 438 3.3.5 Allocation and reallocation

439 Plant N uptake by roots is allocated to leaves and stem to satisfy their N demand. When  
 440 plant N demand is greater than zero, total N uptake ( $U$ ) is divided between leaves, stem, and root  
 441 components in proportion to their demands such that the allocation fractions for N ( $a_i, i =$   
 442  $L, S, R$ ) are calculated as

$$\begin{aligned}
 a_i &= \frac{\Delta_i}{\Delta_{WP}}, i = L, S, R \\
 A_{R2L} &= a_L (U_{NH_4} + U_{NO_3}) \\
 A_{R2S} &= a_S (U_{NH_4} + U_{NO_3})
 \end{aligned}
 \tag{12}$$

444 where  $A_{R2L}$  and  $A_{R2S}$  are the amounts of N allocated from root to leaves and stem components,  
 445 respectively, as shown in equations (A5) and (A7). During periods of negative NPP due to adverse  
 446 climatic conditions (e.g., during winter or drought seasons) the plant N demand is set to zero but  
 447 passive N uptake, associated with transpiration, may still be occurring if the leaves are still on.  
 448 Even though there is no N demand, passive N uptake still needs to be partitioned among the  
 449 vegetation components. During periods of negative NPP allocation fractions for N are, therefore,  
 450 calculated in proportion to the minimum PFT-dependent C:N ratios of the leaves, stem, and root  
 451 components as follows.

$$a_i = \frac{1/C:N_{i,\min}}{1/C:N_{L,\min} + 1/C:N_{S,\min} + 1/C:N_{R,\min}}, i = L, S, R
 \tag{13}$$

453 For grasses, which do not have a stem component, equations (12) and (13) are modified  
 454 accordingly by removing the terms associated with the stem component.

455 Three additional rules override these general allocation rule specifically for deciduous  
 456 tree PFTs (or deciduous PFTs in general). First, no N allocation is made to leaves once leaf fall is  
 457 initiated for deciduous tree PFTs and plant N uptake is proportioned between stem and root  
 458 components based on their demands in a manner similar to equation (12). Second, for deciduous  
 459 tree PFTs, a fraction of leaf N is resorbed from leaves back into stem and root as follows

$$\begin{aligned}
 R_{L2R} &= r_L LF_L \frac{N_{R,NS}}{N_{R,NS} + N_{S,NS}} \\
 R_{L2S} &= r_L LF_L \frac{N_{S,NS}}{N_{R,NS} + N_{S,NS}}
 \end{aligned}
 \tag{14}$$

461  
 462 where  $r_L$  is the leaf resorption coefficient, as mentioned earlier, and  $LF_L$  is the leaf litter fall rate.  
 463 Third, and similar to resorption, at the time of leaf onset for deciduous tree PFTs, N is reallocated  
 464 to leaves (in conjunction with reallocated carbon as explained in Asaadi et al. (2018)) from stem  
 465 and root components.

$$\begin{aligned}
 R_{R2L} &= \frac{R_{R2L,C}}{C:N_L} \frac{N_{R,NS}}{N_{R,NS} + N_{S,NS}} \\
 R_{S2L} &= \frac{R_{S2L,C}}{C:N_L} \frac{N_{S,NS}}{N_{R,NS} + N_{S,NS}}
 \end{aligned}
 \tag{15}$$

467 where  $R_{R2L,C}$  and  $R_{S2L,C}$  represent reallocation of carbon from non-structural stem and root  
 468 components to leaves and division by  $C:N_L$  converts the flux into N units. This reallocated N, at  
 469 the time of leaf onset, is proportioned between non-structural pools of stem and root according  
 470 to their sizes.

### 471 3.3.6 N mineralization, immobilization, and humification

472 Decomposition of litter ( $R_{h,D}$ ) and soil organic matter ( $R_{h,H}$ ) releases C to the atmosphere  
473 and this flux is calculated by the heterotrophic respiration module of CLASSIC. The litter and soil  
474 carbon decomposition rates used here are the same as in the standard model version (Melton  
475 and Arora, 2016; their Table A3). The amount of N mineralized is calculated straightforwardly by  
476 division with the current C:N ratios of the respective pools and contributes to the  $\text{NH}_4^+$  pool.

$$477 \quad \begin{aligned} M_{D,NH4} &= \frac{R_{h,D}}{C:N_D} \\ M_{H,NH4} &= \frac{R_{h,H}}{C:N_H} \end{aligned} \quad (16)$$

478 An implication of mineralization contributing to the  $\text{NH}_4^+$  pool, in addition to BNF and fertilizer  
479 inputs that also contribute solely to the  $\text{NH}_4^+$  pool, is that the simulated  $\text{NH}_4^+$  pool is typically  
480 larger than the  $\text{NO}_3^-$  pool. The exception is the dry and arid regions where the lack of  
481 denitrification, as discussed below in Section 3.4.2., leads to a build-up of the  $\text{NO}_3^-$  pool.

482 Immobilization of mineral N from the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools into the soil organic matter  
483 pool is meant to keep the soil organic matter C:N ratio ( $C:N_H$ ) at its specified value of 13 for all  
484 PFTs in a manner similar to Wania et al. (2012) and Zhang et al. (2018). A value of 13 is within the  
485 range of observation-based estimates which vary from about 8 to 25 (Zinke et al., 1998; Tipping  
486 et al., 2016). Although  $C:N_H$  varies geographically, the driving factors behind this variability  
487 remain unclear. It is even more difficult to establish if increasing atmospheric  $\text{CO}_2$  is changing  
488  $C:N_H$  given the large heterogeneity in soil organic C and N densities, and the difficulty in  
489 measuring small trends for such large global pools. We therefore make the assumption that the  
490  $C:N_H$  does not change with time. An implication of this assumption is that as GPP increases with  
491 increasing atmospheric  $\text{CO}_2$  rises, and plant litter becomes enriched in C with increasing C:N ratio

492 of litter, more and more N is locked up in the soil organic matter pool because its C:N ratio is  
 493 fixed. As a result, mineral N pools of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  decrease in size and plant N content  
 494 subsequently follows. This is consistent with studies of plants grown in elevated  $\text{CO}_2$   
 495 environment. For example, Cotrufo et al. (1998) summarize results from 75 studies and find an  
 496 average 14% reduction in N concentration for above-ground tissues. Wang et al. (2019) find  
 497 increased C concentration by 0.8–1.2% and a reduction in N concentration by 7.4–10.7% for rice  
 498 and winter wheat crop rotation system under elevated  $\text{CO}_2$ . Another implication of using  
 499 specified fixed  $C:N_H$  is that it does not matter if plant N uptake or immobilization is given  
 500 preferred access to the mineral N pool since in the long term, by design, N will accumulate in the  
 501 soil organic matter in response to atmospheric  $\text{CO}_2$  increase.

502 Immobilization from both the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools ( $\text{gN m}^{-2} \text{ day}^{-1}$ ) is calculated in  
 503 proportion to their pool sizes, employing the fixed  $C:N_H$  ratio as

$$\begin{aligned}
 504 \quad O_{\text{NH}_4} &= \max\left(0, \left(\frac{C_H}{C:N_H} - N_H\right) \frac{N_{\text{NH}_4}}{N_{\text{NH}_4} + N_{\text{NO}_3}}\right) k_O \\
 O_{\text{NO}_3} &= \max\left(0, \left(\frac{C_H}{C:N_H} - N_H\right) \frac{N_{\text{NO}_3}}{N_{\text{NH}_4} + N_{\text{NO}_3}}\right) k_O
 \end{aligned}
 \tag{17}$$

505 where  $k_O$  is rate constant with a value of  $1.0 \text{ day}^{-1}$ . Finally, the carbon flux of humified litter from  
 506 the litter to the soil organic matter pool ( $H_{C,D2H}$ ) is also associated with a corresponding N flux  
 507 that depends on the C:N ratio of the litter pool.

$$508 \quad H_{N,D2H} = \frac{H_{C,D2H}}{C:N_D}
 \tag{18}$$

### 509 **3.4 N cycling in mineral pools and N outputs**

510 This section presents the parameterizations of nitrification (which results in transfer of N  
511 from the  $\text{NH}_4^+$  to the  $\text{NO}_3^-$  pool) and the associated gaseous fluxes of  $\text{N}_2\text{O}$  and  $\text{NO}$  (referred to as  
512 nitrifier denitrification), gaseous fluxes of  $\text{N}_2\text{O}$ ,  $\text{NO}$ , and  $\text{N}_2$  associated with denitrification,  
513 volatilization of  $\text{NH}_4^+$  into  $\text{NH}_3$ , and leaching of  $\text{NO}_3^-$  in runoff.

### 514 3.4.1 Nitrification

515 Nitrification, the oxidative process converting ammonium to nitrate, is driven by microbial  
516 activity and as such constrained both by high and low soil moisture (Porporato et al., 2003). At  
517 high soil moisture content there is little aeration of soil and this constrains aerobic microbial  
518 activity, while at low soil moisture content microbial activity is constrained by moisture  
519 limitation. In CLASSIC, the heterotrophic respiration from soil carbon is constrained similarly but  
520 rather than using soil moisture the parameterization is based on soil matric potential (Arora,  
521 2003; Melton et al., 2015). Here, we use the exact same parameterization. In addition to soil  
522 moisture, nitrification ( $\text{gN m}^{-2} \text{day}^{-1}$ ) is modelled as a function of soil temperature and the size  
523 of the  $\text{NH}_4^+$  pool as follows

$$524 \quad I_{\text{NO}_3} = \eta f_I(T_{0.5}) f_I(\psi) N_{\text{NH}_4} \quad (19)$$

525 where  $\eta$  is the nitrification coefficient ( $\text{day}^{-1}$ , see Table A1),  $f_I(\psi)$  is the dimensionless soil  
526 moisture scalar that varies between 0 and 1 and depends on soil matric potential ( $\psi$ ),  $f_I(T_{0.5})$  is  
527 the dimensionless soil temperature scalar that depends on soil temperature ( $T_{0.5}$ ) averaged over  
528 the top 0.5 m soil depth over which nitrification is assumed to occur (following Xu-Ri and Prentice,  
529 2008), and  $N_{\text{NH}_4}$  is the ammonium pool size ( $\text{gN m}^{-2}$ ), as mentioned earlier. Both  $f_I(T_{0.5})$  and

530  $f_I(\psi)$  are parameterized following Arora (2003) and Melton et al. (2015).  $f_I(T_{0.5})$  is a Q<sub>10</sub> type  
 531 function with a temperature dependent Q<sub>10</sub>

$$532 \quad f_I(T_{0.5}) = Q_{10,I}^{(T_{0.5}-20)/10}, Q_{10,I} = 1.44 + 0.56 (\tanh(0.075(46 - T_{0.5}))) \quad (20)$$

533 The reference temperature for nitrification is set to 20 °C following Lin et al. (2000).  $f_I(\psi)$  is  
 534 parameterized as a step function of soil matric potential ( $\psi$ ) as

$$535 \quad f_I(\psi) = \begin{cases} 0.5 & \text{if } \psi \leq \psi_{sat} \\ 1 - 0.5 \frac{\log(0.4) - \log(\psi)}{\log(0.4) - \log(\psi_{sat})} & \text{if } 0.4 > \psi \geq \psi_{sat} \\ 1 & \text{if } 0.6 \geq \psi \geq 0.4 \\ 1 - 0.8 \frac{\log(\psi) - \log(0.6)}{\log(100) - \log(0.6)} & \text{if } 100 > \psi > 0.6 \\ 0.2 & \text{if } \psi > 100 \end{cases} \quad (21)$$

536 where the soil matric potential ( $\psi$ ) is found, following Clapp and Hornberger (1978), as a function  
 537 of soil moisture ( $\theta$ )

$$538 \quad \psi(\theta) = \psi_{sat} \left( \frac{\theta}{\theta_{sat}} \right)^{-B} \quad (22)$$

539 Saturated matric potential ( $\psi_{sat}$ ), soil moisture at saturation (i.e., porosity) ( $\theta_{sat}$ ), and the  
 540 parameter  $B$  are calculated as functions of percent sand and clay in soil following Clapp and  
 541 Hornberger (1978) as shown in Melton et al. (2015). The soil moisture scalar  $f_I(\psi)$  is calculated  
 542 individually for each soil layer and then averaged over the soil depth of 0.5 m over which  
 543 nitrification is assumed to occur.

544 Gaseous fluxes of NO ( $I_{NO}$ ) and N<sub>2</sub>O ( $I_{N2O}$ ) associated with nitrification, and generated  
 545 through nitrifier denitrification, are assumed to be directly proportional to the nitrification flux  
 546 ( $I_{NO3}$ ) as

547

$$\begin{aligned} I_{NO} &= \eta_{NO} I_{NO3} \\ I_{N2O} &= \eta_{N2O} I_{NO3} \end{aligned} \quad (23)$$

548 where  $\eta_{NO}$  and  $\eta_{N2O}$  are dimensionless fractions (see Table A1) which determine what fractions  
 549 of nitrification flux are emitted as NO and N<sub>2</sub>O.

550 **3.4.2 Denitrification**

551 Denitrification is the stepwise microbiological reduction of nitrate to NO, N<sub>2</sub>O, and ultimately to  
 552 N<sub>2</sub> in complete denitrification. Unlike nitrification, however, denitrification is primarily an  
 553 anaerobic process (Tomasek et al., 2017) and therefore occurs when soil is saturated. As a result,  
 554 we use a different soil moisture scalar than for nitrification. Similar to nitrification, denitrification  
 555 is modelled as a function of soil moisture, soil temperature and the size of the NO<sub>3</sub><sup>-</sup> pool as follows  
 556 to calculate the gaseous fluxes of NO, N<sub>2</sub>O, and N<sub>2</sub>.

557

$$\begin{aligned} E_{NO} &= \mu_{NO} f_E(T_{0.5}) f_E(\theta) N_{NO3} \\ E_{N2O} &= \mu_{N2O} f_E(T_{0.5}) f_E(\theta) N_{NO3} \\ E_{N2} &= \mu_{N2} f_E(T_{0.5}) f_E(\theta) N_{NO3} \end{aligned} \quad (24)$$

558 where  $\mu_{NO}$ ,  $\mu_{N2O}$ , and  $\mu_{N2}$  are coefficients (day<sup>-1</sup>, see Table A1) that determine daily rates of  
 559 emissions of NO, N<sub>2</sub>O, and N<sub>2</sub>. The temperature scalar  $f_E(T_{0.5})$  is exactly the same as the one for  
 560 nitrification ( $f_I(T_{0.5})$ ) since denitrification is also assumed to occur over the same 0.5 m soil  
 561 depth. The soil moisture scalar  $f_E(\theta)$  is given by

562

$$\begin{aligned} f_E(\theta) &= 1 - \tanh\left(2.5 \left(\frac{1-w(\theta)}{1-w_d}\right)^2\right) \\ w(\theta) &= \max\left(0, \min\left(1, \frac{\theta - \theta_w}{\theta_f - \theta_w}\right)\right) \end{aligned} \quad (25)$$

563 where  $w$  is the soil wetness that varies between 0 and 1 as soil moisture varies between wilting  
564 point ( $\theta_w$ ) and field capacity ( $\theta_f$ ), and  $w_d$  (see Table A1) is the threshold soil wetness for  
565 denitrification below which very little denitrification occurs. Since arid regions are characterized  
566 by low soil wetness values, typically below  $w_d$ , this leads to build up of the  $\text{NO}_3^-$  pool in arid  
567 regions.

### 568 **3.4.3 $\text{NO}_3^-$ leaching**

569 Leaching is the loss of water-soluble ions through runoff. In contrast to positively charged  
570  $\text{NH}_4^+$  ions (i.e. cations), the  $\text{NO}_3^-$  ions do not bond to soil particles because of the limited exchange  
571 capacity of soil for negatively charged ions (i.e., anions). As a result, leaching of N in the form of  
572  $\text{NO}_3^-$  ions is a common water quality problem, particularly over cropland regions. The leaching  
573 flux ( $L_{\text{NO}_3}$ ,  $\text{gN m}^{-2} \text{ day}^{-1}$ ) is parameterized to be directly proportional to baseflow ( $b_t$ ,  $\text{Kg m}^{-2} \text{ s}^{-1}$ )  
574 calculated by the physics module of CLASSIC and the size of the  $\text{NO}_3^-$  pool ( $N_{\text{NO}_3}$ ,  $\text{gN m}^{-2}$ ).  
575 Baseflow is the runoff rate from the bottommost soil layer.

$$576 \quad L_{\text{NO}_3} = 86400 \varphi b_t N_{\text{NO}_3} \quad (26)$$

577 where the multiplier 86400 converts units to per day, and  $\varphi$  is the leaching coefficient ( $\text{m}^2 \text{ Kg}^{-1}$ ,  
578 see Table A1) that can be thought of as the soil particle surface area ( $\text{m}^2$ ) that 1 Kg of water (or  
579 about  $0.001 \text{ m}^3$ ) can effectively wash to leach the nutrients.

