Victoria, B.C., V8W 2Y2, Canada

1    **Abstract**

2

3    A terrestrial nitrogen (N) cycle model is coupled to carbon (C) cycle in the framework of the Canadian Land  
4    Surface Scheme Including biogeochemical Cycles (CLASSIC). CLASSIC currently models physical and  
5    biogeochemical processes and simulates fluxes of water, energy, and  $\text{CO}_2$  at the land-atmosphere  
6    boundary. Similar to most models, gross primary productivity in CLASSIC increases in response to  
7    increasing atmospheric  $\text{CO}_2$  concentration. In the current model version, a downregulation  
8    parameterization emulates the effect of nutrient constraints and scales down potential photosynthesis  
9    rates, using a globally constant scalar, as a function of increasing  $\text{CO}_2$ . In the new model when nitrogen  
10   (N) and carbon (C) cycles are coupled, cycling of N through the coupled soil-vegetation system facilitates  
11   the simulation of leaf N amount and maximum carboxylation capacity ( $V_{\text{cmax}}$ ) prognostically. An increase  
12   in atmospheric  $\text{CO}_2$  decreases leaf N amount, and therefore  $V_{\text{cmax}}$ , allowing the simulation of  
13   photosynthesis downregulation as a function of N supply. All primary N cycle processes, that represent  
14   the coupled soil-vegetation system, are modelled explicitly. These include biological N fixation, treatment  
15   of externally specified N deposition and fertilization application, uptake of N by plants, transfer of N to  
16   litter via litterfall, mineralization, immobilization, nitrification, denitrification, ammonia volatilization,  
17   leaching, and the gaseous fluxes of  $\text{NO}$ ,  $\text{N}_2\text{O}$ , and  $\text{N}_2$ . The interactions between terrestrial C and N cycles  
18   are evaluated by perturbing the coupled soil-vegetation system in CLASSIC with one forcing at a time over  
19   the 1850-2017 historical period. These forcings include the increase in atmospheric  $\text{CO}_2$ , change in  
20   climate, increase in N deposition, and increasing crop area and fertilizer input, over the historical period.  
21   Increase in atmospheric  $\text{CO}_2$  increases the C:N ratio of vegetation; climate warming over the historical  
22   period increases N mineralization and leads to a decrease in vegetation C:N ratio; N deposition also  
23   decreases vegetation C:N ratio; and fertilizer input increases leaching,  $\text{NH}_3$  volatilization, and gaseous  
24   losses of  $\text{N}_2$ ,  $\text{N}_2\text{O}$ , and  $\text{NO}$ . These model responses are consistent with conceptual understanding of the  
25   coupled C and N cycles. The simulated terrestrial carbon sink over the 1959-2017 period, from the  
26   simulation with all forcings, is 2.0 Pg C/yr and compares reasonably well with the quasi observation-based  
27   estimate from the 2019 Global Carbon Project (2.1 Pg C/yr). The contribution of increasing  $\text{CO}_2$ , climate  
28   change, and N deposition to carbon uptake by land over the historical period (1850-2017) is calculated to  
29   be 84%, 2%, and 14%, respectively.

30

31 **1. Introduction**

32 The uptake of carbon (C) by land and ocean in response to the increase in anthropogenic  
33 fossil fuel emissions of CO<sub>2</sub> has served to slow down the growth rate of atmospheric CO<sub>2</sub> since  
34 the start of the industrial revolution. At present, about 55% of total carbon emitted into the  
35 atmosphere is taken up by land and ocean (Le Quéré et al., 2018; Friedlingstein et al., 2019). It is  
36 of great policy, societal, and scientific relevance whether land and ocean will continue to provide  
37 this ecosystem service. Over land, as long as photosynthesis is not water limited, the uptake of  
38 carbon in response to increasing anthropogenic CO<sub>2</sub> emissions is driven by two primary factors,  
39 1) the CO<sub>2</sub> fertilization of the terrestrial biosphere, and 2) the increase in temperature, both of  
40 which are associated with increasing [CO<sub>2</sub>]. The CO<sub>2</sub> fertilization effect increases photosynthesis  
41 rates for about 80% of the world's vegetation that uses the C<sub>3</sub> photosynthetic pathway and is  
42 currently limited by [CO<sub>2</sub>] (Still et al., 2003; Zhu et al., 2016). The remaining 20% of vegetation  
43 uses the C<sub>4</sub> photosynthetic pathway that is much less sensitive to [CO<sub>2</sub>]. Warming increases  
44 carbon uptake by vegetation in mid-high latitude regions where growth is currently limited by  
45 low temperatures (Zeng et al., 2011).

46 Even when atmospheric CO<sub>2</sub> is not limiting for photosynthesis, and near surface air  
47 temperature is optimal, vegetation cannot photosynthesize at its maximum possible rate if  
48 available water and nutrients (most importantly nitrogen (N) and phosphorus (P)) constrain  
49 photosynthesis (Vitousek and Howarth, 1991; Reich et al., 2006b). In the absence of water and  
50 nutrients, photosynthesis simply cannot occur. N is a major component of chlorophyll (the  
51 compound through which plants photosynthesize) and amino acids (that are the building blocks  
52 of proteins). The constraint imposed by available water and nutrients implies that the carbon

53 uptake by land over the historical period in response to increasing [CO<sub>2</sub>] is lower than what it  
54 would have been if water and nutrients were not limiting. This lower than maximum theoretically  
55 possible rate of increase of photosynthesis in response to increasing atmospheric CO<sub>2</sub> is referred  
56 to as downregulation (Faria et al., 1996; Sanz-Sáez et al., 2010). Typically, however, the term  
57 downregulation of photosynthesis is used only in the context of nutrients and not water.  
58 Downregulation is defined as a decrease in photosynthetic capacity of plants grown at elevated  
59 CO<sub>2</sub> in comparison to plants grown at baseline CO<sub>2</sub> (McGuire et al., 1995). However, despite the  
60 decrease in photosynthetic capacity, the photosynthesis rate for plants grown at elevated CO<sub>2</sub> is  
61 still higher than the rate for plants grown and measured at baseline CO<sub>2</sub> because of higher  
62 background CO<sub>2</sub>.

63 Earth system models (ESMs) that explicitly represent coupling of the global carbon cycle  
64 and physical climate system processes are the only tools available at present that, in a physically  
65 consistent way, are able to project how land and ocean carbon cycles will respond to future  
66 changes in [CO<sub>2</sub>]. Such models are routinely compared to one another under the auspices of the  
67 Coupled Model Intercomparison Project (CMIP) every 6-7 years. The most recent and sixth phase  
68 of CMIP (CMIP6) is currently underway (Eyring et al., 2016). Interactions between carbon cycle  
69 and climate in ESMs have been compared under the umbrella of the Coupled Climate-Carbon  
70 Cycle Model Intercomparison Project (C<sup>4</sup>MIP) (Jones et al., 2016) which is an approved MIP of  
71 the CMIP. Comparison of land and ocean carbon uptake in C<sup>4</sup>MIP studies (Friedlingstein et al.,  
72 2006; Arora et al., 2013, 2020) indicate that the inter-model uncertainty in future land carbon  
73 uptake across ESMs is more than three times than the uncertainty for the ocean carbon uptake.  
74 The reason for widely varying estimates of future land carbon uptake is that our understanding

75 of biological processes that determine land carbon uptake is much less advanced than the  
76 physical processes which primarily determine carbon uptake over the ocean. In the current  
77 generation of terrestrial ecosystem models, other than leaf level photosynthesis for which a  
78 theoretical framework exists, almost all of the other biological processes are represented on the  
79 basis of empirical observations and parameterized in one way or another. In addition, not all  
80 models include nutrient cycles. In the absence of an explicit representation of nutrient  
81 constraints on photosynthesis, land models in ESMs parameterize downregulation of  
82 photosynthesis in other ways that reduce the rate of increase of photosynthesis to values below  
83 its theoretically maximum possible rate, as  $[CO_2]$  increases (e.g., Arora et al., 2009). Comparison  
84 of models across 5<sup>th</sup> and 6<sup>th</sup> phase of CMIP shows that the fraction of models with land N cycle is  
85 increasing (Arora et al., 2013, 2020).

86 The nutrient constraints on photosynthesis are well recognized (Vitousek and Howarth,  
87 1991; Arneth et al., 2010). Terrestrial carbon cycle models neglect of nutrient limitation on  
88 photosynthesis has been questioned from an ecological perspective (Reich et al., 2006a) and it  
89 has been argued that without nutrient constraints these models will overestimate future land  
90 carbon uptake (Hungate et al., 2003). Since in the real world photosynthesis downregulation does  
91 indeed occur due to nutrient constraints, it may be argued that more confidence can be placed  
92 in future projections of models that explicitly model the interactions between the terrestrial C  
93 and N cycles rather than parameterize it in some other way.

94 Here, we present the implementation of N cycle in the Canadian Land Surface Scheme  
95 Including biogeochemical Cycles (CLASSIC) model, which serves as the land component in the  
96 family of Canadian Earth System Models (Arora et al., 2009, 2011; Swart et al., 2019). Section 2

97 briefly describes existing physical and carbon cycle components and processes of the CLASSIC  
98 model. The conceptual basis of the new N cycle model and its parameterizations are described  
99 in Section 3. Section 4 outlines the methodology and data sets that we have used to perform  
100 various simulations over the 1850-2017 historical period to assess the realism of the coupled C  
101 and N cycles in CLASSIC in response to various forcings. Results from these simulations over the  
102 historical period are presented in Section 5 and finally discussion and conclusions are presented  
103 in Section 6.

104 **2. The CLASSIC land model**

105 **2.1 The physical and carbon biogeochemical processes**

106 The CLASSIC model is the successor to, and based on, the coupled Canadian Land Surface  
107 Scheme (CLASS; Verseghy, 1991; Verseghy et al., 1993) and Canadian Terrestrial Ecosystem  
108 Model (CTEM; Arora and Boer, 2005; Melton and Arora, 2016). CLASS and CTEM model physical  
109 and biogeochemical processes in CLASSIC, respectively. Both CLASS and CTEM have a long history  
110 of development as described in Melton et al. (2019) who also provide an overview of the CLASSIC  
111 land model and describe its new technical developments that launched CLASSIC as a community  
112 model. CLASSIC simulates land-atmosphere fluxes of water, energy, momentum, CO<sub>2</sub>, and CH<sub>4</sub>.  
113 The CLASSIC model can be run at a point scale, e.g. using meteorological and geophysical data  
114 from a FluxNet site, or over a spatial domain, that may be global or regional, using gridded data.  
115 We briefly summarize the primary physical and carbon biogeochemical processes of CLASSIC here  
116 that are relevant in the context of implementation of the N cycle in the model.