### 580 **3.4.4 $\text{NH}_3$ volatilization**

581  $\text{NH}_3$  volatilization ( $V_{\text{NH}_3}$ ,  $\text{gN m}^{-2} \text{day}^{-1}$ ) is parametrized as a function of pool size of  $\text{NH}_4^+$ ,  
 582 soil temperature, soil pH, aerodynamic and boundary layer resistances, and atmospheric  $\text{NH}_3$   
 583 concentration in a manner similar to Riddick et al. (2016) as

$$584 \quad V_{\text{NH}_4} = \vartheta \ 86400 \frac{1}{r_a+r_b} (\chi - [\text{NH}_{3,\text{a}}]) \quad (27)$$

585 where  $\vartheta$  is the dimensionless  $\text{NH}_3$  volatilization coefficient (see Table A1) which is set to less than  
 586 1 to account for the fact that a fraction of ammonia released from the soil is captured by  
 587 vegetation,  $r_a$  ( $\text{s m}^{-1}$ ) is the aerodynamic resistance calculated by the physics module of CLASSIC,  
 588  $\chi$  is the ammonia ( $\text{NH}_3$ ) concentration at the interface of the top soil layer and the atmosphere  
 589 ( $\text{g m}^{-3}$ ),  $[\text{NH}_{3,\text{a}}]$  is the atmospheric  $\text{NH}_3$  concentration specified at  $0.3 \times 10^{-6} \text{ g m}^{-3}$  following  
 590 Riddick et al. (2016), 86400 converts flux units from  $\text{gN m}^{-2} \text{s}^{-1}$  to  $\text{gN m}^{-2} \text{day}^{-1}$ , and  $r_b$  ( $\text{s m}^{-1}$ ) is  
 591 the boundary layer resistance calculated following Thom (1975) as

$$592 \quad r_b = 6.2 u_*^{-0.67} \quad (28)$$

593 where  $u_*$  ( $\text{m/s}$ ) is the friction velocity provided by the physics module of CLASSIC. The ammonia  
 594 ( $\text{NH}_3$ ) concentration at surface ( $\chi$ ), in a manner similar to Riddick et al. (2016), is calculated as

$$595 \quad \chi = 0.26 \frac{N_{\text{NH}_4}}{1+K_H+K_H[H^+]/K_{\text{NH}_4}} \quad (29)$$

596 where the coefficient 0.26 is the fraction of ammonium in the top 10 cm soil layer assuming  
 597 exponential distribution of ammonium along the soil depth (given by  $3e^{-3z}$ , where  $z$  is the soil  
 598 depth),  $K_H$  (dimensionless) is the Henry's law constant for  $\text{NH}_3$ ,  $K_{\text{NH}_4}$  ( $\text{mol L}^{-1}$ ) is the dissociation  
 599 equilibrium constant for aqueous  $\text{NH}_3$ , and  $H^+$  ( $\text{mol L}^{-1}$ ) is the concentration of hydrogen ion

600 that depends on the soil pH ( $H^+ = 10^{-pH}$ ).  $K_H$  and  $K_{NH_4}$  are modelled as functions of soil  
 601 temperature of the top 10 cm soil layer ( $T_{0.1}$ ) following Riddick et al. (2016) as

$$\begin{aligned}
 602 \quad K_H &= 4.59 T_{0.1} \exp\left(4092 \left(\frac{1}{T_{0.1}} - \frac{1}{T_{ref,v}}\right)\right) \\
 603 \quad K_{NH_4} &= 5.67 \times 10^{-10} \exp\left(-6286 \left(\frac{1}{T_{0.1}} - \frac{1}{T_{ref,v}}\right)\right)
 \end{aligned}
 \tag{30}$$

603 where  $T_{ref,v}$  is the reference temperature of 298.15 K.

604

### 605 3.5 Coupling of C and N cycles

606 As mentioned earlier, the primary objective of coupling of C and N cycles is to be able to  
 607 simulate  $V_{cmax}$  as a function of leaf N content ( $N_L$ ) for each PFT. This coupling is represented  
 608 through the following relationship

$$609 \quad V_{cmax} = \Lambda (\Gamma_1 N_L + \Gamma_2)
 \tag{31}$$

610 where  $\Gamma_1$  ( $13 \mu\text{mol CO}_2 \text{ gN}^{-1} \text{ s}^{-1}$ ) and  $\Gamma_2$  ( $8.5 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) are global constants, except for  
 611 the broadleaf evergreen tree PFT for which a lower value of  $\Gamma_1$  ( $5.1 \mu\text{mol CO}_2 \text{ gN}^{-1} \text{ s}^{-1}$ ) is used as  
 612 discussed below.  $\Lambda$  ( $\leq 1$ ) is a scalar that reduces calculated  $V_{cmax}$  when C:N ratio of any plant  
 613 component ( $C: N_i, i = L, S, R$ ) exceeds its specified maximum value ( $C: N_{i,max}, i = L, S, R$ ) (see  
 614 Table AA1).

$$\begin{aligned}
 615 \quad \Lambda &= \exp(-\omega k_\Lambda) \\
 \omega &= e_L b_L + e_S b_S + e_R b_R
 \end{aligned}
 \tag{32}$$

616 
$$e_i = \max(0, C:N_i - C:N_{i,\max})$$
  
617 
$$b_i = \frac{1/C:N_{i,\max}}{1/C:N_{L,\max} + 1/C:N_{S,\max} + 1/C:N_{R,\max}}, i = L, S, R$$
 (33)

617 where  $k_\Lambda$  is a dimensionless parameter (see Table A1) and  $\omega$  is dimensionless term that  
618 represents excess C:N ratios above specified maximum thresholds ( $e_i, i = L, S, R$ ) weighted by  
619  $b_i, i = L, S, R$ . When plant components do not exceed their specified maximum C:N ratio  
620 thresholds,  $e_i$  is zero and  $\Lambda$  is one. When plants components exceed their specified maximum  
621 C:N ratio thresholds,  $\Lambda$  starts reducing below one. This decreases  $V_{\text{cmax}}$  and thus photosynthetic  
622 uptake which limits the rate of increase of C:N ratio of plant components, depending on the value  
623 of  $k_\Lambda$ .

624 The linear relationship between photosynthetic capacity and  $N_L$  (Evans, 1989; Field and  
625 Mooney, 1986; Garnier et al., 1999) (used in equation 31) and between photosynthetic capacity  
626 and leaf chlorophyll content (Croft et al., 2017) is empirically observed. We have avoided using  
627 PFT-dependent values of  $\Gamma_1$  and  $\Gamma_2$  for easy optimization of these parameter values but also  
628 because such an optimization can potentially hide other model deficiencies. More importantly,  
629 using PFT-independent values of  $\Gamma_1$  and  $\Gamma_2$  yields a more elegant framework whose successful  
630 evaluation will provide confidence in the overall model structure.

631 As shown later in the results section, using  $\Gamma_1$  and  $\Gamma_2$  as global constants yields GPP values  
632 that are higher in the tropical region than an observation-based estimate. This is not surprising  
633 since tropical and mid-latitude regions are known to be limited by P (Vitousek, 1984; Aragão et  
634 al., 2009; Vitousek et al., 2010; Du et al., 2020) and our framework currently doesn't model P  
635 cycle explicitly. An implication of productivity that is limited by P is that changes in  $N_L$  are less

636 important. In the absence of explicit treatment of the P cycle, we therefore simply use a lower  
637 value of  $\Gamma_1$  for the broadleaf evergreen tree PFT which, in our modelling framework, exclusively  
638 represents a tropical PFT. Although, a simple way to express P limitation, this approach yields the  
639 best comparison with observation-based GPP, as shown later, because the effect of P limitation  
640 is most pronounced in the high productivity tropical regions.

641 The second pathway of coupling between the C and N cycles occurs through  
642 mineralization of litter and soil organic matter. During periods of higher temperature,  
643 heterotrophic C respiration fluxes increase from the litter and soil organic matter pools and this  
644 in turn implies an increased mineralization flux (via equation 16) leading to more mineral N  
645 available for plants to uptake.

## 646 **4.0 Methodology**

### 647 **4.1 Model simulations and input data sets**

648 We perform CLASSIC model simulations with the N cycle for the pre-industrial period  
649 followed by several simulations for the historical 1851-2017 period to evaluate the model's  
650 response to different forcings, as summarized below. The simulation for the pre-industrial period  
651 uses forcings that correspond to year 1850 and the model is run for thousands of years until its  
652 C and N pools come into equilibrium. Global thresholds of net atmosphere-land C flux of 0.05  
653 Pg/yr and net atmosphere-land N flux of 0.5 Tg N/yr are used to ensure the model pools have  
654 reached equilibrium. The pre-industrial simulation, therefore, yields the initial conditions from  
655 which the historical simulations for the period 1851-2017 are launched. To spin the mineral N  
656 pools to their initial values, the plant N uptake and other organic processes were turned off while

657 the model used specified values of  $V_{\text{cmax}}$  and only the inorganic part of N cycle was operative.  
658 Once the inorganic mineral soil N pools reached near equilibrium, the organic processes were  
659 turned on. The model also uses an accelerated spin up procedure for the slow pools of soil organic  
660 matter and mineral N. The input and output terms are multiplied by a factor greater than one  
661 and this magnifies the change in pool size and therefore accelerates the spin up. Once the model  
662 pools reach near equilibrium, the factor is set back to one.

663 To evaluate the model's response to various forcings over the historical period we  
664 perform several simulations turning on one forcing at a time as summarized in Table 1. The  
665 objective of these simulations is to see if the model response to individual forcings is consistent  
666 with expectations. For example, in the CO<sub>2</sub>-only simulation only atmospheric CO<sub>2</sub> concentration  
667 increases over the historical period, while all other forcings stay at their 1850 levels. In the N-  
668 DEP-only simulation only N deposition increases over the historical period, and similarly for other  
669 runs in Table 1. A "FULL" simulations with all forcings turned on is then also performed which we  
670 compare to the original model without a N cycle which uses the photosynthesis downregulation  
671 parameterization (termed "ORIGINAL" in Table 1). Finally, a separate pre-industrial simulation is  
672 also performed that uses the same  $\Gamma_1$  and  $\Gamma_2$  globally (FULL-no-implicit-P-limitation). This  
673 simulation is used to illustrate the effect of neglecting P limitation for the broadleaf evergreen  
674 tree PFT in the tropics.

675 For the historical period, the model is driven with time-varying forcings that include CO<sub>2</sub>  
676 concentration, population density (used by the fire module of the model for calculating  
677 anthropogenic fire ignition and suppression), land cover, and meteorological data. In addition,  
678 for the N cycle module, the model requires time-varying atmospheric N deposition and fertilizer

679 data. The atmospheric CO<sub>2</sub> and meteorological data (CRU-JRA) are same as those used for the  
680 TRENDY model intercomparison project for terrestrial ecosystem models for year 2018 (Le Quéré  
681 et al., 2018). The CRU-JRA meteorological data is based on 6-hourly Japanese Reanalysis (JRA).  
682 However, since reanalysis data typically do match observations they are adjusted for monthly  
683 values based on the Climate Research Unit (CRU) data. This yields a blended product with sub-  
684 daily temporal resolution that comes from the reanalysis and monthly means/sums that match  
685 the CRU data to yield a meteorological product that can be used by models that require sub-daily  
686 or daily meteorological forcing. These data are available for the period 1901-2017. Since no  
687 meteorological data are available for the 1850-1900 period, we use 1901-1925 meteorological  
688 data repeatedly for this duration and also for the pre-industrial spin up. The assumption is that  
689 since there is no significant trend in the CRU-JRA data over this period, these data can be reliably  
690 used to spin up the model to equilibrium. The land cover data used to force the model are based  
691 on a geographical reconstruction of the historical land cover driven by the increase in crop area  
692 following Arora and Boer (2010) but using the crop area data prepared for the Global Carbon  
693 Project (GCP) 2018 following Hurtt et al. (2006). Since land cover is prescribed, the competition  
694 between PFTs for space for the simulations reported here is switched off. The population data  
695 for the period 1850-2017 are based on Klein Goldewijk et al. (2017) and obtained from  
696 <ftp://ftp.pbl.nl/./hyde/hyde3.2/baseline/zip/>. The time-independent forcings consist of soil  
697 texture and permeable depth data.

698           Time-varying atmospheric N deposition and fertilizer data used over the historical period  
699 are also specified as per the TRENDY protocol. The fertilizer data are based on the N<sub>2</sub>O model  
700 intercomparison project (NMIP) (Tian et al., 2018) and available for the period 1860-2014. For

701 the period before 1860, 1860 fertilizer application rates are used. For the period after 2014,  
702 fertilizer application rates for 2014 are used. Atmospheric N deposition data are from input4MIPs  
703 (<https://esgf-node.llnl.gov/search/input4mips/>) and are the same as used by models  
704 participating in CMIP6 for the historical period (1850-2014). For years 2015-2017 the N  
705 deposition data corresponding to those from representative concentration pathway (RCP) 8.5  
706 scenario are used. Figure 2 shows the time series of global annual values of externally specified  
707 fertilizer input, and deposition of ammonium and nitrate, based on the TRENDY protocol, for the  
708 six primary simulations. Geographical distribution of these inputs are also shown for the last 20  
709 years from the FULL simulation corresponding to the 1998-2017 period. In Figure 2 (panels a, c  
710 and e) ammonium and nitrate deposition, and fertilizer input stay at their pre-industrial level for  
711 simulations in which these forcings do not increase over the historical period. As mentioned  
712 earlier, N deposition is split evenly into ammonium and nitrate. The values in parenthesis in  
713 Figure 2a legend, and in subsequent time series plots, show average values over the 1850s, the  
714 last 20 years (1998-2017) of the simulations, and the change between these two periods. The  
715 present day values of fertilizer input and N deposition are consistent with other estimates  
716 available in the literature (Table 2). The fertilizer input rate in the simulation with all forcings  
717 except land use change (FULL-no-LUC, blue line), that is with no increase in crop area over its  
718 1850 value, is 50 Tg N yr<sup>-1</sup> compared to 91 Tg N yr<sup>-1</sup> in the FULL simulation, averaged over the  
719 1998-2017 period. The additional 41 Tg N yr<sup>-1</sup> of fertilizer input occurs in the FULL simulation due  
720 to the increase in crop area but also due to the increasing fertilizer application rates over the  
721 historical period. Geographical distribution of the fertilizer application rates in Figure 2b shows  
722 that they are concentrated in regions with crop area and with values as high as 16 gN m<sup>-2</sup> yr<sup>-1</sup>

723 especially in eastern China. The N deposition rates (Figure 2d, 2f) are more evenly distributed  
724 geographically than the fertilizer applications rates, as would be expected, since emissions are  
725 transported downstream from their point sources. Areas with high emissions like the eastern  
726 United States, India, eastern China, and Europe, however, still stand out as areas that receive  
727 higher N deposition.

## 728 **4.2 Evaluation data sources**

729 We compare globally-summed annual values of N pools and fluxes with observations and  
730 other models, and where available their geographical distribution and seasonality. In general,  
731 however, much less observation-based data are available to evaluate simulated terrestrial N  
732 cycle components than for C cycle components. As a result, N pools and fluxes are primarily  
733 compared to results from both observation-based studies and other modelling studies  
734 (Bouwman et al., 2013; Fowler et al., 2013; Galloway et al., 2004; Vitousek et al., 2013; Zaehle,  
735 2013). Since the primary purpose of the N cycle in our framework is to constrain the C cycle, we  
736 also compare globally-summed annual values of GPP and net atmosphere-land CO<sub>2</sub> flux, and their  
737 zonal distribution with available observation-based and other estimates. The observation-based  
738 estimate of GPP is from Beer et al. (2010), who apply diagnostic models to extrapolate ground-  
739 based carbon flux tower observations from about 250 stations to the global scale. Observation-  
740 based net atmosphere-land CO<sub>2</sub> flux is from Global Carbon Project's 2019 assessment  
741 (Friedlingstein et al., 2019).