117 **2.1.1 Physical processes**

118                   The physical processes of CLASSIC which simulate fluxes of water, energy and momentum,  
119    are calculated over vegetated, snow, and bare fractions on a model grid at a sub-daily time step  
120    of 30 minutes. The vegetation is described in terms of four plant functional types (PFTs):  
121    needleleaf trees, broadleaf trees, crops, and grasses. In the current study, the fractional coverage  
122    of these four PFTs are specified over the historical period. The structural attributes of vegetation  
123    are described by leaf area index (LAI), vegetation height, canopy mass, and rooting distribution  
124    through the soil layers and these are all simulated dynamically by the biogeochemical module of  
125    CLASSIC. In the model version used here, 20 ground layers starting with 10 layers of 0.1 m  
126    thickness are used. The thickness of layers gradually increases to 30 m for a total ground depth  
127    of over 61 m. The depth to bedrock varies geographically and is specified based on a soil depth  
128    data set. Liquid and frozen soil moisture contents, and soil temperature, are determined  
129    prognostically for permeable soil layers. CLASSIC also prognostically models the temperature,  
130    mass, albedo, and density of a single layer snow pack (when the climate permits snow to exist).  
131    Interception and throughfall of rain and snow by the canopy, and the subsequent unloading of  
132    snow, are also modelled. The energy and water balance over the land surface, and the transfer  
133    of heat and moisture through soil, affect the temperature and soil moisture content of soil layers  
134    all of which consequently affect the carbon and nitrogen cycle processes.

135

### 136    **2.1.2 Biogeochemical processes**

137                   The biogeochemical processes in CLASSIC are based on CTEM, and described in detail in  
138    the appendix of Melton and Arora (2016). The biogeochemical component of CLASSIC simulates

139 the land-atmosphere exchange of CO<sub>2</sub> and while doing so simulates vegetation as a dynamic  
140 component. The biogeochemical module of CLASSIC uses information about net radiation, and  
141 liquid and frozen soil moisture contents of all the soil layers along with air temperature to  
142 simulate photosynthesis and prognostically calculates amount of carbon in the model's three live  
143 (leaves, stem, and root) and two dead (litter and soil) carbon pools for each PFT. The C amount  
144 in these pools is represented as amount of C per unit land area (kg C/m<sup>2</sup>). The litter and soil carbon  
145 pools are not tracked for each soil layer. Litter is assumed to be near surface and an exponential  
146 distribution for soil carbon is assumed with values decreasing with soil depth. Photosynthesis in  
147 CLASSIC is modelled at the same sub-daily time as the physical processes. The remainder of the  
148 biogeochemical processes are modelled at a daily time step. These include: 1) autotrophic and  
149 heterotrophic respirations from all the live and dead carbon pools, respectively, 2) allocation of  
150 photosynthate from leaves to stem and roots, 3) leaf phenology, 4) turnover of live vegetation  
151 components that generates litter, 5) mortality, 6) land use change (LUC), 7) fire (Arora and  
152 Melton, 2018), and 8) competition between PFTs for space (not switched on in this study).

153 Figure A1 in the appendix shows the existing structure of CLASSIC's carbon pools along  
154 with the addition of non-structural carbohydrate pools for each of the model's live vegetation  
155 components. The non-structural pools are not yet represented in the current operational version  
156 of CLASSIC (Melton et al., 2019). The addition of non-structural carbohydrate pools is explained  
157 in Asaadi et al. (2018) and helps improve leaf phenology for cold deciduous tree PFTs. The N cycle  
158 model presented here is built on the research version of CLASSIC that consists of non-structural  
159 and structural carbon pools for the leaves (L), stem (S), and root (R) components and the two  
160 dead carbon pools in litter or detritus (D) and soil or humus (H) (Figure A1). We briefly describe

161 these carbon pools and fluxes between them, since N cycle pools and fluxes are closely tied to  
162 carbon pools and fluxes. The gross primary productivity (GPP) flux enters the leaves from the  
163 atmosphere. This non-structural photosynthate is allocated between leaves, stem, and roots. The  
164 non-structural carbon then moves into the structural carbohydrates pool. Once this conversion  
165 occurs structural carbon cannot be converted back to non-structural labile carbon. The model  
166 attempts to maintain a minimum fraction of non-structural to total carbon in each component of  
167 about 0.05 (Asaadi et al., 2018). Non-structural carbon is moved from stem and root components  
168 to leaves, at the time of leaf onset for deciduous PFTs, and this is termed reallocation. The  
169 movement of non-structural carbon is indicated by red arrows. Maintenance and growth  
170 respiration (indicated by subscript *m* and *g* in Figure A1), which together constitute autotrophic  
171 respiration, occur from the non-structural components of the three live vegetation components.  
172 Litterfall from the structural and non-structural components of the vegetation components  
173 contributes to the litter pool. Leaf litterfall is generated due to normal turnover of leaves as well  
174 as cold and drought stresses, and reduction in day length. Stem and root litter is generated due  
175 to their turnover based on their specified life spans. Heterotrophic respiration occurs from the  
176 litter and soil carbon pools depending on soil moisture and temperature, and humified litter is  
177 moved from litter to the soil carbon pool.

178 All these terrestrial ecosystem processes and the amount of carbon in the live and dead  
179 carbon pools are modelled explicitly for nine PFTs that map directly onto the four base PFTs used  
180 in the physics module of CLASSIC. Needleleaf trees are divided into their deciduous and  
181 evergreen phenotypes, broadleaf trees are divided into cold deciduous, drought deciduous, and  
182 evergreen phenotypes, and crops and grasses are divided based on their photosynthetic

183 pathways into C<sub>3</sub> and C<sub>4</sub> versions. The sub-division of PFTs is required for modelling  
184 biogeochemical processes. For instance, simulating leaf phenology requires the distinction  
185 between evergreen and deciduous phenotypes of needleleaf and broadleaf trees. However, once  
186 LAI is known, a physical process (such as the interception of rain and snow by canopy leaves) does  
187 not need to know the underlying evergreen or deciduous nature of leaves.

188 The prognostically determined biomasses in leaves, stem, and roots are used to calculate  
189 structural vegetation attributes that are required by the physics module. Leaf biomass is used to  
190 calculate LAI using PFT-dependent specific leaf area. Stem biomass is used to calculate vegetation  
191 height for tree and crop PFTs, and LAI is used to calculate vegetation height for grasses. Finally,  
192 root biomass is used to calculate rooting depth and distribution which determines the fraction of  
193 roots in each soil layer. Only total root biomass is tracked; fine and coarse root biomasses are not  
194 separately tracked. Fraction of fine roots is calculated as a function of total root biomass, as  
195 shown later.

196 The approach for calculating photosynthesis in CLASSIC is based on the standard Farquhar  
197 et al. (1980) model for C<sub>3</sub> photosynthetic pathway, and Collatz et al. (1992) for the C<sub>4</sub>  
198 photosynthetic pathway and presented in detail in Arora (2003). The model calculates gross  
199 photosynthesis rate that is co-limited by the photosynthetic enzyme Rubisco, by the amount of  
200 available light, and by the capacity to transport photosynthetic products for C<sub>3</sub> plants or the CO<sub>2</sub>-  
201 limited capacity for C<sub>4</sub> plants. In the real world, the maximum Rubisco limited rate (V<sub>cmax</sub>) depends  
202 on the leaf N amount since photosynthetic capacity and leaf N are strongly correlated (Evans,  
203 1989; Field and Mooney, 1986; Garnier et al., 1999). Leaf N amount may be represented per unit  
204 leaf area (gN/m<sup>2</sup>), per unit ground area (gN/m<sup>2</sup>), or per unit leaf mass (gN/gC or %) (Loomis, 1997;

205 Li et al., 2018). In the current operational version of CLASSIC, the N cycle is not represented and  
206 the PFT-dependent values of  $V_{cmax}$  are therefore specified based on Kattge et al. (2009) who  
207 compile  $V_{cmax}$  values using observation-based data from more than 700 measurements. Along  
208 with available light, and the capacity to transport photosynthetic products, the GPP in the model  
209 is determined by specified PFT-dependent values of  $V_{cmax}$ .

210 In the current CLASSIC version a parameterization of photosynthesis downregulation is included  
211 which, in the absence of the N cycle, implicitly attempts to simulate the effects of nutrient  
212 constraints. This parameterization, based on approaches which express GPP as a logarithmic  
213 function of  $[CO_2]$  (Cao et al., 2001; Alexandrov and Oikawa, 2002), is explained in detail in Arora  
214 et al. (2009) and briefly summarized here. To parameterize photosynthesis downregulation with  
215 increasing  $[CO_2]$  the unconstrained or potential GPP (for each time step and each PFT in a grid  
216 cell) is multiplied by the global scalar  $\xi(c)$

217 
$$G = \xi(c) G_p \quad (1)$$

218 
$$\xi(c) = \frac{1+\gamma_d \ln(c/c_0)}{1+\gamma_p \ln(c/c_0)} \quad (2)$$

219 where  $c$  is  $[CO_2]$  at time  $t$  and its initial value is  $c_0$ , the parameter  $\gamma_p$  indicates the “potential” rate  
220 of increase of GPP with  $[CO_2]$  (indicated by the subscript  $p$ ), the parameter  $\gamma_d$  represents the  
221 downregulated rate of increase of GPP with  $[CO_2]$  (indicated by the subscript  $d$ ). When  $\gamma_d < \gamma_p$   
222 the modelled gross primary productivity ( $G$ ) increases in response to  $[CO_2]$  at a rate determined  
223 by the value of  $\gamma_d$ . In the absence of the N cycle, the term  $\xi(c)$  thus emulates down-regulation  
224 of photosynthesis as  $CO_2$  increases. For example, values of  $\gamma_d=0.35$  and  $\gamma_p=0.90$ , yield a value of

225  $\xi(c) = 0.87$  (indicating a 13% downregulation) for  $c=390$  ppm (corresponding to year 2010) and  
226  $c_0=285$  ppm.