## 742 **5.0 Results**

### 743 **5.1 N inputs**

744 Figure 3 (panels a, c, e) shows the time series of annual values BNF and its natural and  
745 anthropogenic components from the six primary simulations summarized in Table 1. BNF stays  
746 at its pre-industrial value of around 80 Tg N yr<sup>-1</sup> in the CO<sub>2</sub>-only and N-DEP-only simulations. In  
747 the CLIM-only (indicated by magenta coloured line) and the FULL-no-LUC (blue line) simulations  
748 the change in climate, associated with increases in temperature and precipitation over the 1901-  
749 2017 period (see Figure A2 in the appendix), increases BNF to about 85 Tg N yr<sup>-1</sup>. In our  
750 formulation (equation 3) BNF is positively impacted by increases in temperature and  
751 precipitation. In the LUC+FERT-only simulation (dark green line) the increase in crop area  
752 contributes to an increase in global BNF with a value around 110 Tg N yr<sup>-1</sup> for the present day,  
753 since a higher BNF per unit crop area is assumed than for natural vegetation. Finally, in the FULL  
754 simulation (red line) the 1998-2017 average value is around 117 Tg N yr<sup>-1</sup> due both to changes in  
755 climate over the historical period and the increase in crop area. Our present day value of global  
756 BNF is broadly consistent with other modelling and data-based studies as summarized in Table 2.  
757 Panels c and e in Figure 3 show the decomposition of the total terrestrial BNF into its natural  
758 (over non-crop PFTs) and anthropogenic (over C<sub>3</sub> and C<sub>4</sub> crop PFTs) components. The increase in  
759 crop area over the historical period decreases natural BNF from its pre-industrial value of 59 to  
760 54 Tg N yr<sup>-1</sup> for the present day as seen for the LUC+FERT-only simulation (green line) in Figure  
761 3c, while anthropogenic BNF over agricultural area increases from 21 to 56 Tg N yr<sup>-1</sup> (Figure 3e).  
762 Figure 3c and 3e show that the increase in BNF (Figure 3a) in the FULL simulation is caused  
763 primarily by an increase in crop area. Our present day values of natural and anthropogenic BNF  
764 are also broadly consistent with other modelling and data-based studies as summarized in Table  
765 2.

766 Figure 3 (panels b, d, and f) shows the geographical distribution of simulated BNF and its  
767 natural and anthropogenic components. The geographical distribution of BNF (Figure 3a) looks  
768 very similar to the current distribution of vegetation (not shown) with warm and wet regions  
769 showing higher values than cold and dry regions since BNF is parameterized as a function of  
770 temperature and soil moisture. Anthropogenic BNF only occurs in regions where crop area exists  
771 according to the specified land cover and it exhibits higher values than natural BNF in some  
772 regions because of its higher value per unit area (see section 3.2.1).

773 At the global scale, and for the present day, natural BNF ( $59 \text{ Tg N yr}^{-1}$ ) is overwhelmed by  
774 anthropogenic sources: anthropogenic BNF ( $60 \text{ Tg N yr}^{-1}$ ), fertilizer input ( $91.7 \text{ Tg N yr}^{-1}$ ), and  
775 atmospheric N deposition increase since the pre-industrial era ( $\sim 45 \text{ Tg N yr}^{-1}$ ). Currently humanity  
776 fixes more N than the natural processes (Vitousek, 1994).

## 777 **5.2 C and N pools, fluxes response to historical changes in forcings**

778 To understand the model response to changes in various forcings over the historical  
779 period we first look at the evolution of global values of primary C and N pools, and fluxes, shown  
780 in Figures 4 through 8. Figure 4a shows the time evolution of global annual GPP values, the  
781 primary flux of C into the land surface, for the six primary simulations, the ORIGINAL simulation  
782 performed with the model version with no N cycle, and the ORIG-UNCONST simulation with no  
783 photosynthesis downregulation (see Table 1). The unconstrained increase in GPP ( $35.6 \text{ Pg C yr}^{-1}$   
784 over the historical period) in the ORIG-UNCONST simulation (dark cyan line) is governed by the  
785 standard photosynthesis model equations following Farquhar et al. (1980) and Collatz et al.  
786 (1992) for  $C_3$  and  $C_4$  plants, respectively. Downregulation of photosynthesis in the ORIGINAL

787 simulation (purple line) is modelled on the basis of equation (1), while in the FULL simulation (red  
788 line) photosynthesis downregulation results from a decrease in  $V_{\text{cmax}}$  values (Figure 5d) due to a  
789 decrease in leaf N content (Figure 5b). We will compare the FULL and ORIGINAL simulations in  
790 more detail later. The simulations with individual forcings, discussed below, provide insight into  
791 the combined response of GPP to all forcings in the FULL simulation.

### 792 **5.2.1 Response to increasing CO<sub>2</sub>**

793 The response of C and N cycles to increasing CO<sub>2</sub> in the CO<sub>2</sub>-only simulation (orange lines  
794 in Figure 4) is the most straightforward to interpret. A CO<sub>2</sub> increase causes GPP to increase by 7.5  
795 Pg C yr<sup>-1</sup> above its pre-industrial value (Figure 4a), which in turn causes vegetation (Figure 4b),  
796 leaf (Figure 4c), and soil (Figure 4d) carbon mass to increase as well. The vegetation and leaf N  
797 amounts (orange line, Figures 5a and 5b), in contrast, decrease in response to increasing CO<sub>2</sub>.  
798 This is because N gets locked up in the soil organic matter pool (Figure 5c) in response to an  
799 increase in the soil C mass (due to the increasing GPP), litter inputs which are now rich in C (due  
800 to CO<sub>2</sub> fertilization) but poor in N (since N inputs are still at their pre-industrial level), and the fact  
801 that the C:N ratio of the soil organic matter is fixed at 13. This response to elevated CO<sub>2</sub> which  
802 leads to increased C and decreased N in vegetation is consistent with meta-analysis of 75 field  
803 experiments of elevated CO<sub>2</sub> (Cotrufo et al., 1998). A decrease in N in leaves (orange line, Figure  
804 5b) leads to a concomitant decrease in maximum carboxylation capacity ( $V_{\text{cmax}}$ ) (orange line,  
805 Figure 5d) and as a result GPP increases at a much slower rate in the CO<sub>2</sub>-only simulation than in  
806 the ORIG-UNCONST simulation (Figure 4a). Due to the N accumulation in the soil organic matter  
807 pool, the NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> (Figures 5e and 5f) pools also decrease in size in the CO<sub>2</sub>-only simulation.

808 Figure 6 shows the time series of N demand, plant N uptake and its split between passive  
809 and active N uptakes. The plant N demand in the CO<sub>2</sub>-only simulation (Figure 6a, orange line)  
810 increases from its pre-industrial value of 1512 Tg N/yr to 1639 Tg N/yr for the present day since  
811 the increasing C input from increasing GPP requires higher N input to maintain preferred  
812 minimum C:N ratio of plant tissues. However, since mineral N pools decrease in size over the  
813 historical period in this simulation (Figures 5e and 5f), the total plant N uptake (Figure 6b)  
814 reduces. Passive plant N uptake is directly proportional to pool sizes of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> and  
815 therefore it reduces in response to increasing CO<sub>2</sub>. Active plant N uptake, which compensates for  
816 insufficient passive N uptake compared to the N demand, also eventually starts to decline as it  
817 also depends on mineral N pool sizes. The eventual result of increased C supply and reduced N  
818 supply is an increase in the C:N ratio of all plant components and litter (Figure 7). The  
819 preindustrial total N uptake of around 960 Tg N/yr (Figure 6b) is lower than the preindustrial N  
820 demand (1512 Tg N/yr, Figure 6a) despite the sum of global NH<sub>4</sub> and NO<sub>3</sub> pool sizes being around  
821 4000 Tg N (Figures 5e and 5f). This is because of the mismatch between where the pools are high  
822 and where the vegetation actually grows and the fact that plant N uptake is limited by its rate.  
823 As a result, in our model, even in the preindustrial era vegetation is N limited.

824 Figure 8 shows the net mineralization flux (the net transfer of mineralized N from litter  
825 and humus pools to the mineral N pools as a result of the decomposition of organic matter),  
826 nitrification (N flux from NH<sub>4</sub><sup>+</sup> to the NO<sub>3</sub><sup>-</sup> pool), and the gaseous and leaching losses from the  
827 mineral pools. The net mineralization flux reduces in the CO<sub>2</sub>-only simulation (Figure 8a, orange  
828 line) as N gets locked up in the soil organic matter. A reduction in the NH<sub>4</sub><sup>+</sup> pool size in response  
829 to increasing CO<sub>2</sub> also yields a reduction in the nitrification flux over the historical period (Figure

830 8b, orange line) since nitrification depends on the  $\text{NH}_4^+$  pool size (equation 19). Finally, leaching  
831 from the  $\text{NO}_3^-$  pool (Figure 8c),  $\text{NH}_3$  volatilization (Figure 8d), and the gaseous losses associated  
832 with nitrification from the  $\text{NH}_4^+$  pool (Figure 8e) and denitrification from the  $\text{NO}_3^-$  pool (Figure 8f)  
833 all reduce in response to reduction in pool sizes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in the  $\text{CO}_2$ -only simulation.

### 834 **5.2.2 Response to changing climate**

835 The perturbation due to climate change alone over the historical period in the CLIM-only  
836 simulation (magenta coloured lines in Figures 4 to 8) is smaller than that due to increasing  $\text{CO}_2$ .  
837 In Figure 4a, changes in climate over the historical period increase GPP slightly by  $3.60 \text{ Pg C yr}^{-1}$   
838 which in turn slightly increases vegetation (including leaf) C mass (Figure 4b,c). The litter and soil  
839 carbon mass (Figure 4d), however, decrease slightly due to increased decomposition rates  
840 associated with increasing temperature (see Figure A2b). Both the increase in BNF due to  
841 increasing temperature (magenta line in Figure 2a), and the reduction in litter and soil N mass  
842 (Figure 5c) due to increasing decomposition and higher net N mineralization (Figure 8a, magenta  
843 line), make more N available. This results in a slight increase in vegetation and leaf N mass  
844 (Figures 5a and 5b) and the  $\text{NH}_4^+$  (Figure 5e) pool which is the primary mineral pool in soils under  
845 vegetated regions. The global  $\text{NO}_3^-$  pool, in contrast, decreases in the CLIM-only simulation  
846 (Figure 5f) with the reduction primarily occurring in arid regions where the  $\text{NO}_3^-$  amounts are very  
847 large (see Figure 9 that shows the geographical distribution of the primary C and N pools). The  
848 geographical distribution of  $\text{NH}_4^+$  (Figure 9a) generally follows the geographical distribution of  
849 BNF, but with higher values in areas where cropland exists and where N deposition is high. The  
850 geographical distribution of  $\text{NO}_3^-$  (Figure 9b) generally shows lower values than  $\text{NH}_4^+$  except in  
851 the desert regions where lack of denitrification leads to a large buildup of the  $\text{NO}_3^-$  pool (as

852 explained earlier in section 3.4.2). Although Figure 9 shows the geographical distribution of  
853 mineral N pools from the FULL simulation, the geographical distribution of pools are broadly  
854 similar between different simulations with obvious differences such as lack of hot spots of N  
855 deposition and fertilizer input in simulations in which these forcings stay at their pre-industrial  
856 levels. Figure 9 also shows the simulated geographical distribution of C and N pools in the  
857 vegetation and soil organic matter. The increase in GPP due to changing climate increases the N  
858 demand (Figure 6a, magenta line) but unlike the CO<sub>2</sub>-only simulation, the plant N uptake  
859 increases since the NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> pools increase in size over the vegetated area in response to  
860 increased mineralization (Figure 8a, magenta line) and increased BNF (Figure 3a, magenta line).  
861 The increase in plant N uptake comes from the increase in passive plant N uptake (Figure 6c)  
862 while the active plant N uptake reduces (Figure 6d). Active and passive plant N uptakes are  
863 inversely correlated. This is by design since active plant N uptake increases when passive plant N  
864 uptake reduces and vice-versa, although eventually both depend on the size of available mineral  
865 N pools. Enhancement of plant N uptake due to changes in climate, despite increases in GPP  
866 associated with a small increase in  $V_{cmax}$  (Figure 5d), leads to a small reduction in the C:N ratio of  
867 all plant tissues (Figure 7). The litter C:N, in contrast, shows a small increase since not all N makes  
868 its way to the litter as a specified fraction of 0.54 (Table A1) leaf N is resorbed from deciduous  
869 trees leaves prior to leaf fall (Figure 7e). Although the leaf C:N ratio decreases in the CLIM only  
870 simulation, in response to increased BNF and increased mineralization, this decrease is not large  
871 enough to overcome the effect of resorption and as a result the C:N litter increases.

872 Finally, the small increase in pool sizes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  leads to a small increase in  
873 leaching, volatilization, and gaseous losses associated with nitrification and denitrification (Figure  
874 8).

### 875 **5.2.3 Response to N deposition**

876 The simulated response of GPP to changes in N deposition (brown line) over the historical  
877 period is smaller than that for  $\text{CO}_2$  and climate (Figure 4a). The small increase in GPP of  $2.0 \text{ Pg C}$   
878  $\text{yr}^{-1}$  leads to commensurately small increases in vegetation (Figure 4b) and litter plus soil (Figure  
879 4d) C mass. Vegetation and leaf N mass (Figure 5a,b) also increase in response to N deposition  
880 and so do mineral pools of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  (Figure 5e,f). The increase in GPP in the simulation with  
881 N deposition results from an increase in  $V_{\text{cmax}}$  rates (Figure 5d) associated with an increase in leaf  
882 N content (Figure 5b). N demand increases marginally and so does plant N uptake in response to  
883 N deposition (Figure 6). As would be intuitively expected, the C:N ratio of the whole plant, its  
884 components of leaves, stem, and root, and litter decreases slightly in response to N deposition  
885 (Figure 7). Net N mineralization, nitrification, leaching, volatilization, and gaseous losses  
886 associated with nitrification and denitrification all increase in response to N deposition (Figure  
887 8).

### 888 **5.2.4 Response to LUC and fertilizer input**

889 The simulated response to LUC, which reflects an increase in crop area, and increased  
890 fertilizer deposition rates over the historical period is shown by dark green lines in Figures 4  
891 through 8. The increase in fertilizer input is a much bigger perturbation to the N cycle system  
892 than N deposition. Figure 2 shows that at the global scale the fertilizer inputs increase from 0 to

893 ~92 Tg N/yr over the historical period, while the combined  $\text{NH}_4^+$  and  $\text{NO}_3^-$  N deposition rate  
894 increases from around 20 to 65 Tg N/yr. In addition, because of higher per unit area BNF rates  
895 over crop area than natural vegetation, the increase in crop area in this simulation leads to an  
896 increase in anthropogenic BNF from about 20 to 56 Tg N/yr over the historical period. All together  
897 increasing crop area and fertilizer inputs imply an additional ~130 Tg N/yr being input into the  
898 terrestrial N cycle at the present day since the pre-industrial period, compared to an increase of  
899 only 45 Tg N/yr for the N deposition forcing.

900         The global increase in fertilizer input over the historical period leads to higher  $\text{NH}_4^+$  and  
901  $\text{NO}_3^-$  pools (Figures 5e and 5f). Although both fertilizer and BNF contribute to the  $\text{NH}_4^+$  pool, the  
902  $\text{NO}_3^-$  pool also increases through the nitrification flux (Figure 8b). An increase in crop area over  
903 the historical period results in deforestation of natural vegetation that reduces vegetation  
904 biomass (Figure 4b). However, soil carbon mass also decreases (Figure 4d) despite higher litter  
905 inputs. This is because a higher soil decomposition rate is assumed over cropland areas to  
906 simulate soil carbon loss as empirical measurements of soil carbon show over deforested areas  
907 which are converted to croplands (Wei et al., 2014). Fertilizer application only occurs over crop  
908 areas which increases the  $V_{\text{cmax}}$  rates for crops and, as expected, this yields an increase in globally-  
909 averaged  $V_{\text{cmax}}$  (Figure 5d). A corresponding large increase in leaf N content (Figure 5b) is,  
910 however, not seen because vegetation (and therefore leaf) N (Figure 5a,b) is also lost through  
911 deforestation. In addition,  $V_{\text{cmax}}$  is essentially a flux (expressed per unit leaf area) that is averaged  
912 over the whole year while leaf and vegetation N pools are sampled at the end of each year and  
913 all crops in the northern hemisphere above 30° N are harvested before the year end. Vegetation  
914 N mass, in fact, decreases in conjunction with vegetation C mass (Figure 4b). Plant N demand

915 reduces (Figure 6a) and plant N uptake increases (Figure 6b) driven by crop PFTs in response to  
916 fertilizer input, as would be intuitively expected. The increase in plant N uptake comes from the  
917 increase in passive N uptake, in response to increases in pool sizes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  over crop  
918 areas, while active plant N uptake decreases since passive uptake can more than keep up with  
919 the demand over cropland area. While the C:N ratio of vegetation biomass decreases over  
920 cropland area in response to fertilizer input (not shown) this is not seen in the globally-averaged  
921 C:N ratio of vegetation (Figure 7a) and its components because C and N are also lost through  
922 deforestation and the fact that crop biomass is harvested. The C:N of the global litter pool,  
923 however, decreases in response to litter from crops which gets rich in N as fertilizer application  
924 rates increase. Finally, in Figure 8, global net N mineralization, nitrification, leaching,  
925 volatilization, and gaseous losses associated with nitrification and denitrification all increase by  
926 a large amount in response to an increase in fertilizer input.