227 Note that while the original model version does not include N cycle, it is capable of  
228 simulating realistic geographical distribution of GPP that partly comes from the specification of  
229 observation-based  $V_{cmax}$  values (which implicitly takes into account C and N interactions in a non-  
230 dynamic way) but more so the fact that the geographical distribution of GPP (and therefore net  
231 primary productivity, NPP), to the first order, depends on climate. The specified  $V_{cmax}$  values for  
232 the 9 PFTs in CLASSIC vary by about 2 times, from about 35 to 75  $\mu\text{-mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ . The simulated  
233 GPP in the model, however, varies from zero in the Sahara desert to about  $3000 \text{ gC m}^{-2} \text{ year}^{-1}$  in  
234 the Amazonian rainforest indicating the overarching control of climate in determining the  
235 geographical distribution of GPP. This is further illustrated by the Miami NPP model, for instance,  
236 which is able to simulate the geographical distribution of NPP using only mean annual  
237 temperature and precipitation (Leith, 1975) since both the C and N cycles are governed primarily  
238 by climate. The current version of CLASSIC is also able to reasonably simulate the terrestrial C  
239 sink over the second half of the 20<sup>th</sup> century and early 21<sup>st</sup> century. CLASSIC (with its former  
240 CLASS-CTEM name) has regularly contributed to the annual Trends in Net Land–Atmosphere  
241 Carbon Exchange (TRENDY) model intercomparison since 2016 which contributes results to the  
242 Global Carbon Project’s annual assessments – the most recent one being Friedlingstein et al.  
243 (2019). What is then the purpose of coupling C and N cycles?

244

245 **3. Implementation of the N cycle in CLASSIC**

246        The primary objective of implementation of the N cycle is to model  $V_{cmax}$  as a function of  
247    leaf N amount so as to make the use of multiplier  $\xi(c)$  obsolete in the model, and allow to project  
248    future carbon uptake that is constrained by available N. Modelling of leaf N as a prognostic  
249    variable, however, requires modelling the full N cycle over land. N enters the soil in the inorganic  
250    mineral form through biological fixation of N, fertilizer application, and atmospheric N deposition  
251    in the form of ammonium and nitrate. N cycling through plants implies uptake of inorganic  
252    mineral N by plants, its return to soil through litter generation in the organic form, and its  
253    conversion back to mineral form during decomposition of organic matter in litter and soil. Finally,  
254    N leaves the coupled soil-vegetation system through leaching in runoff and through various  
255    gaseous forms to the atmosphere. This section describes how these processes are implemented  
256    and parameterized in the CLASSIC modelling framework. While the first order interactions  
257    between C and N cycles are described well by the current climate, their temporal dynamics over  
258    time require to explicitly model these processes.

259        Globally, terrestrial N cycle processes are even less constrained than the C cycle  
260    processes. As a result, the model structure and parameterizations are based on conceptual  
261    understanding and mostly empirical observations of N cycle related biological processes. We  
262    attempt to achieve balance between a parsimonious and simple model structure and the ability  
263    to represent the primary feedbacks and interactions between different model components.

264    **3.1 Model structure, and N pools and fluxes**

265        N is associated with each of the model's three live vegetation components and the two  
266    dead carbon pools (shown in Figure A1). In addition, separate mineral pools of ammonium ( $\text{NH}_4^+$ )

267 and nitrate ( $\text{NO}_3^-$ ) are considered. Similar to the C pools, the N pools are represented as N amount  
268 per unit land area. Given the lower absolute amounts of N than C, over land, we represent them  
269 in units of grams as opposed to kilograms ( $\text{gN}/\text{m}^2$ ). Figure 1 shows the C and N pools together in  
270 one graphic along with the fluxes of N and C between various pools. The structural and non-  
271 structural N pools in root are written as  $N_{R,S}$  and  $N_{R,NS}$ , respectively, and similarly for stem ( $N_{S,S}$   
272 and  $N_{S,NS}$ ) and leaves ( $N_{L,S}$  and  $N_{L,NS}$ ), and together the structural and non-structural pools make  
273 up the total N pools in leaf ( $N_L = N_{L,S} + N_{L,NS}$ ), root ( $N_R = N_{R,S} + N_{R,NS}$ ), and stem ( $N_S = N_{S,S} +$   
274  $N_{S,NS}$ ) components. The fluxes between the pools in Figure 1 characterize the prognostic nature  
275 of the pools as defined by the rate change equations summarized in section A1 in the appendix.  
276 The model structure allows the C:N ratio of the live leaves ( $C:N_L = C_L/N_L$ ), stem ( $C:N_S =$   
277  $C_S/N_S$ ), and root ( $C:N_R = C_R/N_R$ ) components, and the dead litter (or debris) pool ( $C:N_D =$   
278  $C_D/N_D$ ) to evolve prognostically. The C:N ratio of soil organic matter ( $C:N_H = C_H/N_H$ ), however,  
279 is assumed to be constant at 13 following Wania et al. (2012) (see also references therein). The  
280 implications of this assumption are discussed later.

281 The individual terms of the rate change equations of the 10 prognostic N pools (equations  
282 A1 through A8, and equations A10 and A11 in the appendix), corresponding to Figure 1, are  
283 specified or parameterized as explained in the following sections. These parameterizations are  
284 divided into three groups and related to 1) N inputs, 2) N cycling in vegetation and soil, and 3) N  
285 cycling in mineral pools and N outputs.

286

287 **3.2 N inputs**

288 **3.2.1 Biological N fixation**

289 Biological N fixation (BNF,  $B_{NH_4}$ ) is caused by both free living bacteria in the soil and by  
 290 bacteria symbiotically living within nodules of host plants' roots. Here, the bacteria convert free  
 291 nitrogen from the atmosphere to ammonium, which is used by the host plants. Like any other  
 292 microbial activity, BNF is limited both by drier soil moisture conditions and cold temperatures.  
 293 Cleveland et al. (1999) attempt to capture this by parameterizing BNF as a function of actual  
 294 evapotranspiration (AET). AET is a function primarily of soil moisture (through precipitation and  
 295 soil water balance) and available energy. In places where vegetation exists, AET is also affected  
 296 by vegetation characteristics including LAI and rooting depth. Here, we parameterize BNF ( $B_{NH_4}$ ,  
 297  $\text{gN m}^{-2} \text{ day}^{-1}$ ) as a function of modelled soil moisture and temperature to depth of 0.5 m  
 298 (following the use of similar depth by Xu-Ri and Prentice (2008)) which yields a very similar  
 299 geographical distribution of BNF as the Cleveland et al. (1999) approach as seen later in Section  
 300 4.

$$301 \quad \begin{aligned} B_{NH_4} &= (\sum_c \alpha_c f_c + \sum_n \alpha_n f_n) f(T_{0.5}) f(\theta_{0.5}) \\ f(T_{0.5}) &= 2^{(T_{0.5}-25)/10} \\ f(\theta_{0.5}) &= \min\left(0, \max\left(1, \frac{\theta_{0.5}-\theta_w}{\theta_{fc}-\theta_w}\right)\right) \end{aligned} \quad (3)$$

302 where  $\alpha_c$  and  $\alpha_n$  ( $\text{gN m}^{-2} \text{ day}^{-1}$ ) are BNF coefficients for crop ( $c$ ) and non-crop or natural ( $n$ ) PFTs,  
 303 which are area weighted using the fractional coverages  $f_c$  and  $f_n$  of crop and non-crop PFTs that  
 304 are present in a grid cell,  $f(T)$  is the dependence on soil temperature based on a  $Q_{10}$  formulation  
 305 and  $f(\theta)$  is the dependence on soil moisture which varies between 0 and 1.  $\theta_{fc}$  and  $\theta_w$  are the  
 306 soil moisture at field capacity and wilting points, respectively.  $T_{0.5}$  ( $^{\circ}\text{C}$ ) and  $\theta_{0.5}$  ( $\text{m}^3 \text{ m}^{-3}$ ) in  
 307 equation (3) are averaged over the 0.5 m soil depth over which BNF is assumed to occur. We do

308 not make the distinction between symbiotic and non-symbiotic BNF since this requires explicit  
309 knowledge of geographical distribution of N fixing PFTs which are not represented separately in  
310 our base set of nine PFTs. A higher value of  $\alpha_c$  is used compared to  $\alpha_n$  to account for the use of  
311 N fixing plants over agricultural areas. Biological nitrogen fixation has been an essential  
312 component of many farming systems for considerable periods, with evidence for the agricultural  
313 use of legumes dating back more than 4,000 years (O'Hara, 1998). A higher  $\alpha_c$  than  $\alpha_n$  is also  
314 consistent with Fowler et al. (2013) who report BNF of 58 and 60 Tg N yr<sup>-1</sup> for natural and  
315 agricultural ecosystems for present day. Since the area of natural ecosystems is about five times  
316 the current cropland area, this implies BNF rate per unit land area is higher for crop ecosystems  
317 than for natural ecosystems. Values of  $\alpha_c$  than  $\alpha_n$  and other model parameters are summarized  
318 in Table A1.

319 Similar to Cleveland et al. (1999), our approach does not lead to a significant change in  
320 BNF with increasing atmospheric CO<sub>2</sub>, other than through changes in soil moisture and  
321 temperature. At least two meta-analyses, however, suggest that an increase in atmospheric CO<sub>2</sub>  
322 does lead to an increase in BNF through increased symbiotic activity associated with an increase  
323 in both nodule mass and number (McGuire et al., 1995; Liang et al., 2016). Models have  
324 attempted to capture this by simulating BNF as a function of NPP (Thornton et al., 2007; Wania  
325 et al., 2012). The caveat with this approach and the implications of our BNF approach are  
326 discussed in Section 6.

327 **3.2.2 Atmospheric N deposition**

328           Atmospheric N deposition is externally specified. The model reads in spatially- and  
329   temporally-varying annual deposition rates from a file. Deposition is assumed to occur at the  
330   same rate throughout the year so the same daily rate ( $\text{gN m}^{-2} \text{ day}^{-1}$ ) is used for all days of a given  
331   year. If separate information for ammonium ( $\text{NH}_4^+$ ) and nitrate ( $\text{NO}_3^-$ ) deposition rates is available  
332   then it is used otherwise deposition is assumed to be split equally between  $\text{NH}_4^+$  and  $\text{NO}_3^-$   
333   (indicated as  $P_{\text{NH}_4}$  and  $P_{\text{NO}_3}$  in equations A1 and A2).