927 **5.2.5 Response to all forcings**

928 We can now evaluate and understand the simulated response of the FULL simulation to  
929 all forcings (red line in Figures 4 through 8). The increase in GPP in the FULL simulation (14.5 Pg  
930 C/yr) in Figure 4a over the historical period is driven by GPP increase associated with increase in  
931  $\text{CO}_2$  (7.5 Pg C/yr), changing climate (3.6 Pg C/yr), and N deposition (2.0 Pg C/yr). The increases  
932 associated with these individual forcings add up to 13.1 Pg C/yr indicating that synergistic effects  
933 between forcings contribute to the additional 1.4 Pg C/yr increase in GPP. The changes in  
934 vegetation and soil plus litter carbon mass (Figures 4b and 4d) in the FULL simulation are similarly  
935 driven by these three factors but, in addition, LUC contributes to decreases in vegetation and soil  
936 carbon mass as natural vegetation is deforested to accommodate for increases in crop area.

937 Vegetation and leaf N mass (Figures 5a and 5b) decrease in the FULL simulation driven primarily  
938 by the response to increasing CO<sub>2</sub> (orange line compared to the red line) while changes in litter  
939 and soil N mass are affected variably by all forcings (Figure 5c). Changes in V<sub>cmax</sub> (Figure 5d) are  
940 similarly affected by all forcings: increasing CO<sub>2</sub> leads to a decrease in globally-averaged V<sub>cmax</sub>  
941 values while changes in climate, N deposition, and fertilizer inputs lead to increases in V<sub>cmax</sub>  
942 values with the net result being a small decrease over the historical period. The increase in global  
943 NH<sub>4</sub><sup>+</sup> mass in the FULL simulation is driven primarily by the increase in fertilizer input (Figure 5e,  
944 red versus green line) while the changes in NO<sub>3</sub><sup>-</sup> mass are primarily the result of changes in  
945 climate (Figure 5f, magenta line) which causes a decrease in NO<sub>3</sub><sup>-</sup> mass from about 1940 to 1970  
946 and N deposition and fertilizer input (Figure 5f, green and brown lines) which contribute to the  
947 increase in NO<sub>3</sub><sup>-</sup> mass later on in the historical period. The increase in N demand (Figure 6a) over  
948 the historical period is also driven primarily by the increase in atmospheric CO<sub>2</sub>. Plant N uptake  
949 (Figure 6b) decreases in response to increasing CO<sub>2</sub> but increases in response to changes in  
950 climate, N deposition, and fertilizer inputs such that the net change over the historical is a small  
951 decrease. The increase in the C:N ratio of vegetation and its components (leaves, stem, and root)  
952 is driven primarily by an increase in atmospheric CO<sub>2</sub> (Figure 7a, red versus orange line). Litter  
953 C:N in the FULL simulation, in contrast, does not change substantially over the historical period  
954 in a globally-averaged sense as the increase in the C:N ratio of litter associated with an increase  
955 in atmospheric CO<sub>2</sub> is mostly compensated by the decrease associated with an increase in N  
956 deposition and fertilizer application. The simulated change in global net N mineralization (Figure  
957 8a) in the FULL simulation, over the historical period, is small since the decrease in net N  
958 mineralization due to increasing CO<sub>2</sub> (orange line) is compensated by the increase caused by

959 changes in climate, N deposition, and fertilizer inputs (magenta, brown, and green lines  
960 respectively). The remaining fluxes of nitrification,  $\text{NO}_3^-$  leaching,  $\text{NH}_3$  volatilization, and gaseous  
961 losses associated with nitrification and denitrification in the FULL simulation (Figure 8) are all  
962 strongly influenced by fertilizer input (green line compared to red line).

963 Table 2 compares simulated values of all primary N pools and fluxes from the FULL  
964 simulation with other modelling and quasi observation-based studies. Simulated values are  
965 averaged over the 1998-2017 period. Where available, time-periods for other modelling and  
966 quasi observation-based studies to which estimates correspond are also noted. For the most part  
967 simulated pools and fluxes lie within the range of existing studies with the exception of  $\text{N}_2$  and  
968  $\text{NO}$  emissions that are somewhat higher.

#### 969 **5.2.6 Response to all forcings except LUC**

970 The FULL-no-LUC simulation includes all forcings except LUC (blue line in Figures 4  
971 through 8) and corroborates several of the points mentioned above. In this simulation crop area  
972 stays at its 1850 value. Figure 2b (blue line) shows increasing global fertilizer input in this  
973 simulation despite crop area staying at its 1850 value since fertilizer application rates per unit  
974 area increase over the historical period. In the absence of the LUC, vegetation C mass (Figure 4b)  
975 and soil plus litter C (Figure 4d) and N (Figure 5c) are higher in the FULL-no-LUC compared to the  
976 FULL simulation. N demand (Figure 6a) is slightly higher in FULL-no LUC than in FULL simulation  
977 because there is more standing vegetation biomass that is responding to increasing  $\text{CO}_2$ . The  
978 increase in volatilization, leaching, and gaseous losses associated with nitrification and  
979 denitrification (Figures 8c-8f) are all primarily caused by increased fertilizer input over the

980 specified 1850 crop area. The increase in N losses associated with these processes, over the  
981 historical period, is much lower in the FULL-no-LUC simulation than in the FULL simulation since  
982 crop area stays at its 1850 values.

### 983 **5.3 Comparison of FULL and ORIGINAL simulations**

984 We now compare the results from the FULL simulation that includes the N cycle with that  
985 from the ORIGINAL simulation that does not include the N cycle. Both simulations are driven with  
986 all forcings over the historical period. Figure 4a shows that the global GPP values in the FULL (red  
987 line) and ORIGINAL (purple line) simulations are quite similar although the rate of increase of GPP  
988 in the FULL simulation is slightly higher than in the ORIGINAL simulation. As a result, simulated  
989 global vegetation biomass is somewhat higher in the FULL simulation (Figure 4b). The simulated  
990 global litter and soil carbon mass (Figure 4d) is, however, lower in the FULL simulation (1073 Pg  
991 C) compared to the ORIGINAL simulation (1142 Pg C) and this decrease mainly comes from a  
992 decrease at higher latitudes (not shown) due to a decrease in GPP (Figure 10a). The lower GPP in  
993 the FULL simulation, combined with the slow decomposition at cold high latitudes, results in a  
994 lower equilibrium for litter and soil carbon compared with the ORIGINAL simulation. Litter mass  
995 contributes about 80 Pg C to the total dead carbon mass. Overall both estimates of 1073 Pg C  
996 and 1142 Pg C are somewhat lower than the bulk density corrected estimate of 1230 Pg C based  
997 on the Harmonized World Soil Database (HWSD) v.1.2 (Köchy et al., 2015). One reason for this is  
998 that CLASSIC does not yet represent permafrost related soil C processes.

999 Figure 10a shows that the zonal distribution of GPP from the FULL and ORIGINAL  
1000 simulations, for the 1998-2017 period, compares reasonably well to the observation-based

1001 estimate from Beer et al. (2010). The FULL simulation has slightly lower productivity at high-  
1002 latitudes than the ORIGINAL simulation, as mentioned above. Overall, however, the inclusion of  
1003 the N cycle does not change the zonal distribution of GPP in the model substantially, which is  
1004 determined primarily by the geographical distribution of climate. Figure 10b compares the zonal  
1005 distribution of GPP from the pre-industrial simulation (corresponding to 1850s) from the FULL  
1006 and FULL-with-no-implicit-P-limitation simulations to illustrate the high GPP in the tropics where  
1007 P and not N limitation affects GPP and the reason for choosing a lower value of  $\Gamma_1$  in equation  
1008 (31) for the broadleaf evergreen tree PFT.

1009         The global GPP in the ORIGINAL and FULL simulations averaged over the period 1998-  
1010 2017 (120.0 and 120.4 PgC/yr, respectively) are around 15% lower compared to that in the ORIG-  
1011 UNCONST simulation (142 PgC/yr), as shown in Figure 4a, yielding a global downregulation factor  
1012 of about 0.85. Figure 10c shows how downregulation works in the ORIGINAL and FULL  
1013 simulations in a zonally-averaged sense. Ratios of annual GPP averaged over the 1998-2017  
1014 period from the ORIGINAL versus ORIG-UNCONST simulations, and FULL versus ORIG-UNCONST  
1015 simulations were first calculated for each grid cell and then zonally-averaged over the land grid  
1016 cells. Ratios can be misleading especially for grid cells with low values, for example, in the desert  
1017 regions. In addition, these ratios also depend on the specified  $V_{cmax}$  values in the ORIG-UNCONST  
1018 simulation. In Figure 10c, the purple line for the ORIGINAL simulation exhibits values around 0.8  
1019 consistent with the global downregulation of around 0.85 and the fact that the same scalar  
1020 downregulation multiplier is used everywhere on the globe (equation 1). The red line for the FULL  
1021 simulation, however, indicates a pattern of higher downregulation at high-latitudes. The peaks  
1022 in red line, especially the one around 23°N (Sahara desert), are due to higher values in selected

1023 grid cells in dry and arid regions where the build-up of  $\text{NO}_3^-$  in the soil (due to reduced  
1024 denitrification) increases  $V_{\text{cmax}}$  and thus GPP in the run with N cycle leading to higher ratios  
1025 although the absolute GPP values still remain low.

1026 Figure 11a compares globally-summed net atmosphere-land  $\text{CO}_2$  flux from the FULL,  
1027 FULL-no-LUC, and ORIGINAL simulations with quasi observation-based estimates from the 2019  
1028 Global Carbon Project (Friedlingstein et al., 2019). There are two kinds of estimates in Figure 11a  
1029 from Friedlingstein et al. (2019): the first is the net atmosphere-land  $\text{CO}_2$  flux for the decades  
1030 spanning the 1960s to the 2000s which are shown as rectangular boxes with their corresponding  
1031 mean values and ranges, and the second is the terrestrial sink from 1959 to 2018 (dark yellow  
1032 line). Positive values indicate a sink of carbon over land and negative values a source. The  
1033 difference between the net atmosphere-land  $\text{CO}_2$  flux and the terrestrial sink is that the  
1034 terrestrial sink minus the LUC emissions yields the net atmosphere-land  $\text{CO}_2$  flux. The  
1035 atmosphere-land  $\text{CO}_2$  flux from the FULL-no-LUC simulation (blue line) is directly comparable to  
1036 the terrestrial sink since 1959, since the FULL-no-LUC simulation includes no LUC, and shows that  
1037 the simulated terrestrial sink compares fairly well to the estimates from Friedlingstein et al.  
1038 (2019). Averaged over the period 1959-2017, the modelled and Global Carbon Project values are  
1039 2.0 and 2.1 Pg C/yr, respectively. The net atmosphere-land  $\text{CO}_2$  flux from the FULL simulation  
1040 mostly lies within the uncertainty range for the five decades considered, although it is on the  
1041 higher side compared to estimates from Friedlingstein et al. (2019). The reason for this is that  
1042 LUC emissions in CLASSIC are much lower than observation-based estimates, as discussed below  
1043 in context of Figure 11c. CLASSIC simulates LUC emissions only in response to changes in crop  
1044 area whereas changes in pasture area and wood harvesting also contribute to LUC emissions. The

1045 net-atmosphere land CO<sub>2</sub> flux from the ORIGINAL simulation compares better with the estimates  
1046 from Friedlingstein et al. (2019), than the FULL simulation, because the photosynthesis down-  
1047 regulation parameter in the ORIGINAL simulation has been adjusted despite discrepancies in  
1048 simulated LUC processes.

1049 Figure 11b compares the zonal distribution of simulated net atmosphere-land CO<sub>2</sub> flux  
1050 from the FULL and ORIGINAL simulations with the model-mean and range from the terrestrial  
1051 ecosystem models that participated in the 2019 TRENDY model intercomparison and contributed  
1052 results to 2019 Global Carbon Project (Friedlingstein et al., 2019). The carbon sink simulated by  
1053 CLASSIC in the northern hemisphere is broadly comparable to the model-mean estimate from  
1054 the TRENDY models. However, in the tropics CLASSIC simulates a much stronger sink than the  
1055 model-mean, likely because of its lower LUC emissions.

#### 1056 **5.4 Contribution of forcings to land C sink and sources**

1057 Figure 11c shows cumulative net atmosphere-land CO<sub>2</sub> flux for the 1850-2017 period from  
1058 the six primary simulations with N cycle. These simulations facilitate the attribution of carbon  
1059 uptake and release over the historical period to various forcings. The cumulative terrestrial sink  
1060 in the FULL-no-LUC simulation for the period 1850-2017 is simulated to be ~153 Pg C and this  
1061 compares reasonably well with the estimate of  $185 \pm 50$  Pg C for the period 1850-2014 from Le  
1062 Quéré et al. (2018). Increase in CO<sub>2</sub> (~115 Pg C), change in climate (~3 Pg C), and N deposition  
1063 (~19 Pg C) all contribute to this terrestrial sink. These three contributions add up to 137 Pg C so  
1064 the additional 16 Pg C is contributed by the synergistic effects between the three forcings.  
1065 Quantified in this way, the contribution of increasing CO<sub>2</sub> (115 out of 137 Pg C), climate change

1066 (3 out of 137 Pg C), and N deposition (19 out of 137 Pg C) to carbon uptake by land over the  
1067 historical period (1850-2017) is calculated to be 84%, 2%, and 14%, respectively. Cumulative LUC  
1068 emissions simulated for the period 1850-2017 by CLASSIC can be estimated using a negative  
1069 cumulative net-atmosphere-land CO<sub>2</sub> flux of ~66 Pg C from the LUC+FERT-only simulation or by  
1070 the differencing the FULL and FULL-no-LUC simulations (~71 Pg C). While LUC emissions are highly  
1071 uncertain, both of these estimates are much lower than the 195 ± 75 Pg C estimate from Le Quéré  
1072 et al. (2018).

## 1073 **6.0 Discussion and conclusions**

1074 The interactions between terrestrial C and N cycles are complex and our understanding  
1075 of these interactions, and their representation in models, is based on empirical observations of  
1076 various terrestrial ecosystem processes. In this paper, we have evaluated the response of these  
1077 interactions by perturbing the coupled C and N cycle processes in the CLASSIC model with one  
1078 forcing at a time over the historical period: 1) increase in CO<sub>2</sub>, 2) change in climate, 3) increase in  
1079 N deposition, and 4) LUC with increasing fertilizer input. These simulations are easier to interpret  
1080 and the model response can be evaluated against both our conceptual knowledge as well as  
1081 empirical observation-based data. Our assumption is that, if the model response to individual  
1082 forcings is realistic and consistent with expectations based on empirical observations then the  
1083 response of the model to all forcings combined will also be realistic and easier to interpret,  
1084 although we do expect and see synergistic effects between forcings.

1085 The simulated response of coupled C and N cycles in CLASSIC to increasing atmospheric  
1086 CO<sub>2</sub> is an increase in the C:N ratio of vegetation components due to an increase in their C content

1087 but also a decrease in their N content. This model response is conceptually consistent with a  
1088 meta-analysis of 75 field experiments of elevated CO<sub>2</sub> as reported in Cotrufo et al. (1998) who  
1089 find an average reduction in tissue N concentration of 14%. Most studies analyzed in the Cotrufo  
1090 et al. (1998) meta-analysis used ambient CO<sub>2</sub> of around 350 ppm and elevated CO<sub>2</sub> of around  
1091 650-700 ppm. In comparison, the plant N concentration in CLASSIC reduces by ~26% in response  
1092 to a gradual increase in atmospheric CO<sub>2</sub> from 285 ppm to 407 ppm (an increase of 122 ppm)  
1093 over the 1850-2017 period (whole plant C:N ratio increases from 142.6 to 194.1 in the CO<sub>2</sub>-only  
1094 simulation, Figure 7a). These two estimates cannot be compared directly - the majority (59%) of  
1095 Free-Air Carbon dioxide Enrichment (FACE) experiments last less than 3 years (Jones et al., 2014)  
1096 and the vegetation experiences a large CO<sub>2</sub> change of around 300-350 ppm while the duration of  
1097 our historical simulation is 167 years and the gradual increase in CO<sub>2</sub> of 122 ppm over the  
1098 historical period is much smaller.

1099         The response of our model to CO<sub>2</sub> increase over the historical period is also consistent  
1100 with the meta-analysis of McGuire et al. (1995) who report an average decrease in leaf N  
1101 concentration of 21% in response to elevated CO<sub>2</sub> based on 77 studies, which is the primary  
1102 reason for downregulation of photosynthetic capacity. The simulated decrease in leaf N  
1103 concentration in our study for the CO<sub>2</sub>-only experiment is around 27% (leaf C:N ratio increases  
1104 from 42.8 to 58.6 in the CO<sub>2</sub>-only simulation, Figure 7b). Although, the same caveats that apply  
1105 to the comparison with the Cotrufo et al. (1998) study also apply to this comparison. The  
1106 decrease in whole plant and leaf N concentrations in our results is conceptually consistent with  
1107 the meta-analyses of McGuire et al. (1995) and Cotrufo et al. (1998). The decrease in whole plant  
1108 N concentration in our CO<sub>2</sub>-only and FULL simulations is the result of an increase in both tissue

1109 C amount and a decrease in N amount. The decrease in tissue N amount is, in fact, necessary in  
1110 our modelling framework to induce the required downregulation of photosynthesis to simulate  
1111 the land carbon sink realistically over the historical period.

1112         The meta-analysis of Liang et al. (2016) reports an increase in above and belowground  
1113 plant N pools in response to elevated CO<sub>2</sub> associated with increase in BNF but since their results  
1114 are based on pool sizes they cannot be compared directly to the N concentration based results  
1115 from McGuire et al. (1995) and Cotrufo et al. (1998). Liang et al. (2016) also report results from  
1116 short-term ( $\leq 3$  years) and long-term (between 3 to 15 years) studies separately (their Figure 3).  
1117 They show that the increase in total plant and litter N pools become smaller for long-term studies.  
1118 Regardless, the difference in time scales of empirical studies and the real world is a caveat that  
1119 will always make it difficult to evaluate model results over long time scales.

1120         The response of C and N cycles to changes in climate in our model (in the CLIM-only  
1121 simulation) is also conceptually realistic. Globally, GPP increases in response to climate that  
1122 gradually gets warmer and wetter (see Figure A2) and as a result vegetation biomass increases.  
1123 Soil carbon mass, however, decreases (despite increase in NPP inputs) since warmer  
1124 temperatures also increase heterotrophic respiration (not shown). As a result of increased  
1125 decomposition of soil organic matter, net N mineralization increases and together with increased  
1126 BNF the overall C:N ratio of vegetation and leaves decreases, which leads to a  $V_{cmax}$  increase. The  
1127 small increase in  $V_{cmax}$ , due to increased mineralization, thus also contributes to an increase in  
1128 GPP over and above that due to a change in climate alone, and therefore compensates for the  
1129 amount of carbon lost due to increased soil organic matter decomposition associated with  
1130 warmer temperatures. This behaviour is consistent with land C cycle models showing a reduction

1131 in the absolute value of the strength of the carbon-climate feedback when they include coupling  
1132 of C and N cycles (Arora et al., 2020).

1133         The modelled differences in PFT specific values of  $V_{\text{cmax}}$ , in our framework, come through  
1134 differences in simulated values of leaf N content ( $N_L$ ) that depend on BNF (given that BNF is the  
1135 primary natural source of N input into the coupled soil-vegetation system) but also differences  
1136 in mineralization that are governed by climate.  $N_L$  values, however, also depend on leaf  
1137 phenology, allocation of carbon and nitrogen, turnover rates, transpiration (which brings in N  
1138 through passive uptake), and almost every aspect of plant biogeochemistry which affects a PFT's  
1139 net primary productivity and therefore N demand. Modelled increases in GPP in response to N  
1140 deposition come through an increase in leaf N content and therefore  $V_{\text{cmax}}$  values.

1141         Finally, changes in land use associated with an increase in crop area, and the associated  
1142 increase in fertilizer application rates lead to the largest increase in  $\text{NO}_3^-$  leaching,  $\text{NH}_3$   
1143 volatilization, and gaseous losses associated with nitrification and denitrification among all  
1144 forcings. Overall, the model response to perturbation by all individual forcings is realistic,  
1145 conceptually expected, and of the right sign (positive or negative) although it is difficult to  
1146 evaluate the magnitude of these responses in the absence of directly comparable observation-  
1147 based estimates.

1148         Despite the model responses to individual forcings that appears consistent with our  
1149 conceptual understanding of coupled C and N cycles, our modelling framework misses an  
1150 important feedback process that has been observed in the FACE and other experiments related  
1151 to changes in natural BNF. FACE sites and other empirical studies report an increase in natural

1152 BNF rates at elevated CO<sub>2</sub> (McGuire et al., 1995; Liang et al., 2016) and a decrease in natural BNF  
1153 rates when additional N is applied to soils (Salvagiotti et al., 2008; Ochoa-Hueso et al., 2013). On  
1154 a broad scale this is intuitively expected but the biological processes behind changes in BNF rates  
1155 remain largely unclear. A response can still be parameterized even if the underlying physical and  
1156 biological processes are not well understood. For instance, Goll et al. (2012) parameterize BNF as  
1157 an increasing and saturating function of NPP,  $BNF = 1.8 (1.0 - \exp(-0.003 NPP))$ . This  
1158 approach, however, does not account for the driver behind the increase in NPP - increasing  
1159 atmospheric CO<sub>2</sub>, change in environmental conditions (e.g., wetter and warmer conditions), or  
1160 increased N deposition. Clearly, increasing BNF if the NPP increase is due to N deposition is  
1161 inconsistent with empirical observations. Over the historical period an increase in atmospheric  
1162 CO<sub>2</sub> has been associated with an increase in N deposition so to some extent changes in BNF due  
1163 to both forcings will cancel each other. We realize the importance of changes in BNF, given it is  
1164 the single largest natural flux of N into the coupled soil-vegetation system yet highly uncertain,  
1165 and aim to address these issues in a future version of the model by exploring existing BNF  
1166 formulations. Meyerholt et al. (2016), for example, demonstrate the uncertainty arising from the  
1167 use of five different BNF parameterizations in the context of the O-CN model. They use  
1168 formulations that parameterize BNF as a function of 1) evapotranspiration, 2) NPP, 3) leaf C:N  
1169 ratio, that takes into account energy cost for N fixation (Fisher et al., 2010), 4) plant N demand,  
1170 and 5) an optimality-based approach that follows Rastetter et al. (2001) in which BNF only occurs  
1171 when the carbon cost of N fixation is lower than the carbon cost of root N uptake. The approach  
1172 used in our study is closest to the one that is based on evapotranspiration but makes the  
1173 distinction in BNF rates over natural and agricultural areas.

1174           The reduction of photosynthesis rates in response to N limitation is the most important  
1175 linkage between C and N cycles and yet it too is parameterized differently across models. Given  
1176 that leaf N content and photosynthetic capacity are strongly correlated (Evans, 1989; Field and  
1177 Mooney, 1986; Garnier et al., 1999), photosynthesis downregulation due to N limitation reduces  
1178 photosynthetic capacity, and thus the GPP flux. Yet models reduce both NPP (Wiltshire et al.,  
1179 2020) and  $V_{\text{cmax}}$  rates, and thus GPP, (Zaehle and Friend, 2010; Wania et al., 2012; von Bloh et al.,  
1180 2018) in response to N limitation.  $V_{\text{cmax}}$  rates may themselves be parameterized as a function leaf  
1181 N content directly (von Bloh et al., 2018; Zaehle and Friend, 2010) or leaf C:N ratio (Wania et al.,  
1182 2012). In this study, we have parameterized  $V_{\text{cmax}}$  rates as a function of leaf N content (equation  
1183 31) since the use of leaf C:N ratio leads to an incorrect seasonal variation of  $V_{\text{cmax}}$ . If an increase  
1184 in leaf C:N ratio, as a result of increase in atmospheric  $\text{CO}_2$ , leads to a decrease in  $V_{\text{cmax}}$  rates over  
1185 the historical period then it implies that  $V_{\text{cmax}}$  is inversely related to leaf C:N ratios. Since leaf C:N  
1186 ratio peak during the growing season (Li et al., 2017) this also implies  $V_{\text{cmax}}$  rates are lower during  
1187 the growing season than at its start and this is in contrast to observations that show an increase  
1188 in  $V_{\text{cmax}}$  during the growing season (e.g., see Fig. 1a of Bauerle et al. (2012)).

1189           Our framework assumes a constant C:N ratio of 13 for soil organic matter ( $C:N_H$ ), an  
1190 assumption also made in other models (e.g., Wania et al., 2012; Zhang et al., 2018). This  
1191 assumption is also broadly consistent with Zhao et al. (2019) who attempt to model C:N of soil  
1192 organic matter, among other soil properties, as a function of mean annual temperature and  
1193 precipitation using machine learning algorithms (their Figure 2h). It is difficult to currently  
1194 establish if increasing atmospheric  $\text{CO}_2$  is changing  $C:N_H$  given the large heterogeneity in soil  
1195 organic C and N densities, and the difficulty in measuring small trends for such large global pools.

1196 A choice of a somewhat different value for all PFTs or had we chosen specified constant PFT-  
1197 dependent values of  $C:N_H$  is of relatively less importance in this context since the model is spun  
1198 to equilibrium for 1850 conditions anyway. It is the change in  $C:N_H$  over time that is of  
1199 importance. The assumption of constant  $C:N_H$  is the key to yielding a decrease in vegetation N  
1200 mass, and therefore leaf N mass and  $V_{\text{cmax}}$ , as  $\text{CO}_2$  increases, in our framework. Without a  
1201 decrease in  $V_{\text{cmax}}$  in our modelling framework, in response to elevated  $\text{CO}_2$ , we cannot achieve  
1202 the downregulation noted by McGuire et al. (1995) in their meta-analysis, and the simulated  
1203 carbon sink over the historical period would be greater than observed as noted above. It is  
1204 possible that we are simulating the reduction in leaf N mass, in response to elevated  $\text{CO}_2$ , for a  
1205 wrong reason in which case our model processes need to be revisited based on additional  
1206 empirical data. If our assumption of constant or extremely slowly changing  $C:N_H$  is indeed  
1207 severely unrealistic, this necessitates a point of caution that a realistic land carbon sink can be  
1208 simulated over the historical period with such an assumption.

1209         Related to this assumption is also the fact that we cannot make decomposition rates of  
1210 soil organic matter a function of its C:N ratio since it is assumed to be a constant. It is well known  
1211 that after climate, litter and soil organic matter decomposition rates are controlled by their C:N  
1212 ratio (Manzoni et al., 2008). Litter decomposition rates can still be made a function of its C:N ratio  
1213 and we aim to do this for a future model version.

1214         The work presented in this study of coupling C and N cycles in CLASSIC yields a framework  
1215 that we can build upon to make model processes more realistic, test the effect of various model  
1216 assumptions, parameterize existing processes in other ways, include additional processes, and  
1217 evaluate model response at FluxNet sites to constrain model parameters.

## 1218 Appendix

1219

### 1220 A1. Budget equations for N pools

1221 The rates of change of N in the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools (in  $\text{gN m}^{-2}$ ),  $N_{\text{NH}_4}$  and  $N_{\text{NO}_3}$ ,  
1222 respectively, are given by

$$\begin{aligned} 1224 \quad \frac{d N_{\text{NH}_4}}{dt} = & B_{\text{NH}_4} + F_{\text{NH}_4} + P_{\text{NH}_4} + M_{D,\text{NH}_4} + M_{H,\text{NH}_4} \\ 1223 \quad & -U_{\text{NH}_4} - (I_{\text{NO}_3} + I_{\text{N}_2\text{O}} + I_{\text{NO}}) - V_{\text{NH}_3} - O_{\text{NH}_4} \end{aligned} \quad (\text{A1})$$

$$1225 \quad \frac{d N_{\text{NO}_3}}{dt} = P_{\text{NO}_3} + I_{\text{NO}_3} - L_{\text{NO}_3} - U_{\text{NO}_3} - (E_{\text{N}_2} + E_{\text{N}_2\text{O}} + E_{\text{NO}}) - O_{\text{NO}_3} \quad (\text{A2})$$

1226 and all fluxes are represented in units of  $\text{gN m}^{-2} \text{day}^{-1}$ .  $B_{\text{NH}_4}$  is the rate of biological N fixation  
1227 which solely contributes to the  $\text{NH}_4^+$  pool,  $F_{\text{NH}_4}$  is the fertilizer input which is assumed to  
1228 contribute only to the  $\text{NH}_4^+$  pool, and  $P_{\text{NH}_4}$  and  $P_{\text{NO}_3}$  are atmospheric deposition rates that  
1229 contribute to the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools, respectively. Biological N fixation, fertilizer input, and  
1230 atmospheric deposition are the three routes through which N enters the coupled soil-vegetation  
1231 system.  $M_{D,\text{NH}_4}$  and  $M_{H,\text{NH}_4}$  are the mineralization flux from the litter and soil organic matter  
1232 pools, respectively, associated with their decomposition. We assume mineralization of humus  
1233 and litter pools only contributes to the  $\text{NH}_4^+$  pool.  $O_{\text{NH}_4}$  and  $O_{\text{NO}_3}$  indicate immobilization of N  
1234 from the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools, respectively, to the humus N pool which implies microbes (that  
1235 are not represented explicitly) are part of the humus pool. Combined together the terms  
1236  $(M_{D,\text{NH}_4} + M_{H,\text{NH}_4} - O_{\text{NH}_4} - O_{\text{NO}_3})$  yield the net mineralization rate.  $V_{\text{NH}_3}$  is the rate of  
1237 ammonia ( $\text{NH}_3$ ) volatilization and  $L_{\text{NO}_3}$  is the leaching of N that occurs only from the  $\text{NO}_3^-$  pool.

1238 The positively charged ammonium ions are attracted to the negatively charged soil particles and  
 1239 as a result it is primarily the negatively charged nitrate ions that leach through the soil (Porporato  
 1240 et al., 2003; Xu-Ri and Prentice, 2008).  $U_{NH_4}$  and  $U_{NO_3}$  are uptakes of  $NH_4^+$  and  $NO_3^-$  by plants,  
 1241 respectively. The nitrification flux from  $NH_4^+$  to  $NO_3^-$  pool is represented by  $I_{NO_3}$  which also results  
 1242 in the release of the nitrous oxide ( $N_2O$ ), a greenhouse gas, and nitric oxide (NO) through nitrifier  
 1243 denitrification represented by the terms  $I_{N_2O}$  and  $I_{NO}$ , respectively. Finally,  $E_{N_2}$ ,  $E_{N_2O}$ , and  $E_{NO}$   
 1244 are the gaseous losses of  $N_2$  (nitrogen gas),  $N_2O$ , and NO from the  $NO_3^-$  pool associated with  
 1245 denitrification. N is thus lost through the soil-vegetation system via leaching in runoff and  
 1246 through gaseous losses of  $I_{N_2O}$ ,  $I_{NO}$ ,  $E_{N_2}$ ,  $E_{N_2O}$ ,  $E_{NO}$ , and  $V_{NH_3}$ .