334   **3.2.3 Fertilizer application**

335           Geographically and temporally varying annual fertilizer application rates ( $F_{\text{NH}_4}$ ) are also  
336   specified externally and read in. Fertilizer application occurs over the C<sub>3</sub> and C<sub>4</sub> crop fractions of  
337   grid cells. Agricultural management practices are difficult to model since they vary widely  
338   between countries and even from farmer to farmer. For simplicity, we assume fertilizer is applied  
339   at the same daily fertilizer application rate ( $\text{gN m}^{-2} \text{ day}^{-1}$ ) throughout the year in the tropics  
340   (between 30°S and 30°N), given the possibility of multiple crop rotations in a given year. Between  
341   the 30° and 90° latitudes in both northern and southern hemispheres, we assume that fertilizer  
342   application starts on the spring equinox and ends on the fall equinox. The annual fertilizer  
343   application rate is thus distributed over around 180 days. This provides somewhat more realism,  
344   than using the same treatment as in tropical regions, since extra-tropical agricultural areas  
345   typically do not experience multiple crop rotations in a given year. The prior knowledge of start  
346   and end days for fertilizer application makes it easier to figure out how much fertilizer is to be  
347   applied each day and helps ensure that the annual amount read from the externally specified file  
348   is consistently applied.

349

350 **3.3 N cycling in plants and soil**

351 Plant roots take up mineral N from soil and then allocate it to leaves and stem to maintain  
352 an optimal C:N ratio of each component. Both active and passive plant uptakes of N (from both  
353 the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools; explained in Sections 3.3.2 and 3.3.3) are explicitly modelled. The active  
354 N uptake is modelled as a function of fine root biomass, and passive N uptake depends on the  
355 transpiration flux. The modelled plant N uptake also depends on its N demand. Higher N demand  
356 leads to higher mineral N uptake from soil as explained below. Litterfall from vegetation  
357 contributes to the litter pool and decomposition of litter transfers humified litter to the soil  
358 organic matter pool. Decomposition of litter and soil organic matter returns mineralized N back  
359 to the  $\text{NH}_4^+$  pool, closing the soil-vegetation N cycle loop.

360 **3.3.1 Plant N demand**

361 Plant N demand is calculated based on the fraction of NPP allocated to leaves, stem, and  
362 root components and their specified minimum PFT-dependent C:N ratios, similar to other models  
363 (Xu-Ri and Prentice, 2008; Jiang et al., 2019). The assumption is that plants always want to  
364 achieve their desired minimum C:N ratios if enough N is available.

$$\Delta_{WP} = \Delta_L + \Delta_R + \Delta_S$$
$$\Delta_i = \frac{\max(0, NPP \cdot a_{i,C})}{C:N_{i,\min}}, \quad i = L, S, R \quad (4)$$

366 where the whole plant N demand ( $\Delta_{WP}$ ) is the sum of N demand for the leaves ( $\Delta_L$ ), stem ( $\Delta_S$ ),  
367 and root ( $\Delta_R$ ) components,  $a_{i,C}$ ,  $i = L, S, R$  is the fraction of NPP (i.e., carbon as indicated by  
368 letter C in the subscript,  $\text{gC m}^{-2} \text{ day}^{-1}$ ) allocated to leaf, stem, and root components, and

369  $C: N_{i,\min}, i = L, S, R$  are their specified minimum C:N ratios (see Table A1 for these and all other  
370 model parameters). A caveat with this approach when applied at the daily time step, for  
371 biogeochemical processes in our model, is that during periods of time when NPP is negative due  
372 to adverse climatic conditions (e.g., during winter or drought seasons), the calculated demand is  
373 negative. If positive NPP implies there is demand for N, negative NPP cannot be taken to imply  
374 that N must be lost from vegetation. As a result, from a plant's perspective, N demand is assumed  
375 to be zero during periods of negative NPP. N demand is also set to zero when all leaves have been  
376 shed (i.e., when GPP is zero). At the global scale, this leads to about 15% higher annual N demand  
377 than would be the case if negative NPP values were taken into consideration.

378

### 379 **3.3.2 Passive N uptake**

380 N demand is weighed against passive and active N uptake. Passive N uptake depends on  
381 the concentration of mineral N in the soil and the water taken up by the plants through their  
382 roots as a result of transpiration. We assume that plants have no control over N that comes into  
383 the plant through this pathway. This is consistent with existing empirical evidence that too much  
384 N in soil will cause N toxicity (Goyal and Huffaker, 1984), although we do not model N toxicity in  
385 our framework. If the N demand for the current time step cannot be met by passive N uptake  
386 then a plant compensates for the deficit (i.e., the remaining demand) through active N uptake.

387 The  $\text{NH}_4^+$  concentration in the soil moisture within the rooting zone, referred to as  $[\text{NH}_4]$   
388 ( $\text{gN gH}_2\text{O}^{-1}$ ), is calculated as

$$389 [\text{NH}_4] = \frac{N_{\text{NH}_4}}{\sum_{i=1}^{i \leq r_I} 10^6 \theta_i z_i} \quad (5)$$

390 where  $N_{NH_4}$  is ammonium pool size ( $\text{gN m}^{-2}$ ),  $\theta_i$  is the volumetric soil moisture content for soil  
391 layer  $i$  ( $\text{m}^3 \text{m}^{-3}$ ),  $z_i$  is the thickness of soil layer  $i$  (m),  $r_i$  is the soil layer in which the 99% rooting  
392 depth lies as dynamically simulated by the biogeochemical module of CLASSIC following Arora  
393 and Boer (2003). The  $10^6$  term converts units of the denominator term to  $\text{gH}_2\text{O m}^{-2}$ .  $\text{NO}_3^-$   
394 concentration ( $[\text{NO}_3]$ ,  $\text{gN gH}_2\text{O}^{-1}$ ) in the rooting zone is found in a similar fashion. The  
395 transpiration flux  $q_t$  ( $\text{kg H}_2\text{O m}^{-2} \text{s}^{-1}$ ) (calculated in the physics module of CLASSIC) is multiplied  
396 by  $[\text{NH}_4]$  and  $[\text{NO}_3]$  ( $\text{gN gH}_2\text{O}^{-1}$ ) to obtain passive uptake of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  ( $\text{gN m}^{-2} \text{day}^{-1}$ ) as

397

$$\begin{aligned} U_{p,NH_4} &= 86400 \times 10^3 \beta q_t [\text{NH}_4] \\ U_{p,NO_3} &= 86400 \times 10^3 \beta q_t [\text{NO}_3] \end{aligned} \quad (6)$$

398 where the multiplier  $86400 \times 10^3$  converts  $q_t$  to units of  $\text{gH}_2\text{O m}^{-2} \text{day}^{-1}$ , and  $\beta$  (see Table A1) is  
399 the dimensionless mineral N distribution coefficient with a value less than 1 that accounts for the  
400 fact that  $\text{NH}_4^+$  and  $\text{NO}_3^-$  available in the soil are not well mixed in the soil moisture solution, and  
401 not completely accessible to roots, to be taken up by plants.

402 **3.3.3 Active N uptake**

403 The active plant N uptake is parameterized as a function of fine root biomass and the size  
404 of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools in a manner similar to Gerber et al. (2010) and Wania et al. (2012). The  
405 distribution of fine roots across the soil layers is ignored. CLASSIC does not explicitly model fine  
406 root biomass. We therefore calculate the fraction of fine root biomass using an empirical  
407 relationship that is very similar to the relationship developed by Kurz et al. (1996) (their equation  
408 5) but also works below total root biomass of  $0.33 \text{ Kg C m}^{-2}$  (the Kurz et al. (1996) relationship

409 yields a fraction of fine root more than 1.0 below this threshold). The fraction of fine root biomass  
 410 ( $f_r$ ) is given by

411

$$f_r = 1 - \frac{C_R}{C_R + 0.6} \quad (7)$$

412 where  $C_R$  is the root biomass ( $\text{KgC m}^{-2}$ ) simulated by the biogeochemical module of CLASSIC.  
 413 Equation (7) yields fine root fraction approaching 1.0 as  $C_R$  approaches 0, so at very low root  
 414 biomass values all roots are considered fine roots. For grasses the fraction of fine root biomass is  
 415 set to 1. The maximum or potential active N uptake for  $\text{NH}_4^+$  and  $\text{NO}_3^-$  is given by

416

$$U_{a,pot,\text{NH}_4} = \frac{\varepsilon f_r C_R N_{\text{NH}_4}}{k_{p,1/2} r_d + N_{\text{NH}_4} + N_{\text{NO}_3}} \quad (8)$$

$$U_{a,pot,\text{NO}_3} = \frac{\varepsilon f_r C_R N_{\text{NO}_3}}{k_{p,1/2} r_d + N_{\text{NH}_4} + N_{\text{NO}_3}}$$

417 where  $\varepsilon$  (see Table A1) is the efficiency of fine roots to take up N per unit fine root mass per day  
 418 ( $\text{gN gC}^{-1} \text{ day}^{-1}$ ),  $k_{p,1/2}$  (see Table A1) is the half saturation constant ( $\text{gN m}^{-3}$ ),  $r_d$  is the 99% rooting  
 419 depth (m), and  $N_{\text{NH}_4}$  and  $N_{\text{NO}_3}$  are the ammonium and nitrate pool sizes ( $\text{gN m}^{-2}$ ) as mentioned  
 420 earlier. Depending on the geographical location and the time of the year, if passive uptake alone  
 421 can satisfy plant N demand the actual active N uptake of  $\text{NH}_4^+$  ( $U_{a,actual,\text{NH}_4}$ ) and  $\text{NO}_3^-$   
 422 ( $U_{a,actual,\text{NO}_3}$ ) is set to zero. Conversely, during other times both passive and potential active N  
 423 uptakes may not be able to satisfy the demand and in this case actual active N uptake is equal to  
 424 its potential rate. At times other than these, the actual active uptake is lower than its potential  
 425 value. This adjustment of actual active uptake is illustrated in equation (9).

$$\begin{aligned}
& \text{if } (\Delta_{WP} \leq U_{p,NH4} + U_{p,NO3}) \\
& \quad U_{a,actual,NH4} = 0 \\
& \quad U_{a,actual,NO3} = 0 \\
& \text{if } (\Delta_{WP} > U_{p,NH4} + U_{p,NO3}) \wedge (\Delta_{WP} < U_{p,NH4} + U_{p,NO3} + U_{a,pot,NH4} + U_{a,pot,NO3}) \\
& \quad U_{a,actual,NH4} = (\Delta_{WP} - U_{p,NH4} - U_{p,NO3}) \frac{U_{a,pot,NH4}}{U_{a,pot,NH4} + U_{a,pot,NO3}} \\
& \quad U_{a,actual,NO3} = (\Delta_{WP} - U_{p,NH4} - U_{p,NO3}) \frac{U_{a,pot,NO3}}{U_{a,pot,NH4} + U_{a,pot,NO3}} \\
& \text{if } (\Delta_{WP} \geq U_{p,NH4} + U_{p,NO3} + U_{a,pot,NH4} + U_{a,pot,NO3}) \\
& \quad U_{a,actual,NH4} = U_{a,pot,NH4} \\
& \quad U_{a,actual,NO3} = U_{a,pot,NO3}
\end{aligned} \tag{9}$$