1247 The structural and non-structural N pools in root are written as  $N_{R,S}$  and  $N_{R,NS}$ ,  
 1248 respectively, and similarly for stem ( $N_{S,S}$  and  $N_{S,NS}$ ) and leaves ( $N_{L,S}$  and  $N_{L,NS}$ ), and together the  
 1249 structural and non-structural pools make the total N pool in leaf ( $N_L = N_{L,S} + N_{L,NS}$ ), root ( $N_R =$   
 1250  $N_{R,S} + N_{R,NS}$ ), and stem ( $N_S = N_{S,S} + N_{S,NS}$ ) components. The rate change equation for  
 1251 structural and non-structural N pools in root are given by

$$1252 \quad \frac{d N_{R,NS}}{dt} = U_{NH_4} + U_{NO_3} + R_{L2R} - R_{R2L} - A_{R2L} - A_{R2S} - LF_{R,NS} - T_{R,NS2S} \quad (A3)$$

$$1253 \quad \frac{d N_{R,S}}{dt} = T_{R,NS2S} - LF_{R,S} \quad (A4)$$

1254 Similar to the uptake of carbon by leaves and its subsequent allocation to root and stem  
 1255 components, N is taken up by roots and then allocated to leaves and stem.  $A_{R2L}$  and  $A_{R2S}$   
 1256 represent the allocation of N from roots to leaves and stem, respectively. The terms  $R_{L2R}$  and  
 1257  $R_{R2L}$  represent the reallocation of N between the non-structural components of root and leaves.  
 1258  $R_{L2R}$  is the N reallocated from leaves to root representing resorption of a fraction of leaf N during

1259 leaf fall for deciduous tree PFTs.  $R_{R2L}$  indicates reallocation of N from roots to leaves (termed  
 1260 reallocation in Figure 2) at the time of leaf-out for deciduous tree PFTs. At times other than leaf-  
 1261 out and leaf-fall and for other PFTs these two terms are zero.  $T_{R,NS2S}$  is the one way transfer of  
 1262 N from the non-structural to the structural root pool, and similar to the carbon pools, once N is  
 1263 converted to its structural form it cannot be converted back to its non-structural form. Finally,  
 1264 the litterfall due to turnover of roots occurs from both the structural ( $LF_{R,S}$ ) and non-structural  
 1265 ( $LF_{R,NS}$ ) N pools.

1266 The rate change equations for non-structural and structural components of leaves are  
 1267 written as

$$1268 \quad \frac{d N_{L,NS}}{dt} = A_{R2L} - R_{L2R} - R_{L2S} + R_{R2L} + R_{S2L} - LF_{L,NS} - T_{L,NS2S} \quad (A5)$$

$$1269 \quad \frac{d N_{L,S}}{dt} = T_{L,NS2S} - LF_{L,S} \quad (A6)$$

1270 where  $T_{L,NS2S}$  is the one way transfer of N from the non-structural leaf component to its  
 1271 structural N pool and  $R_{S2L}$  indicates reallocation of N from stem to leaves (similar to  $R_{R2L}$ ) at the  
 1272 time of leaf out for deciduous tree PFTs. Litterfall occurs from both the structural ( $LF_{L,S}$ ) and non-  
 1273 structural ( $LF_{L,NS}$ ) N pools of leaves, and all other terms have been previously defined.

1274 Finally, the rate change equations for non-structural and structural components of stem  
 1275 are written as

$$1276 \quad \frac{d N_{S,NS}}{dt} = A_{R2S} + R_{L2S} - R_{S2L} - LF_{S,NS} - T_{S,NS2S} \quad (A7)$$

$$1277 \quad \frac{d N_{S,S}}{dt} = T_{S,NS2S} - LF_{S,S} \quad (A8)$$

1278 where  $LF_{S,NS}$  and  $LF_{S,S}$  represent stem litter from the non-structural and structural components,  
 1279  $T_{S,NS2S}$  is the one way transfer of N from the non-structural stem component to its structural N  
 1280 pool. All other terms have been previously defined.

1281 Adding equations (6) through (11) yields rate of change of N in the entire vegetation pool  
 1282 ( $N_V$ ) as

$$\frac{d N_V}{dt} = \frac{d N_{R,NS}}{dt} + \frac{d N_{R,S}}{dt} + \frac{d N_{L,NS}}{dt} + \frac{d N_{L,S}}{dt} + \frac{d N_{S,NS}}{dt} + \frac{d N_{S,S}}{dt} = \frac{d N_R}{dt} + \frac{d N_L}{dt} + \frac{d N_S}{dt}$$

$$\frac{d N_V}{dt} = U_{NH_4} + U_{NO_3} - LF_{R,NS} - LF_{R,S} - LF_{L,NS} - LF_{L,S} - LF_{S,NS} - LF_{S,S}$$

$$= U_{NH_4} + U_{NO_3} - LF_R - LF_L - LF_S$$
(A9)

1284 which indicates how the dynamically varying vegetation N pool is governed by mineral N uptake  
 1285 from the  $NH_4^+$  and  $NO_3^-$  pools and litterfall from the structural and non-structural components of  
 1286 the leaves, stem, and root pools.  $LF_R$  is the total N litter generation from the root pool and sum  
 1287 of litter generation from its structural and non-structural components ( $LF_R = LF_{R,S} + LF_{R,NS}$ ),  
 1288 and similarly for the leaves ( $LF_L$ ) and the stem ( $LF_S$ ) pools.

1289 The rate change equations for the organic N pools in the litter ( $N_D$ ) and soil ( $N_H$ ) pools  
 1290 are written as follows.

$$\frac{d N_D}{dt} = LF_R + LF_L + LF_S - H_{N,D2H} - M_{D,NH_4}$$
(A10)

$$\frac{d N_H}{dt} = H_{N,D2H} + O_{NH_4} + O_{NO_3} - M_{H,NH_4}$$
(A11)

1293 where  $H_{N,D2H}$  is the transfer of humidified organic matter from litter to the soil organic matter  
 1294 pool, and all other terms have been previously defined.

1295

1297 **Acknowledgments**

1298 We are grateful and thank Joe Melton and Paul Bartlett for their comments on an earlier version  
1299 of this manuscript.

1300

1301 **Code/Data availability**

1302 Model code for the operational CLASSIC model can be obtained from  
1303 <https://gitlab.com/ccma/classic>. Changes made to the operational version to include N cycle  
1304 and the results shown here can be obtained from the second author.

1305

1306 **Author contributions**

1307 A.A. implemented the N cycle in the CLASSIC code, put together all the N cycle related input  
1308 data, and performed all the simulations. V.A. and A.A. wrote the manuscript.

1309

1310 **Competing interests**

1311 There are no competing interests.

1340

1341 **Table 1:** Historical simulations performed over the period 1851-2017 to evaluate the model's  
 1342 response to various forcings. All forcings are time varying. All forcings are also spatially explicit  
 1343 except atmospheric CO<sub>2</sub> for which a globally constant value is specified.

1344

Simulation name	Forcing that varies over the historical period	N cycle
<b>Primary simulations performed to evaluate N cycle response to various forcings</b>		
1. CO2-only	Atmospheric CO <sub>2</sub> concentration	Runs with N cycle
2. CLIM-only	1901-1925 meteorological data are used twice over the 1850-1900 period. For the 1901-2017 period, meteorological data for the correct year is used.	
3. LUC+FERT-only	Land cover with increasing crop area, and fertilizer application rates over the crop area	
4. N-DEP-only	N deposition of ammonia and nitrate	
5. FULL	All forcings	
6. FULL-no-LUC	All forcings except increasing crop area	
<b>Other simulations</b>		
7. ORIGINAL	All forcings	Runs without N cycle using the original model configuration.
8. ORIG-UNCONST	All forcings but with downregulation turned off	
9. FULL-no-implicit-P-limitation	All forcings but using same $\Gamma_1$ and $\Gamma_2$ globally	Run with N cycle

1345

1346

1347

1348 **Table 2:** Comparison of simulated global N pools and fluxes, from the FULL simulation, with other  
 1349 modelling and quasi observation-based studies (references for which are noted as superscripts  
 1350 and listed below the table). The time-periods to which the other modelling and quasi  
 1351 observation-based estimates correspond are also noted, where available. The estimates are for  
 1352 land. Simulated fluxes and pool corresponds to the period 1997-2018.

1360

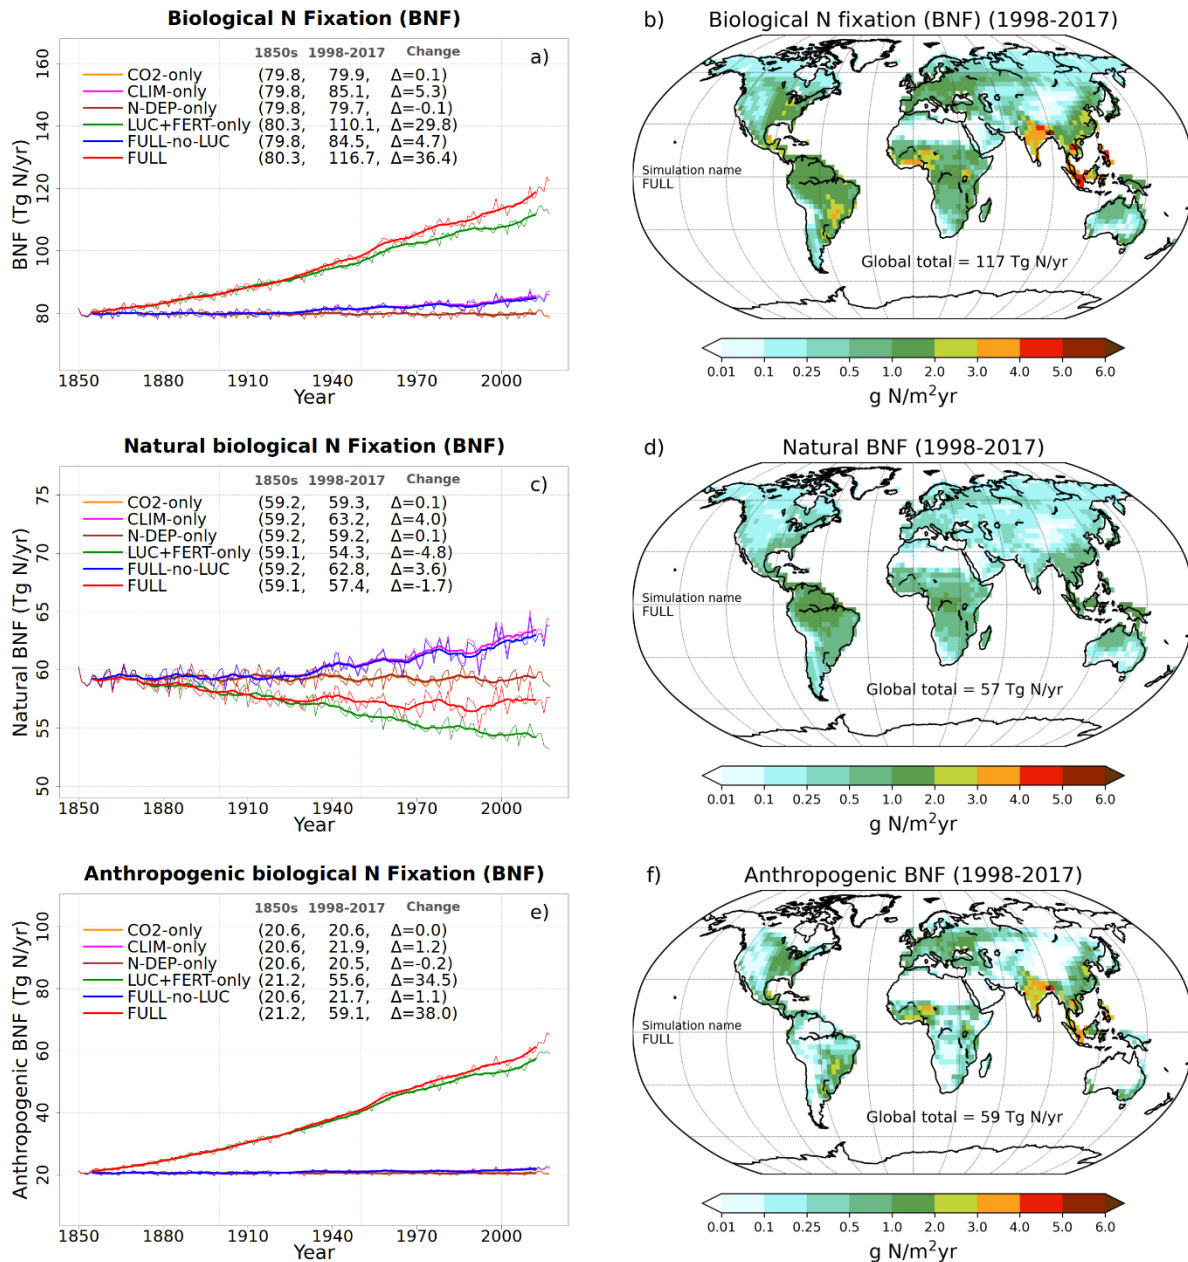

1361 Figure 1: The structure of CLASSIC model used in this study. The eight prognostic carbon pools  
1362 are shown in green colour and carbon fluxes in red colour. The ten prognostic nitrogen pools are  
1363 shown in orange colour and nitrogen fluxes are shown in blue colour.

1364

1365

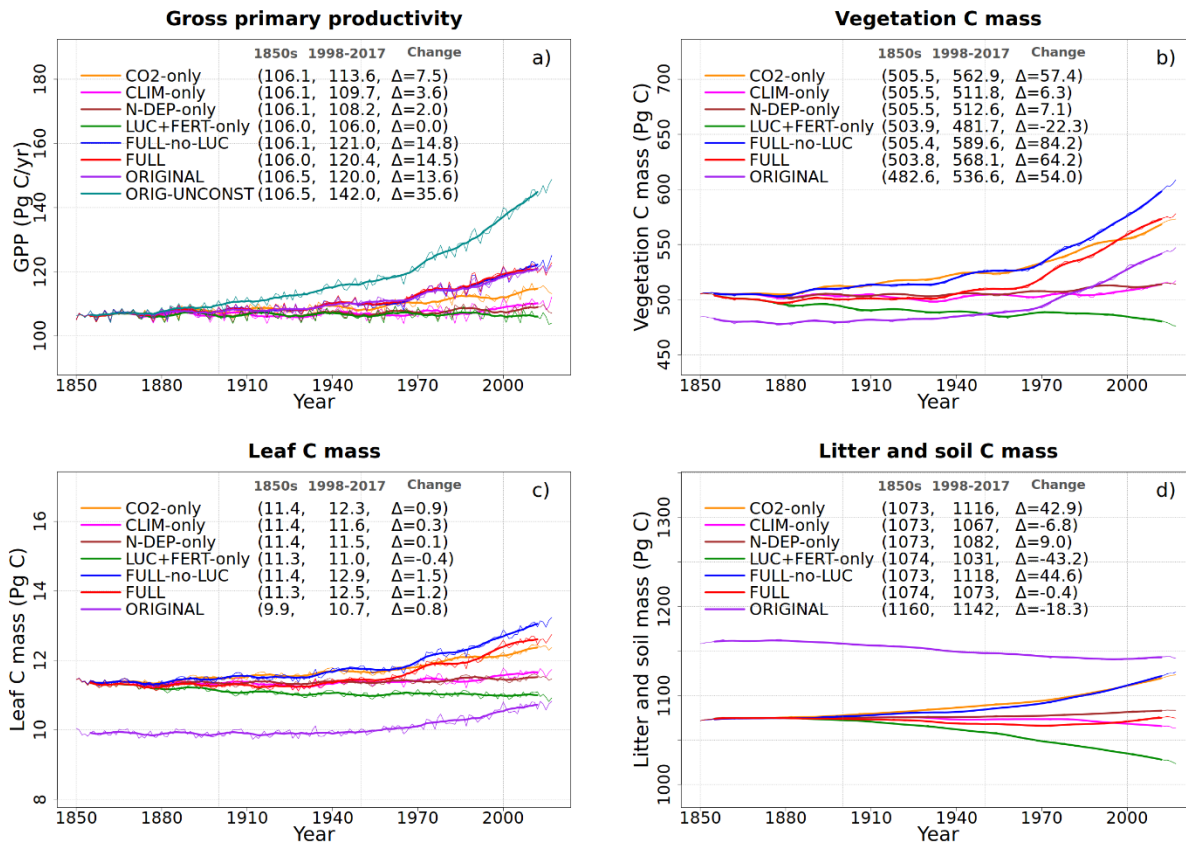

1366 Figure 2: Time series and geographical distribution of global annual values of externally specified  
 1367 N inputs. Fertilizer input (a, b), atmospheric deposition of ammonium (c, d) and atmospheric  
 1368 deposition of nitrate (e, f). The values in the parenthesis for legend entries in the time series plots  
 1369 show averages for the 1850s, the 1998-2017 period, and the change between these two periods.  
 1370 The thin lines in the time series plots show the annual values and the thick lines their 10-year  
 1371 moving average. The geographical plots show the average values over the last 20-years of the  
 1372 FULL simulation corresponding to the 1998-2017 period. Note that in the time series plots lines  
 1373 from some simulations are hidden behind lines from other simulations and this can be inferred  
 1374 from the legend entries which shows averages for the 1850s, the 1998-2017 period.