427 Finally, the total N uptake ( $U$ ), uptake of  $\text{NH}_4^+$  ( $U_{NH4}$ ) and  $\text{NO}_3^-$  ( $U_{NO3}$ ), are calculated as

$$\begin{aligned}
& U = U_{p,NH4} + U_{p,NO3} + U_{a,actual,NH4} + U_{a,actual,NO3} \\
& U_{NH4} = U_{p,NH4} + U_{a,actual,NH4} \\
& U_{NO3} = U_{p,NO3} + U_{a,actual,NO3}
\end{aligned} \tag{10}$$

429

430 **3.3.4 Litterfall**

431 Nitrogen litterfall from the vegetation components is directly tied to the carbon litterfall  
 432 calculated by the phenology module of CLASSIC through their current C:N ratios.

$$433 \quad LF_i = \frac{(1-r_L) LF_{i,C}}{C:N_i}, i = L, S, R \tag{11}$$

434 where  $LF_{i,C}$  is the carbon litterfall rate ( $\text{gC day}^{-1}$ ) for component  $i$ , calculated by the phenology  
 435 module of CLASSIC, and division by its current C:N ratio yields the nitrogen litterfall rate,  $r_L$  (see  
 436 Table A1) is the leaf resorption coefficient that simulates the resorption of N from leaves of  
 437 deciduous tree PFTs before they are shed and  $r_i = 0, i = R, S$ . Litter from each vegetation

438 component is proportioned between structural and non-structural components according to  
439 their pool sizes.

440 **3.3.5 Allocation and reallocation**

441 Plant N uptake by roots is allocated to leaves and stem to satisfy their N demand. When  
442 plant N demand is greater than zero, total N uptake ( $U$ ) is divided between leaves, stem, and root  
443 components in proportion to their demands such that the allocation fractions for N ( $a_i, i =$   
444  $L, S, R$ ) are calculated as

$$445 \quad \begin{aligned} a_i &= \frac{\Delta_i}{\Delta_{WP}}, i = L, S, R \\ A_{R2L} &= a_L (U_{NH4} + U_{NO3}) \\ A_{R2S} &= a_S (U_{NH4} + U_{NO3}) \end{aligned} \quad (12)$$

446 where  $A_{R2L}$  and  $A_{R2S}$  are the amounts of N allocated from root to leaves and stem components,  
447 respectively, as shown in equations (A5) and (A7). During periods of negative NPP due to adverse  
448 climatic conditions (e.g., during winter or drought seasons) the plant N demand is set to zero but  
449 passive N uptake, associated with transpiration, may still be occurring if the leaves are still on.  
450 Even though there is no N demand, passive N uptake still needs to be partitioned among the  
451 vegetation components. During periods of negative NPP allocation fractions for N are, therefore,  
452 calculated in proportion to the minimum PFT-dependent C:N ratios of the leaves, stem, and root  
453 components as follows.

$$454 \quad a_i = \frac{1/C:N_{i,\min}}{1/C:N_{L,\min} + 1/C:N_{S,\min} + 1/C:N_{R,\min}}, i = L, S, R \quad (13)$$

455 For grasses, which do not have a stem component, equations (12) and (13) are modified  
456 accordingly by removing the terms associated with the stem component.

457 Three additional rules override these general allocation rule specifically for deciduous  
 458 tree PFTs (or deciduous PFTs in general). First, no N allocation is made to leaves once leaf fall is  
 459 initiated for deciduous tree PFTs and plant N uptake is proportioned between stem and root  
 460 components based on their demands in a manner similar to equation (12). Second, for deciduous  
 461 tree PFTs, a fraction of leaf N is resorbed from leaves back into stem and root as follows

$$462 \quad R_{L2R} = r_L LF_L \frac{N_{R,NS}}{N_{R,NS} + N_{S,NS}} \quad (14)$$

$$R_{L2S} = r_L LF_L \frac{N_{S,NS}}{N_{R,NS} + N_{S,NS}}$$

463

464 where  $r_L$  is the leaf resorption coefficient, as mentioned earlier, and  $LF_L$  is the leaf litter fall rate.  
 465 Third, and similar to resorption, at the time of leaf onset for deciduous tree PFTs, N is reallocated  
 466 to leaves (in conjunction with reallocated carbon as explained in Asaadi et al. (2018)) from stem  
 467 and root components.

$$468 \quad R_{R2L} = \frac{R_{R2L,C}}{C:N_L} \frac{N_{R,NS}}{N_{R,NS} + N_{S,NS}} \quad (15)$$

$$R_{S2L} = \frac{R_{S2L,C}}{C:N_L} \frac{N_{S,NS}}{N_{R,NS} + N_{S,NS}}$$

469 where  $R_{R2L,C}$  and  $R_{S2L,C}$  represent reallocation of carbon from non-structural stem and root  
 470 components to leaves and division by  $C:N_L$  converts the flux into N units. This reallocated N, at  
 471 the time of leaf onset, is proportioned between non-structural pools of stem and root according  
 472 to their sizes.

473 **3.3.6 N mineralization, immobilization, and humification**

474            Decomposition of litter ( $R_{h,D}$ ) and soil organic matter ( $R_{h,H}$ ) releases C to the atmosphere  
475    and this flux is calculated by the heterotrophic respiration module of CLASSIC. The litter and soil  
476    carbon decomposition rates used here are the same as in the standard model version (Melton  
477    and Arora, 2016; their Table A3). The amount of N mineralized is calculated straightforwardly by  
478    division with the current C:N ratios of the respective pools and contributes to the  $\text{NH}_4^+$  pool.

479

$$M_{D,NH4} = \frac{R_{h,D}}{C:N_D} \quad (16)$$
$$M_{H,NH4} = \frac{R_{h,H}}{C:N_H}$$

480    An implication of mineralization contributing to the  $\text{NH}_4^+$  pool, in addition to BNF and fertilizer  
481    inputs that also contribute solely to the  $\text{NH}_4^+$  pool, is that the simulated  $\text{NH}_4^+$  pool is typically  
482    larger than the  $\text{NO}_3^-$  pool. The exception is the dry and arid regions where the lack of  
483    denitrification, as discussed below in Section 3.4.2., leads to a build-up of the  $\text{NO}_3^-$  pool.

484            Immobilization of mineral N from the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools into the soil organic matter  
485    pool is meant to keep the soil organic matter C:N ratio ( $C:N_H$ ) at its specified value of 13 for all  
486    PFTs in a manner similar to Wania et al. (2012) and Zhang et al. (2018). A value of 13 is within the  
487    range of observation-based estimates which vary from about 8 to 25 (Zinke et al., 1998; Tipping  
488    et al., 2016). Although  $C:N_H$  varies geographically, the driving factors behind this variability  
489    remain unclear. It is even more difficult to establish if increasing atmospheric  $\text{CO}_2$  is changing  
490     $C:N_H$  given the large heterogeneity in soil organic C and N densities, and the difficulty in  
491    measuring small trends for such large global pools. We therefore make the assumption that the  
492     $C:N_H$  does not change with time. An implication of this assumption is that as GPP increases with  
493    increasing atmospheric  $\text{CO}_2$  rises, and plant litter becomes enriched in C with increasing C:N ratio

494 of litter, more and more N is locked up in the soil organic matter pool because its C:N ratio is  
 495 fixed. As a result, mineral N pools of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  decrease in size and plant N amount  
 496 subsequently follows. This is consistent with studies of plants grown in elevated  $\text{CO}_2$   
 497 environment. For example, Cotrufo et al. (1998) summarize results from 75 studies and find an  
 498 average 14% reduction in N concentration (gN/gC) for above-ground tissues. Wang et al. (2019)  
 499 find increased C concentration by 0.8–1.2% and a reduction in N concentration by 7.4–10.7% for  
 500 rice and winter wheat crop rotation system under elevated  $\text{CO}_2$ . Another implication of using  
 501 specified fixed  $C:N_H$  is that it does not matter if plant N uptake or immobilization is given  
 502 preferred access to the mineral N pool since in the long term, by design, N will accumulate in the  
 503 soil organic matter in response to atmospheric  $\text{CO}_2$  increase.

504 Immobilization from both the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools ( $\text{gN m}^{-2} \text{ day}^{-1}$ ) is calculated in  
 505 proportion to their pool sizes, employing the fixed  $C:N_H$  ratio as

$$506 \quad \begin{aligned} O_{\text{NH}_4} &= \max \left( 0, \left( \frac{C_H}{C:N_H} - N_H \right) \frac{N_{\text{NH}_4}}{N_{\text{NH}_4} + N_{\text{NO}_3}} \right) k_O \\ O_{\text{NO}_3} &= \max \left( 0, \left( \frac{C_H}{C:N_H} - N_H \right) \frac{N_{\text{NO}_3}}{N_{\text{NH}_4} + N_{\text{NO}_3}} \right) k_O \end{aligned} \quad (17)$$

507 where  $k_O$  is rate constant with a value of  $1.0 \text{ day}^{-1}$ . Finally, the carbon flux of humified litter from  
 508 the litter to the soil organic matter pool ( $H_{C,D2H}$ ) is also associated with a corresponding N flux  
 509 that depends on the C:N ratio of the litter pool.

$$510 \quad H_{N,D2H} = \frac{H_{C,D2H}}{C:N_D} \quad (18)$$

511 **3.4 N cycling in mineral pools and N outputs**

512        This section presents the parameterizations of nitrification (which results in transfer of N  
513    from the  $\text{NH}_4^+$  to the  $\text{NO}_3^-$  pool) and the associated gaseous fluxes of  $\text{N}_2\text{O}$  and  $\text{NO}$  (referred to as  
514    nitrifier denitrification), gaseous fluxes of  $\text{N}_2\text{O}$ ,  $\text{NO}$ , and  $\text{N}_2$  associated with denitrification,  
515    volatilization of  $\text{NH}_4^+$  into  $\text{NH}_3$ , and leaching of  $\text{NO}_3^-$  in runoff.