1375

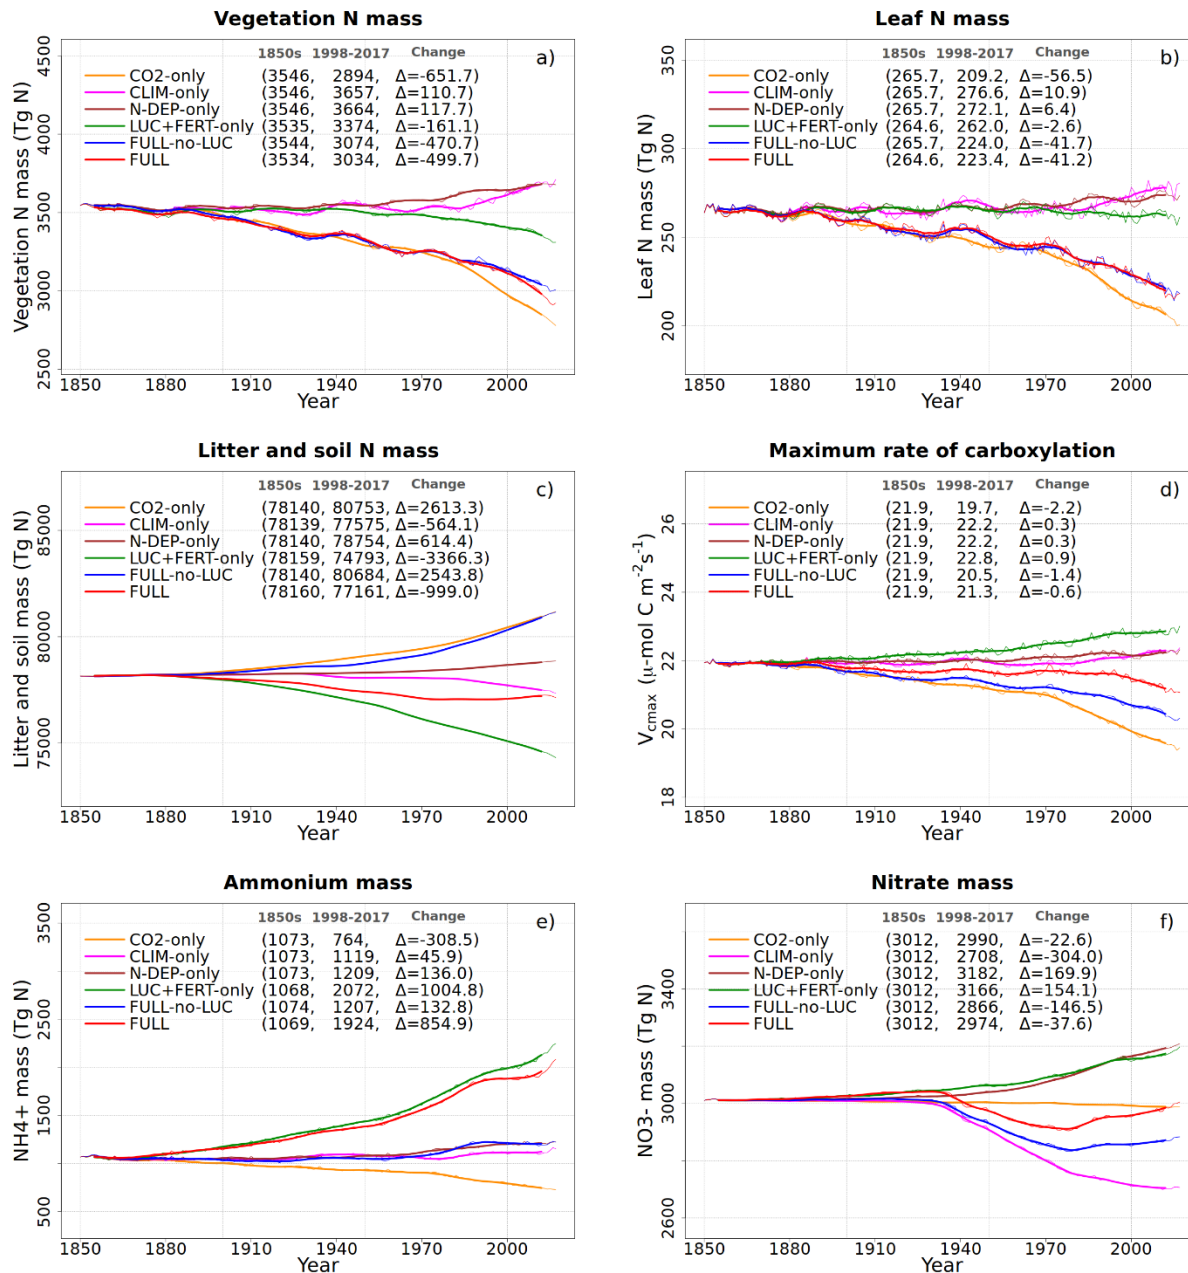

1376 Figure 3: Time series and geographical distribution of annual values biological N fixation (BNF)  
 1377 (a,b) and its natural (c, d) and anthropogenic (e, f) components. The values in the parenthesis for  
 1378 legend entries in the time series plots show averages for the 1850s, the 1998-2017, and  
 1379 the change between these two periods. The thin lines in the time series plots show the annual  
 1380 values and the thick lines their 10-year moving average. The geographical plots show the average  
 1381 values over the last 20-years of the FULL simulation corresponding to the 1998-2017 period. Note  
 1382 that in the time series plots lines from some simulations are hidden behind lines from other  
 1383 simulations and this can be inferred from the legend entries which shows averages for the 1850s,  
 1384 the 1998-2017 period.

1386

1387 Figure 4: Global annual values of gross primary productivity (a), vegetation carbon (b), leaf carbon (c), and litter and soil carbon (d) for the primary simulations performed. The values in  
 1388 the parenthesis for legend entries show averages for the 1850s, the 1998-2017 period, and the  
 1389 change between 1850s and 1998-2017 periods. The thin lines show the annual values and the  
 1390 thick lines their 10-year moving average.  
 1391

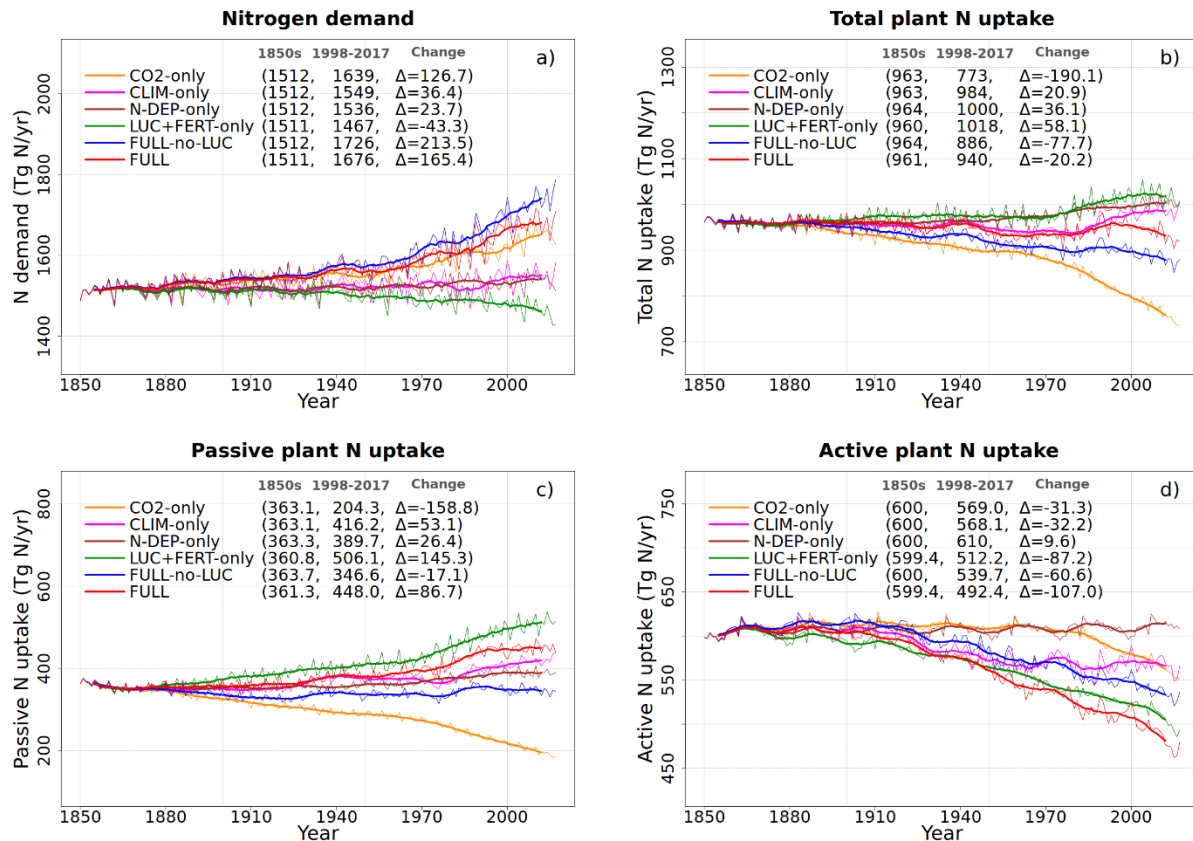

1392

1393

1394 Figure 5: Global annual values of N in vegetation (a), leaves (b), litter and soil organic matter (c)  
 1395 pools,  $V_{cmax}$  (d), and ammonium (e), and nitrate (f) pools for the primary simulations performed.  
 1396 The values in the parenthesis for legend entries show averages for the 1850s, the 1998-2017  
 1397 period, and the change between 1850s and 1998-2017 periods. The thin lines show the annual  
 1398 values and the thick lines their 10-year moving average.

1399

1400

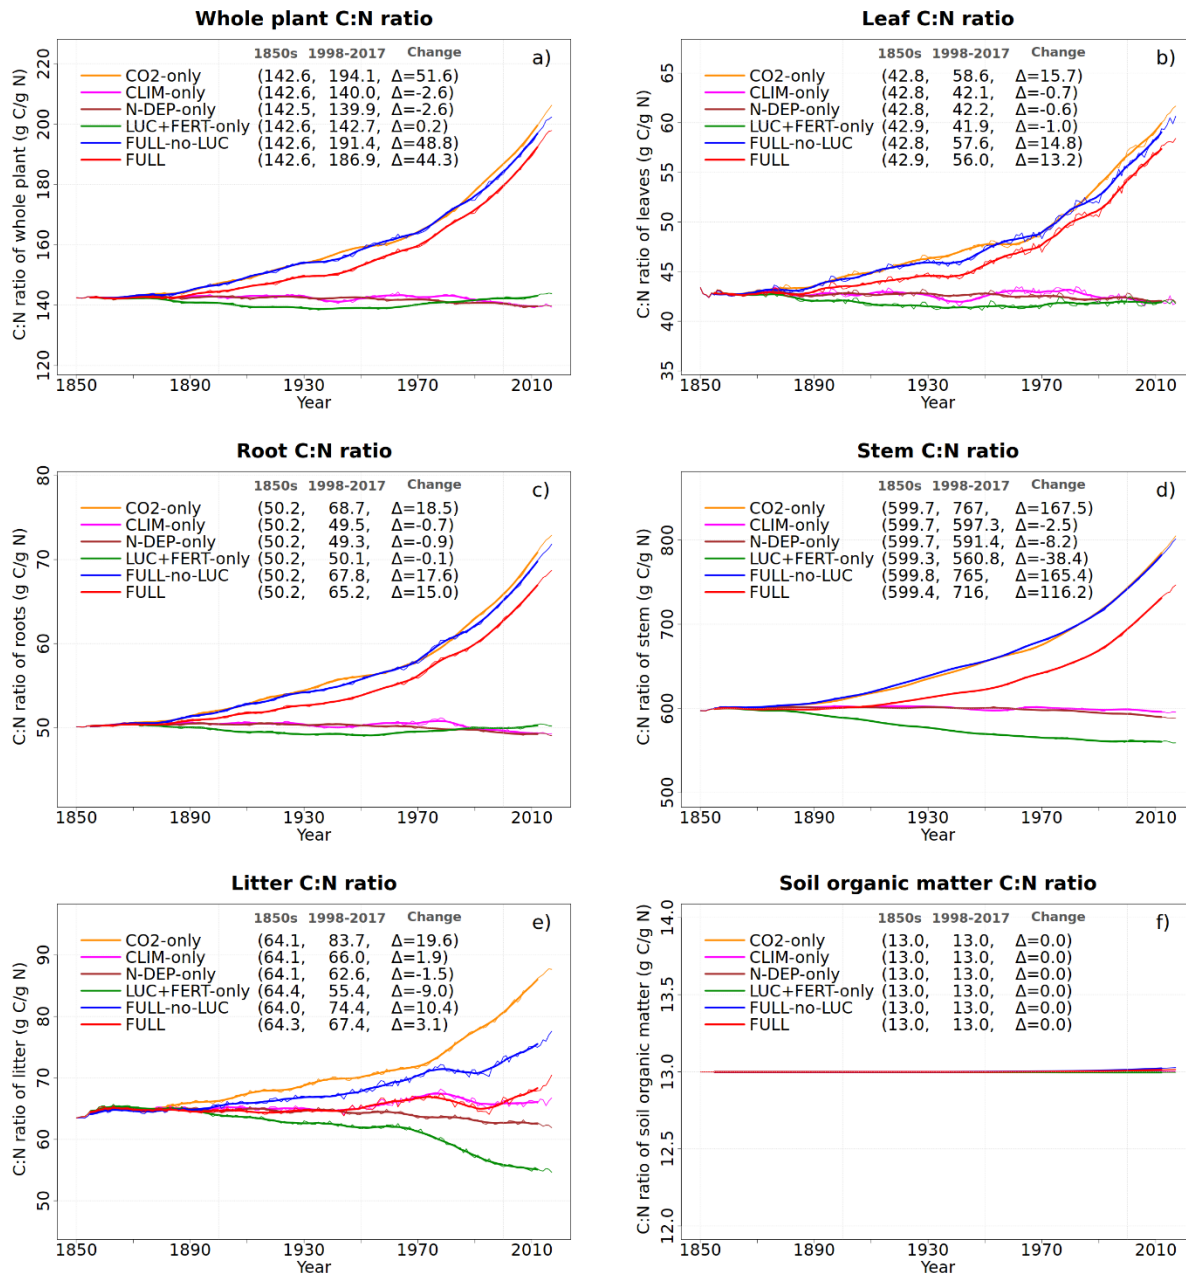

1401

1402 Figure 6: Global annual values of N demand (a), total plant N uptake (b) and its split into passive  
 1403 (c) and active (d) components for the primary simulations performed. The values in the  
 1404 parenthesis for legend entries show averages for the 1850s, the 1998-2017 period, and the  
 1405 change between 1850s and 1998-2017 periods. The thin lines show the annual values and the  
 1406 thick lines their 10-year moving average.

1407

1408

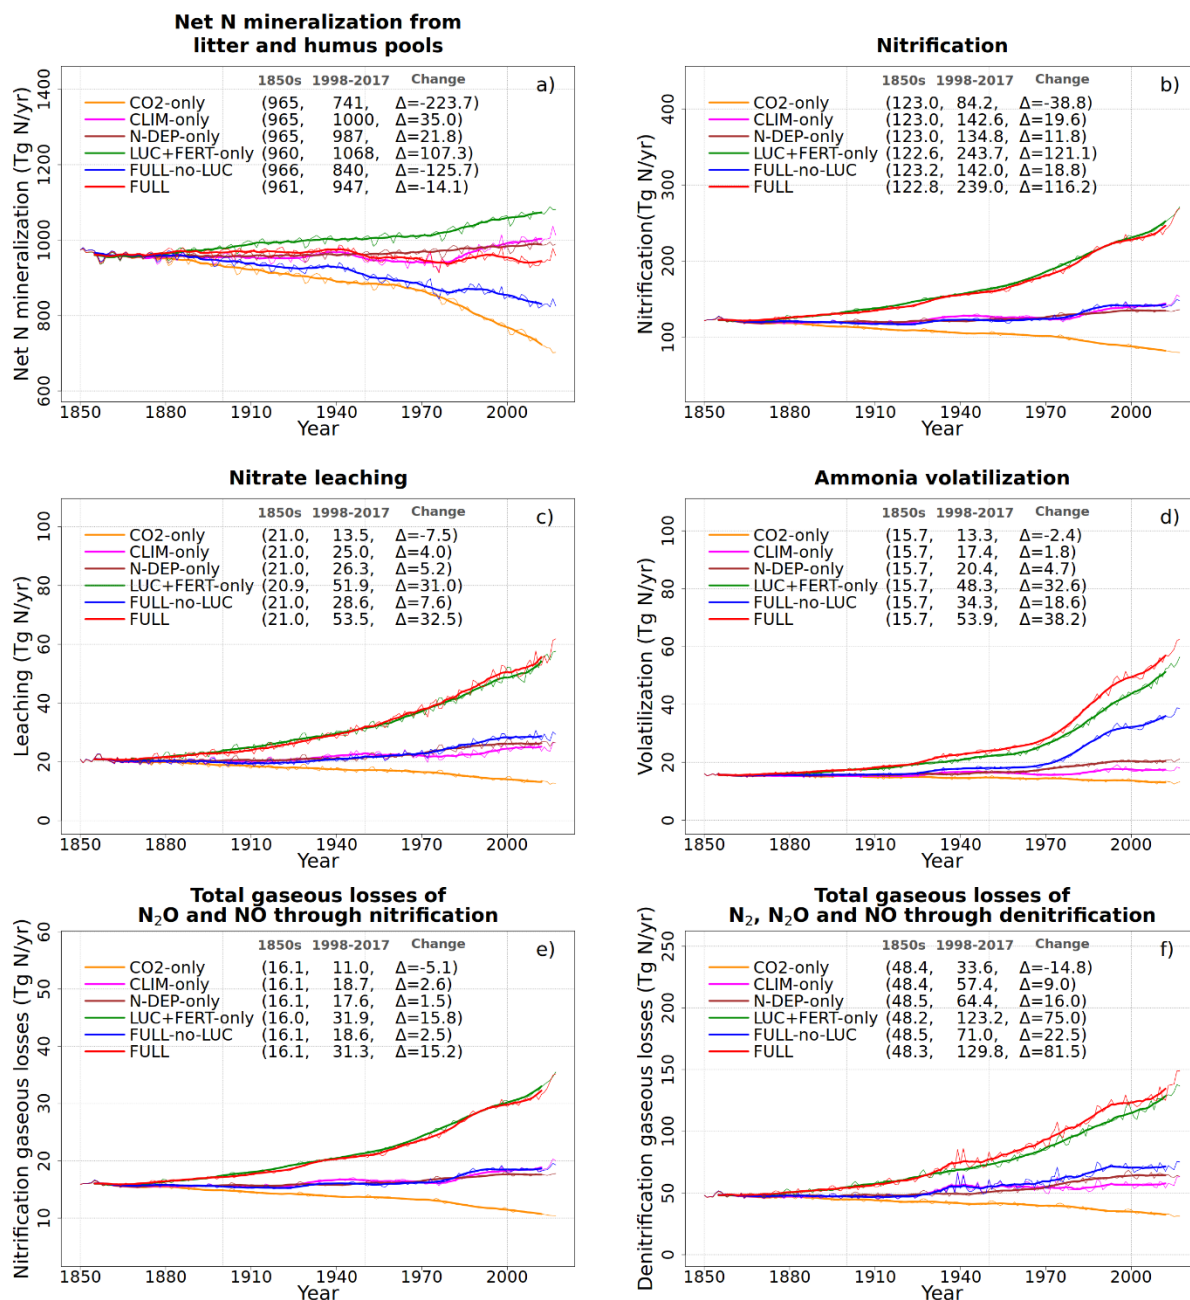

1410

1411 Figure 7: Global annual values of C:N ratios for whole plant (a), leaves (b), root (c), stem (d),  
 1412 litter (e) and soil organic matter (f) pools from the primary six simulations. The values in the  
 1413 parenthesis for legend entries show averages for the 1850s, the 1998-2017 period, and the  
 1414 change between 1850s and 1998-2017 periods. The thin lines show the annual values and the  
 1415 thick lines their 10-year moving average.

1416

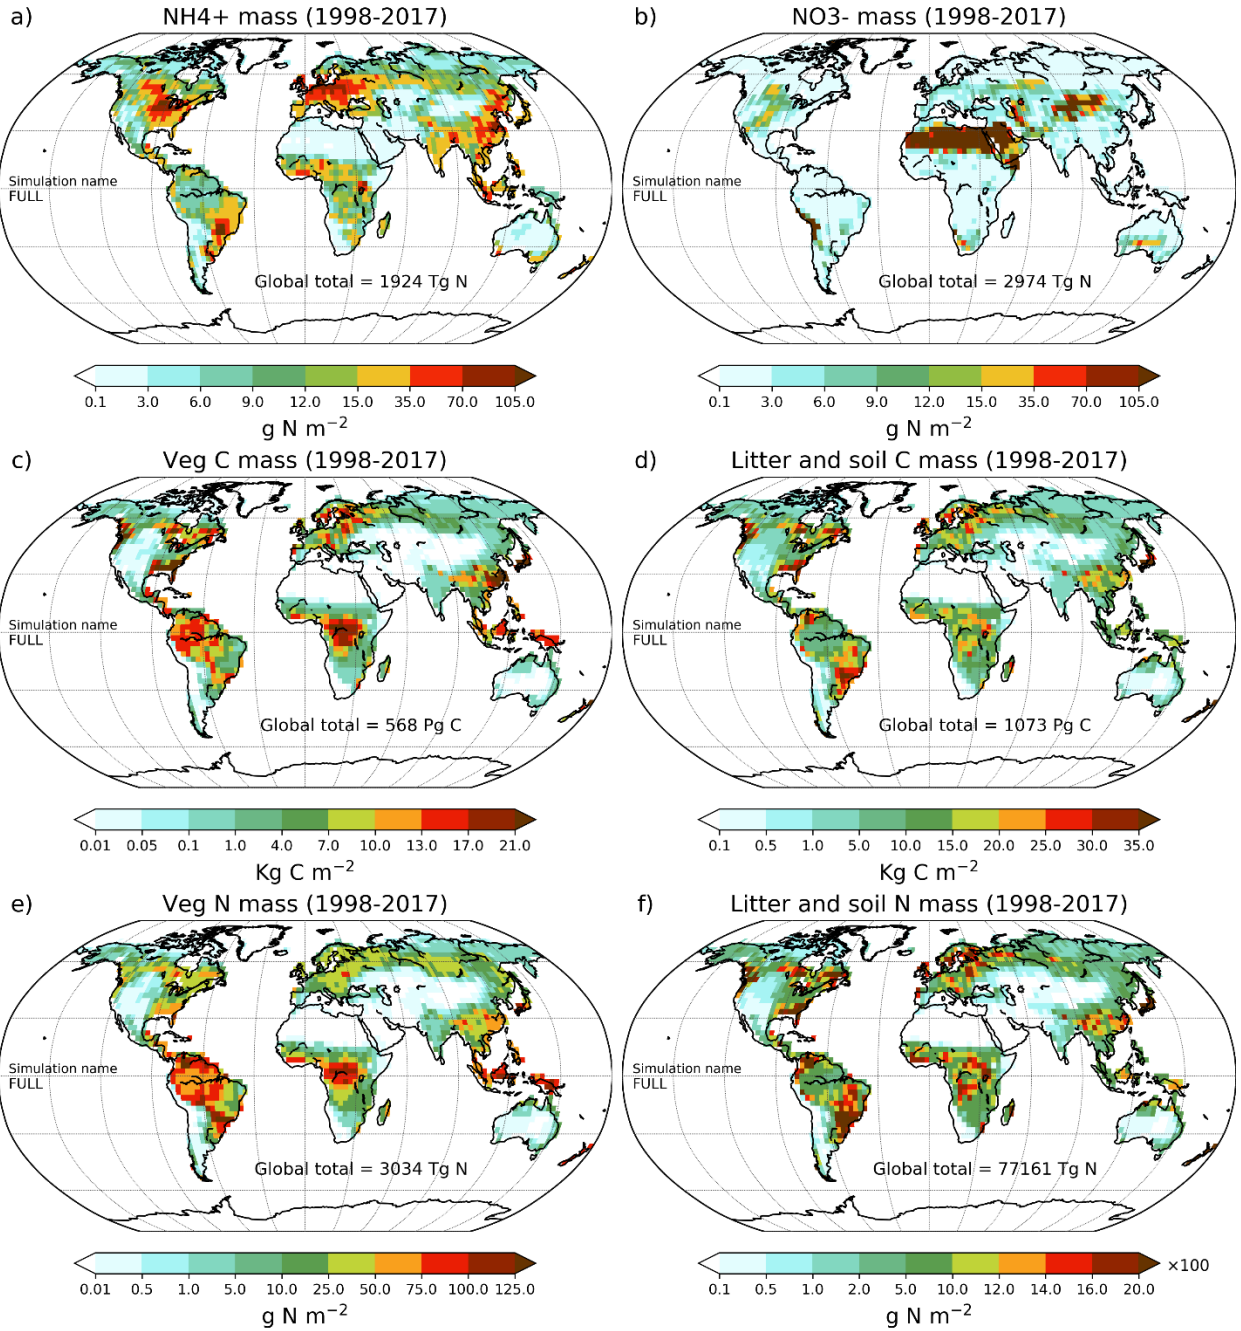

1418

1419 Figure 8: Global annual values of net mineralization (a), nitrification (b), NO<sub>3</sub>- leaching (c), NH<sub>3</sub>  
 1420 volatilization (d), and gaseous losses associated with nitrification (e) and denitrification (f) from  
 1421 the primary six simulations. The values in the parenthesis for legend entries show averages for  
 1422 the 1850s, the 1998-2017 period, and the change between 1850s and 1998-2017 periods. The  
 1423 thin lines show the annual values and the thick lines their 10-year moving average.

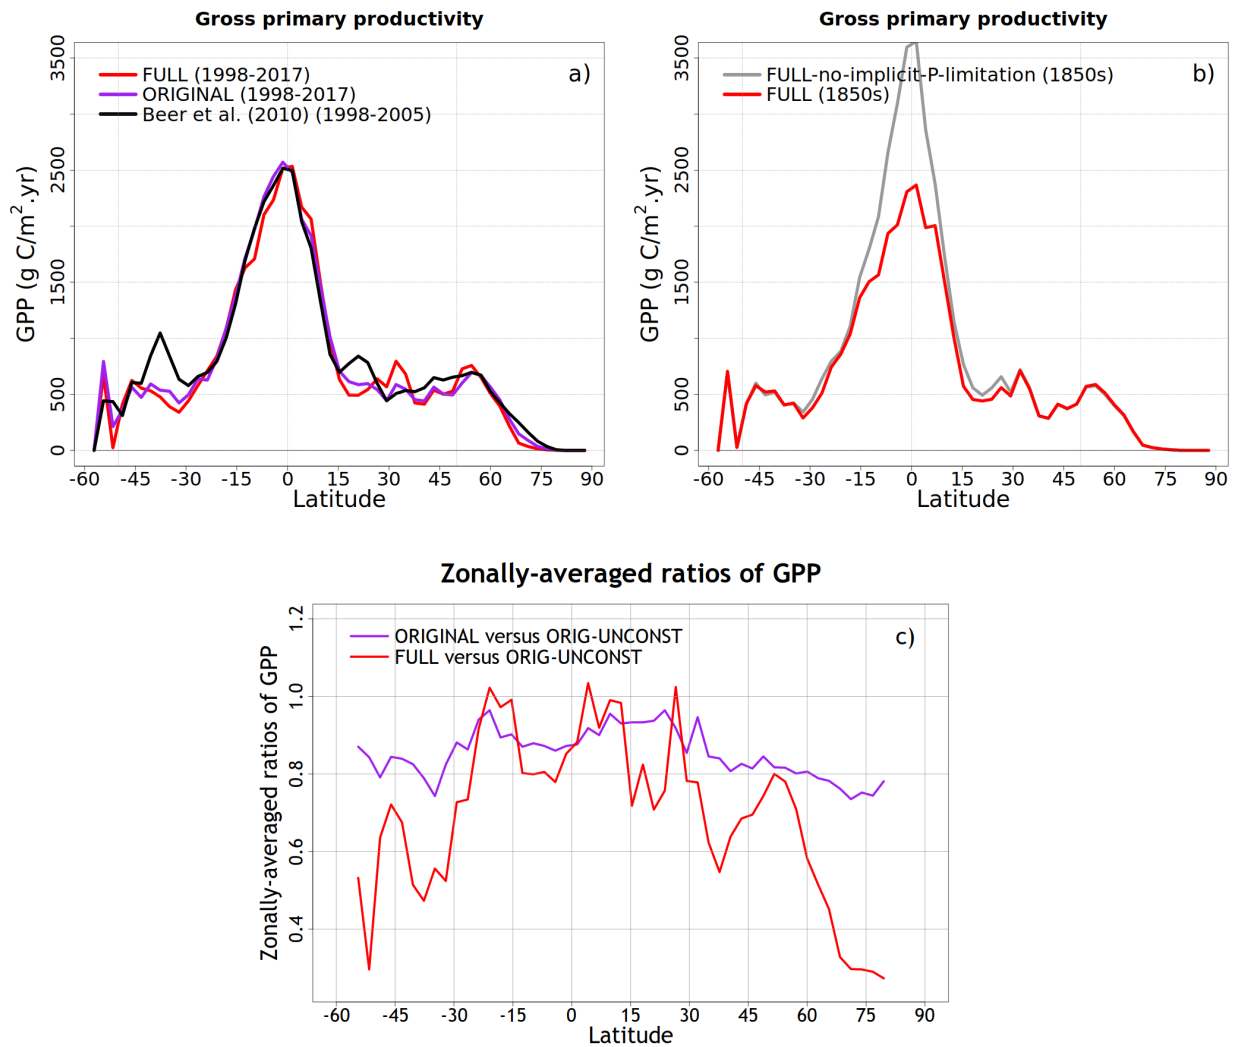

1424

1425

1426 Figure 9: Geographical distribution of primary C and N pools. Ammonium (a), nitrate (b),  
 1427 vegetation C mass (c), litter and soil C mass (d), vegetation N mass (e), and litter and soil N mass  
 1428 (f). The global total values shown are averaged over the 1998-2017 period.

1429

1432 Figure 10: Comparison of zonal distribution of gross primary productivity (GPP) and the effect of  
 1433 GPP downregulation compared to the ORIG-UNCONST simulation. Panel (a) compares zonal  
 1434 distribution of GPP from FULL and ORIGINAL simulations with observation-based estimate from  
 1435 Beer at al. (2010) for the present day. Panel (b) compares the zonal distribution of GPP from the  
 1436 pre-industrial simulation, corresponding to 1850 conditions, from the FULL and FULL-no-  
 1437 implicit-P-limitation simulations to illustrate the effect of not reducing the  $\Gamma_1$  parameter for  
 1438 calculating  $V_{cmax}$  for the broadleaf evergreen tree PFT that implicitly accounts for phosphorus  
 1439 limitation. Panel (c) shows the zonally-averaged ratios of GPP from the ORIGINAL and FULL  
 1440 simulations versus those from the ORIG-UNCONST simulations to illustrate how downregulation  
 1441 acts in the ORIGINAL and FULL simulations.

1443

1444

1445 Figure 11: Comparison of simulated net atmosphere-land CO<sub>2</sub> flux from various simulations.  
 1446 Panel (a) compares globally-summed values of net atmosphere-land CO<sub>2</sub> flux from FULL, FULL-  
 1447 no-LUC simulation, and ORIGINAL simulations with estimate of terrestrial sink (dark yellow line)  
 1448 and net atmosphere-land CO<sub>2</sub> flux (grey bars) from Friedlingstein et al. (2019). The thin lines  
 1449 show the annual values and the thick lines their 10-year moving average. Panel (b) compares  
 1450 zonal distribution of net atmosphere-land CO<sub>2</sub> flux from FULL and ORIGINAL simulations with  
 1451 the range from TRENDY models that contributed to the Friedlingstein et al. (2019) study. Panel  
 1452 (c) shows cumulative values of net atmosphere-land CO<sub>2</sub> flux from the six primary simulations  
 1453 to investigate the contribution of each forcing to the cumulative land carbon sink over the  
 1454 historical period.