516    **3.4.1 Nitrification**

517        Nitrification, the oxidative process converting ammonium to nitrate, is driven by microbial  
518    activity and as such constrained both by high and low soil moisture (Porporato et al., 2003). At  
519    high soil moisture content there is little aeration of soil and this constrains aerobic microbial  
520    activity, while at low soil moisture content microbial activity is constrained by moisture  
521    limitation. In CLASSIC, the heterotrophic respiration from soil carbon is constrained similarly but  
522    rather than using soil moisture the parameterization is based on soil matric potential (Arora,  
523    2003; Melton et al., 2015). Here, we use the exact same parameterization. In addition to soil  
524    moisture, nitrification ( $\text{gN m}^{-2} \text{ day}^{-1}$ ) is modelled as a function of soil temperature and the size  
525    of the  $\text{NH}_4^+$  pool as follows

526        
$$I_{\text{NO}_3} = \eta f_I(T_{0.5}) f_I(\psi) N_{\text{NH}_4} \quad (19)$$

527        where  $\eta$  is the nitrification coefficient ( $\text{day}^{-1}$ , see Table A1),  $f_I(\psi)$  is the dimensionless soil  
528    moisture scalar that varies between 0 and 1 and depends on soil matric potential ( $\psi$ ),  $f_I(T_{0.5})$  is  
529    the dimensionless soil temperature scalar that depends on soil temperature ( $T_{0.5}$ ) averaged over  
530    the top 0.5 m soil depth over which nitrification is assumed to occur (following Xu-Ri and Prentice,  
531    2008), and  $N_{\text{NH}_4}$  is the ammonium pool size ( $\text{gN m}^{-2}$ ), as mentioned earlier. Both  $f_I(T_{0.5})$  and

532  $f_I(\psi)$  are parameterized following Arora (2003) and Melton et al. (2015).  $f_I(T_{0.5})$  is a  $Q_{10}$  type  
 533 function with a temperature dependent  $Q_{10}$

534 
$$f_I(T_{0.5}) = Q_{10,I}^{(T_{0.5}-20)/10}, Q_{10,I} = 1.44 + 0.56 (\tanh(0.075(46 - T_{0.5}))) \quad (20)$$

535 The reference temperature for nitrification is set to 20 °C following Lin et al. (2000).  $f_I(\psi)$  is  
 536 parameterized as a step function of soil matric potential ( $\psi$ ) as

537 
$$f_I(\psi) = \begin{cases} 0.5 & \text{if } \psi \leq \psi_{sat} \\ 1 - 0.5 \frac{\log(0.4) - \log(\psi)}{\log(0.4) - \log(\psi_{sat})} & \text{if } 0.4 > \psi \geq \psi_{sat} \\ 1 & \text{if } 0.6 \geq \psi \geq 0.4 \\ 1 - 0.8 \frac{\log(\psi) - \log(0.6)}{\log(100) - \log(0.6)} & \text{if } 100 > \psi > 0.6 \\ 0.2 & \text{if } \psi > 100 \end{cases} \quad (21)$$

538 where the soil matric potential ( $\psi$ ) is found, following Clapp and Hornberger (1978), as a function  
 539 of soil moisture ( $\theta$ )

540 
$$\psi(\theta) = \psi_{sat} \left( \frac{\theta}{\theta_{sat}} \right)^{-B}. \quad (22)$$

541 Saturated matric potential ( $\psi_{sat}$ ), soil moisture at saturation (i.e., porosity) ( $\theta_{sat}$ ), and the  
 542 parameter  $B$  are calculated as functions of percent sand and clay in soil following Clapp and  
 543 Hornberger (1978) as shown in Melton et al. (2015). The soil moisture scalar  $f_I(\psi)$  is calculated  
 544 individually for each soil layer and then averaged over the soil depth of 0.5 m over which  
 545 nitrification is assumed to occur.

546 Gaseous fluxes of NO ( $I_{NO}$ ) and N<sub>2</sub>O ( $I_{N2O}$ ) associated with nitrification, and generated  
 547 through nitrifier denitrification, are assumed to be directly proportional to the nitrification flux  
 548 ( $I_{NO3}$ ) as

549 
$$\begin{aligned} I_{NO} &= \eta_{NO} I_{NO3} \\ I_{N2O} &= \eta_{N2O} I_{NO3} \end{aligned} \quad (23)$$

550 where  $\eta_{NO}$  and  $\eta_{N2O}$  are dimensionless fractions (see Table A1) which determine what fractions  
 551 of nitrification flux are emitted as NO and N<sub>2</sub>O.

552 **3.4.2 Denitrification**

553 Denitrification is the stepwise microbiological reduction of nitrate to NO, N<sub>2</sub>O, and ultimately to  
 554 N<sub>2</sub> in complete denitrification. Unlike nitrification, however, denitrification is primarily an  
 555 anaerobic process (Tomasek et al., 2017) and therefore occurs when soil is saturated. As a result,  
 556 we use a different soil moisture scalar than for nitrification. Similar to nitrification, denitrification  
 557 is modelled as a function of soil moisture, soil temperature and the size of the NO<sub>3</sub><sup>-</sup> pool as follows  
 558 to calculate the gaseous fluxes of NO, N<sub>2</sub>O, and N<sub>2</sub>.

559 
$$\begin{aligned} E_{NO} &= \mu_{NO} f_E(T_{0.5}) f_E(\theta) N_{NO3} \\ E_{N2O} &= \mu_{N2O} f_E(T_{0.5}) f_E(\theta) N_{NO3} \\ E_{N2} &= \mu_{N2} f_E(T_{0.5}) f_E(\theta) N_{NO3} \end{aligned} \quad (24)$$

560 where  $\mu_{NO}$ ,  $\mu_{N2O}$ , and  $\mu_{N2}$  are coefficients (day<sup>-1</sup>, see Table A1) that determine daily rates of  
 561 emissions of NO, N<sub>2</sub>O, and N<sub>2</sub>. The temperature scalar  $f_E(T_{0.5})$  is exactly the same as the one for  
 562 nitrification ( $f_I(T_{0.5})$ ) since denitrification is also assumed to occur over the same 0.5 m soil  
 563 depth. The soil moisture scalar  $f_E(\theta)$  is given by

564 
$$\begin{aligned} f_E(\theta) &= 1 - \tanh \left( 2.5 \left( \frac{1-w(\theta)}{1-w_d} \right)^2 \right) \\ w(\theta) &= \max \left( 0, \min \left( 1, \frac{\theta-\theta_w}{\theta_f-\theta_w} \right) \right) \end{aligned} \quad (25)$$

565 where  $w$  is the soil wetness that varies between 0 and 1 as soil moisture varies between wilting  
566 point ( $\theta_w$ ) and field capacity ( $\theta_f$ ), and  $w_d$  (see Table A1) is the threshold soil wetness for  
567 denitrification below which very little denitrification occurs. Since arid regions are characterized  
568 by low soil wetness values, typically below  $w_d$ , this leads to build up of the  $\text{NO}_3^-$  pool in arid  
569 regions.

570 **3.4.3  $\text{NO}_3^-$  leaching**

571 Leaching is the loss of water-soluble ions through runoff. In contrast to positively charged  
572  $\text{NH}_4^+$  ions (i.e. cations), the  $\text{NO}_3^-$  ions do not bond to soil particles because of the limited exchange  
573 capacity of soil for negatively charged ions (i.e., anions). As a result, leaching of N in the form of  
574  $\text{NO}_3^-$  ions is a common water quality problem, particularly over cropland regions. The leaching  
575 flux ( $L_{\text{NO}_3}$ ,  $\text{gN m}^{-2} \text{ day}^{-1}$ ) is parameterized to be directly proportional to baseflow ( $b_t$ ,  $\text{Kg m}^{-2} \text{ s}^{-1}$ )  
576 calculated by the physics module of CLASSIC and the size of the  $\text{NO}_3^-$  pool ( $N_{\text{NO}_3}$ ,  $\text{gN m}^{-2}$ ).  
577 Baseflow is the runoff rate from the bottommost soil layer.

578 
$$L_{\text{NO}_3} = 86400 \varphi b_t N_{\text{NO}_3} \quad (26)$$

579 where the multiplier 86400 converts units to per day, and  $\varphi$  is the leaching coefficient ( $\text{m}^2 \text{ Kg}^{-1}$ ,  
580 see Table A1) that can be thought of as the soil particle surface area ( $\text{m}^2$ ) that 1 Kg of water (or  
581 about  $0.001 \text{ m}^3$ ) can effectively wash to leach the nutrients.

582 **3.4.4  $\text{NH}_3$  volatilization**

583 NH<sub>3</sub> volatilization ( $V_{NH_3}$ , gN m<sup>-2</sup> day<sup>-1</sup>) is parametrized as a function of pool size of NH<sub>4</sub><sup>+</sup>,  
 584 soil temperature, soil pH, aerodynamic and boundary layer resistances, and atmospheric NH<sub>3</sub>  
 585 concentration in a manner similar to Riddick et al. (2016) as

$$586 \quad V_{NH4} = \vartheta \cdot 86400 \cdot \frac{1}{r_a + r_b} (\chi - [\text{NH}_{3,a}]) \quad (27)$$

587 where  $\vartheta$  is the dimensionless  $\text{NH}_3$  volatilization coefficient (see Table A1) which is set to less than  
 588 1 to account for the fact that a fraction of ammonia released from the soil is captured by  
 589 vegetation,  $r_a$  ( $\text{s m}^{-1}$ ) is the aerodynamic resistance calculated by the physics module of CLASSIC,  
 590  $\chi$  is the ammonia ( $\text{NH}_3$ ) concentration at the interface of the top soil layer and the atmosphere  
 591 ( $\text{g m}^{-3}$ ),  $[\text{NH}_{3,a}]$  is the atmospheric  $\text{NH}_3$  concentration specified at  $0.3 \times 10^{-6} \text{ g m}^{-3}$  following  
 592 Riddick et al. (2016), 86400 converts flux units from  $\text{gN m}^{-2} \text{ s}^{-1}$  to  $\text{gN m}^{-2} \text{ day}^{-1}$ , and  $r_b$  ( $\text{s m}^{-1}$ ) is  
 593 the boundary layer resistance calculated following Thom (1975) as

$$r_b = 6.2 u_*^{-0.67} \quad (28)$$

595 where  $u_*$  (m/s) is the friction velocity provided by the physics module of CLASSIC. The ammonia  
 596 ( $\text{NH}_3$ ) concentration at surface ( $\chi$ ), in a manner similar to Riddick et al. (2016), is calculated as

$$597 \quad \chi = 0.26 \frac{N_{NH_4}}{1 + K_H + K_H[H^+]/K_{NH_4}} \quad (29)$$

598 where the coefficient 0.26 is the fraction of ammonium in the top 10 cm soil layer assuming  
 599 exponential distribution of ammonium along the soil depth (given by  $3e^{-3z}$ , where  $z$  is the soil  
 600 depth),  $K_H$  (dimensionless) is the Henry's law constant for  $\text{NH}_3$ ,  $K_{\text{NH}_4}$  ( $\text{mol L}^{-1}$ ) is the dissociation  
 601 equilibrium constant for aqueous  $\text{NH}_3$ , and  $H^+$  ( $\text{mol L}^{-1}$ ) is the concentration of hydrogen ion

602 that depends on the soil pH ( $H^+ = 10^{-pH}$ ).  $K_H$  and  $K_{NH4}$  are modelled as functions of soil  
 603 temperature of the top 10 cm soil layer ( $T_{0.1}$ ) following Riddick et al. (2016) as

$$604 \quad K_H = 4.59 T_{0.1} \exp \left( 4092 \left( \frac{1}{T_{0.1}} - \frac{1}{T_{ref,v}} \right) \right) \quad (30)$$

$$K_{NH4} = 5.67 \times 10^{-10} \exp \left( -6286 \left( \frac{1}{T_{0.1}} - \frac{1}{T_{ref,v}} \right) \right)$$

605 where  $T_{ref,v}$  is the reference temperature of 298.15 K.

606

### 607 **3.5 Coupling of C and N cycles**

608 As mentioned earlier, the primary objective of coupling of C and N cycles is to be able to  
 609 simulate  $V_{cmax}$  as a function of leaf N amount ( $N_L$ , gN/m<sup>2</sup> land) for each PFT. This coupling is  
 610 represented through the following relationship

$$611 \quad V_{cmax} = \Lambda \left( \frac{\Gamma_1 N_L}{3} + \Gamma_2 \right) \quad (31)$$

612 where  $\Gamma_1$  (39  $\mu\text{mol CO}_2 \text{ gN}^{-1} \text{ s}^{-1}$ ) and  $\Gamma_2$  (8.5  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) are global constants, except for  
 613 the broadleaf evergreen tree PFT for which a lower value of  $\Gamma_1$  (15.3  $\mu\text{mol CO}_2 \text{ gN}^{-1} \text{ s}^{-1}$ ) is used  
 614 as discussed below, and the number 3 represents an average LAI over vegetated areas ( $\text{m}^2$   
 615 leaves/ $\text{m}^2$  land).  $\Lambda$  ( $\leq 1$ ) is a scalar that reduces calculated  $V_{cmax}$  when C:N ratio of any plant  
 616 component ( $C:N_i, i = L, S, R$ ) exceeds its specified maximum value ( $C:N_{i,\max}, i = L, S, R$ ) (see  
 617 Table A1).

$$618 \quad \begin{aligned} \Lambda &= \exp(-\omega k_\Lambda) \\ \omega &= e_L b_L + e_S b_S + e_R b_R \end{aligned} \quad (32)$$

619

$$e_i = \max(0, C:N_i - C:N_{i,\max})$$

$$b_i = \frac{1/C:N_{i,\max}}{1/C:N_{L,\max} + 1/C:N_{S,\max} + 1/C:N_{R,\max}}, i = L, S, R \quad (33)$$

620 where  $k_\Lambda$  is a dimensionless parameter (see Table A1) and  $\omega$  is dimensionless term that  
 621 represents excess C:N ratios above specified maximum thresholds ( $e_i, i = L, S, R$ ) weighted by  
 622  $b_i, i = L, S, R$ . When plant components do not exceed their specified maximum C:N ratio  
 623 thresholds,  $e_i$  is zero and  $\Lambda$  is one. When plants components exceed their specified maximum  
 624 C:N ratio thresholds,  $\Lambda$  starts reducing below one. This decreases  $V_{cmax}$  and thus photosynthetic  
 625 uptake which limits the rate of increase of C:N ratio of plant components, depending on the value  
 626 of  $k_\Lambda$ .

627 The linear relationship between photosynthetic capacity and  $N_L$  (Evans, 1989; Field and  
 628 Mooney, 1986; Garnier et al., 1999) (used in equation 31) and between photosynthetic capacity  
 629 and leaf chlorophyll amount (Croft et al., 2017) is empirically observed. We have avoided using  
 630 PFT-dependent values of  $\Gamma_1$  and  $\Gamma_2$  for easy optimization of these parameter values but also  
 631 because such an optimization can potentially hide other model deficiencies. More importantly,  
 632 using PFT-independent values of  $\Gamma_1$  and  $\Gamma_2$  yields a more elegant framework whose successful  
 633 evaluation will provide confidence in the overall model structure.

634 As shown later in the results section, using  $\Gamma_1$  and  $\Gamma_2$  as global constants yields GPP values  
 635 that are higher in the tropical region than an observation-based estimate. This is not surprising  
 636 since tropical and mid-latitude regions are known to be limited by P (Vitousek, 1984; Aragão et  
 637 al., 2009; Vitousek et al., 2010; Du et al., 2020) and our framework currently doesn't model P  
 638 cycle explicitly. An implication of productivity that is limited by P is that changes in  $N_L$  are less

639 important. In the absence of explicit treatment of the P cycle, we therefore simply use a lower  
640 value of  $\Gamma_1$  for the broadleaf evergreen tree PFT which, in our modelling framework, exclusively  
641 represents a tropical PFT. Although, a simple way to express P limitation, this approach yields the  
642 best comparison with observation-based GPP, as shown later, because the effect of P limitation  
643 is most pronounced in the high productivity tropical regions.

644 The second pathway of coupling between the C and N cycles occurs through  
645 mineralization of litter and soil organic matter. During periods of higher temperature,  
646 heterotrophic C respiration fluxes increase from the litter and soil organic matter pools and this  
647 in turn implies an increased mineralization flux (via equation 16) leading to more mineral N  
648 available for plants to uptake.

649 **4.0 Methodology**

650 **4.1 Model simulations and input data sets**

651 We perform CLASSIC model simulations with the N cycle for the pre-industrial period  
652 followed by several simulations for the historical 1851-2017 period to evaluate the model's  
653 response to different forcings, as summarized below. The simulation for the pre-industrial period  
654 uses forcings that correspond to year 1850 and the model is run for thousands of years until its  
655 C and N pools come into equilibrium. Global thresholds of net atmosphere-land C flux of 0.05  
656 Pg/yr and net atmosphere-land N flux of 0.5 Tg N/yr are used to ensure the model pools have  
657 reached equilibrium. The pre-industrial simulation, therefore, yields the initial conditions from  
658 which the historical simulations for the period 1851-2017 are launched. To spin the mineral N  
659 pools to their initial values, the plant N uptake and other organic processes were turned off while

660 the model used specified values of  $V_{cmax}$  and only the inorganic part of N cycle was operative.  
661 Once the inorganic mineral soil N pools reached near equilibrium, the organic processes were  
662 turned on. The model also uses an accelerated spin up procedure for the slow pools of soil organic  
663 matter and mineral N. The input and output terms are multiplied by a factor greater than one  
664 and this magnifies the change in pool size and therefore accelerates the spin up. Once the model  
665 pools reach near equilibrium, the factor is set back to one.

666 To evaluate the model's response to various forcings over the historical period we  
667 perform several simulations turning on one forcing at a time as summarized in Table 1. The  
668 objective of these simulations is to see if the model response to individual forcings is consistent  
669 with expectations. For example, in the CO<sub>2</sub>-only simulation only atmospheric CO<sub>2</sub> concentration  
670 increases over the historical period, while all other forcings stay at their 1850 levels. In the N-  
671 DEP-only simulation only N deposition increases over the historical period, and similarly for other  
672 runs in Table 1. A "FULL" simulations with all forcings turned on is then also performed which we  
673 compare to the original model without a N cycle which uses the photosynthesis downregulation  
674 parameterization (termed "ORIGINAL" in Table 1). Finally, a separate pre-industrial simulation is  
675 also performed that uses the same  $\Gamma_1$  and  $\Gamma_2$  globally (FULL-no-implicit-P-limitation). This  
676 simulation is used to illustrate the effect of neglecting P limitation for the broadleaf evergreen  
677 tree PFT in the tropics.

678 For the historical period, the model is driven with time-varying forcings that include CO<sub>2</sub>  
679 concentration, population density (used by the fire module of the model for calculating  
680 anthropogenic fire ignition and suppression), land cover, and meteorological data. In addition,  
681 for the N cycle module, the model requires time-varying atmospheric N deposition and fertilizer

682 data. The atmospheric CO<sub>2</sub> and meteorological data (CRU-JRA) are same as those used for the  
683 TRENDY model intercomparison project for terrestrial ecosystem models for year 2018 (Le Quéré  
684 et al., 2018). The CRU-JRA meteorological data is based on 6-hourly Japanese Reanalysis (JRA).  
685 However, since reanalysis data typically do not match observations they are adjusted for monthly  
686 values based on the Climate Research Unit (CRU) data. This yields a blended product with sub-  
687 daily temporal resolution that comes from the reanalysis and monthly means/sums that match  
688 the CRU data to yield a meteorological product that can be used by models that require sub-daily  
689 or daily meteorological forcing. These data are available for the period 1901-2017. Since no  
690 meteorological data are available for the 1850-1900 period, we use 1901-1925 meteorological  
691 data repeatedly for this duration and also for the pre-industrial spin up. The assumption is that  
692 since there is no significant trend in the CRU-JRA data over this period, these data can be reliably  
693 used to spin up the model to equilibrium. The land cover data used to force the model are based  
694 on a geographical reconstruction of the historical land cover driven by the increase in crop area  
695 following Arora and Boer (2010) but using the crop area data prepared for the Global Carbon  
696 Project (GCP) 2018 following Hurt et al. (2020). Since land cover is prescribed, the competition  
697 between PFTs for space for the simulations reported here is switched off. The population data  
698 for the period 1850-2017 are based on Klein Goldewijk et al. (2017) and obtained from  
699 <ftp://ftp.pbl.nl/..../hyde/hyde3.2/baseline/zip/>. The time-independent forcings consist of soil  
700 texture and permeable depth data.

701 Time-varying atmospheric N deposition and fertilizer data used over the historical period  
702 are also specified as per the TRENDY protocol. The fertilizer data are based on the N<sub>2</sub>O model  
703 intercomparison project (NMIP) (Tian et al., 2018) and available for the period 1860-2014. For

704 the period before 1860, 1860 fertilizer application rates are used. For the period after 2014,  
705 fertilizer application rates for 2014 are used. Atmospheric N deposition data are from input4MIPs  
706 (<https://esgf-node.llnl.gov/search/input4mips/>) and are the same as used by models  
707 participating in CMIP6 for the historical period (1850-2014). For years 2015-2017 the N  
708 deposition data corresponding to those from representative concentration pathway (RCP) 8.5  
709 scenario are used. Figure 2 shows the time series of global annual values of externally specified  
710 fertilizer input, and deposition of ammonium and nitrate, based on the TRENDY protocol, for the  
711 six primary simulations. Geographical distribution of these inputs are also shown for the last 20  
712 years from the FULL simulation corresponding to the 1998-2017 period. In Figure 2 (panels a, c  
713 and e) ammonium and nitrate deposition, and fertilizer input stay at their pre-industrial level for  
714 simulations in which these forcings do not increase over the historical period. As mentioned  
715 earlier, N deposition is split evenly into ammonium and nitrate. The values in parenthesis in  
716 Figure 2a legend, and in subsequent time series plots, show average values over the 1850s, the  
717 last 20 years (1998-2017) of the simulations, and the change between these two periods. The  
718 present day values of fertilizer input and N deposition are consistent with other estimates  
719 available in the literature (Table 2). The fertilizer input rate in the simulation with all forcings  
720 except land use change (FULL-no-LUC, blue line), that is with no increase in crop area over its  
721 1850 value, is 50 Tg N yr<sup>-1</sup> compared to 91 Tg N yr<sup>-1</sup> in the FULL simulation, averaged over the  
722 1998-2017 period. The additional 41 Tg N yr<sup>-1</sup> of fertilizer input occurs in the FULL simulation due  
723 to the increase in crop area but also due to the increasing fertilizer application rates over the  
724 historical period. Geographical distribution of the fertilizer application rates in Figure 2b shows  
725 that they are concentrated in regions with crop area and with values as high as 16 gN m<sup>-2</sup> yr<sup>-1</sup>

726 especially in eastern China. The N deposition rates (Figure 2d, 2f) are more evenly distributed  
727 geographically than the fertilizer applications rates, as would be expected, since emissions are  
728 transported downstream from their point sources. Areas with high emissions like the eastern  
729 United States, India, eastern China, and Europe, however, still stand out as areas that receive  
730 higher N deposition.

731 **4.2 Evaluation data sources**

732 We compare globally-summed annual values of N pools and fluxes with observations and  
733 other models, and where available their geographical distribution and seasonality. In general,  
734 however, much less observation-based data are available to evaluate simulated terrestrial N  
735 cycle components than for C cycle components. As a result, N pools and fluxes are primarily  
736 compared to results from both observation-based studies and other modelling studies  
737 (Bouwman et al., 2013; Fowler et al., 2013; Galloway et al., 2004; Vitousek et al., 2013; Zaehle,  
738 2013). Since the primary purpose of the N cycle in our framework is to constrain the C cycle, we  
739 also compare globally-summed annual values of GPP and net atmosphere-land CO<sub>2</sub> flux, and their  
740 zonal distribution with available observation-based and other estimates. The observation-based  
741 estimate of GPP is from Beer et al. (2010), who apply diagnostic models to extrapolate ground-  
742 based carbon flux tower observations from about 250 stations to the global scale. Observation-  
743 based net atmosphere-land CO<sub>2</sub> flux is from Global Carbon Project's 2019 assessment  
744 (Friedlingstein et al., 2019).

745 **5.0 Results**

746 **5.1 N inputs – biological N fixation**

747 Figure 3 (panels a, c, e) shows the time series of annual values BNF and its natural and  
748 anthropogenic components from the six primary simulations summarized in Table 1. BNF stays  
749 at its pre-industrial value of around 80 Tg N yr<sup>-1</sup> in the CO2-only and N-DEP-only simulations. In  
750 the CLIM-only (indicated by magenta coloured line) and the FULL-no-LUC (blue line) simulations  
751 the change in climate, associated with increases in temperature and precipitation over the 1901-  
752 2017 period (see Figure A2 in the appendix), increases BNF to about 85 Tg N yr<sup>-1</sup>. In our  
753 formulation (equation 3) BNF is positively impacted by increases in temperature and  
754 precipitation. In the LUC+FERT-only simulation (dark green line) the increase in crop area  
755 contributes to an increase in global BNF with a value around 110 Tg N yr<sup>-1</sup> for the present day,  
756 since a higher BNF per unit crop area is assumed than for natural vegetation. Finally, in the FULL  
757 simulation (red line) the 1998-2017 average value is around 117 Tg N yr<sup>-1</sup> due both to changes in  
758 climate over the historical period and the increase in crop area. Our present day value of global  
759 BNF is broadly consistent with other modelling and data-based studies as summarized in Table 2.  
760 Panels c and e in Figure 3 show the decomposition of the total terrestrial BNF into its natural  
761 (over non-crop PFTs) and anthropogenic (over C<sub>3</sub> and C<sub>4</sub> crop PFTs) components. The increase in  
762 crop area over the historical period decreases natural BNF from its pre-industrial value of 59 to  
763 54 Tg N yr<sup>-1</sup> for the present day as seen for the LUC+FERT-only simulation (green line) in Figure  
764 3c, while anthropogenic BNF over agricultural area increases from 21 to 56 Tg N yr<sup>-1</sup> (Figure 3e).  
765 Figure 3c and 3e show that the increase in BNF (Figure 3a) in the FULL simulation is caused  
766 primarily by an increase in crop area. Our present day values of natural and anthropogenic BNF  
767 are also broadly consistent with other modelling and data-based studies as summarized in Table  
768 2.

769       Figure 3 (panels b, d, and f) shows the geographical distribution of simulated BNF and its  
770   natural and anthropogenic components. The geographical distribution of BNF (Figure 3a) looks  
771   very similar to the current distribution of vegetation (not shown) with warm and wet regions  
772   showing higher values than cold and dry regions since BNF is parameterized as a function of soil  
773   temperature and soil moisture. Anthropogenic BNF only occurs in regions where crop area exists  
774   according to the specified land cover and it exhibits higher values than natural BNF in some  
775   regions because of its higher value per unit area (see section 3.2.1).

776       At the global scale, and for the present day, natural BNF ( $59 \text{ Tg N yr}^{-1}$ ) is overwhelmed by  
777   anthropogenic sources: anthropogenic BNF ( $60 \text{ Tg N yr}^{-1}$ ), fertilizer input ( $91.7 \text{ Tg N yr}^{-1}$ ), and  
778   atmospheric N deposition increase since the pre-industrial era ( $\sim 45 \text{ Tg N yr}^{-1}$ ). Currently humanity  
779   fixes more N than the natural processes (Vitousek, 1994).

780   **5.2 C and N pools, fluxes response to historical changes in forcings**

781       To understand the model response to changes in various forcings over the historical  
782   period we first look at the evolution of global values of primary C and N pools, and fluxes, shown  
783   in Figures 4 through 8. Figure 4a shows the time evolution of global annual GPP values, the  
784   primary flux of C into the land surface, for the six primary simulations, the ORIGINAL simulation  
785   performed with the model version with no N cycle, and the ORIG-UNCONST simulation with no  
786   photosynthesis downregulation (see Table 1). The unconstrained increase in GPP ( $35.6 \text{ Pg C yr}^{-1}$   
787   over the historical period) in the ORIG-UNCONST simulation (dark cyan line) is governed by the  
788   standard photosynthesis model equations following Farquhar et al. (1980) and Collatz et al.  
789   (1992) for  $\text{C}_3$  and  $\text{C}_4$  plants, respectively. Downregulation of photosynthesis in the ORIGINAL

790 simulation (purple line) is modelled on the basis of equation (1), while in the FULL simulation (red  
791 line) photosynthesis downregulation results from a decrease in  $V_{cmax}$  values (Figure 5d) due to a  
792 decrease in leaf N amount (Figure 5b). We will compare the FULL and ORIGINAL simulations in  
793 more detail later. The simulations with individual forcings, discussed below, provide insight into  
794 the combined response of GPP to all forcings in the FULL simulation.

795 **5.2.1 Response to increasing CO<sub>2</sub>**

796 The response of C and N cycles to increasing CO<sub>2</sub> in the CO<sub>2</sub>-only simulation (orange lines  
797 in Figure 4) is the most straightforward to interpret. A CO<sub>2</sub> increase causes GPP to increase by 7.5  
798 Pg C yr<sup>-1</sup> above its pre-industrial value (Figure 4a), which in turn causes vegetation (Figure 4b),  
799 leaf (Figure 4c), and soil (Figure 4d) carbon mass to increase as well. The vegetation and leaf N  
800 amounts (orange line, Figures 5a and 5b), in contrast, decrease in response to increasing CO<sub>2</sub>.  
801 This is because N gets locked up in the soil organic matter pool (Figure 5c) in response to an  
802 increase in the soil C mass (due to the increasing GPP), litter inputs which are now rich in C (due  
803 to CO<sub>2</sub> fertilization) but poor in N (since N inputs are still at their pre-industrial level), and the fact  
804 that the C:N ratio of the soil organic matter is fixed at 13. This response to elevated CO<sub>2</sub> which  
805 leads to increased C and decreased N in vegetation is consistent with meta-analysis of 75 field  
806 experiments of elevated CO<sub>2</sub> (Cotrufo et al., 1998). A decrease in N in leaves (orange line, Figure  
807 5b) leads to a concomitant decrease in maximum carboxylation capacity ( $V_{cmax}$ ) (orange line,  
808 Figure 5d) and as a result GPP increases at a much slower rate in the CO<sub>2</sub>-only simulation than in  
809 the ORIG-UNCONST simulation (Figure 4a). Due to the N accumulation in the soil organic matter  
810 pool, the NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> (Figures 5e and 5f) pools also decrease in size in the CO<sub>2</sub>-only simulation.

811       Figure 6 shows the time series of N demand, plant N uptake and its split between passive  
812    and active N uptakes. The plant N demand in the CO<sub>2</sub>-only simulation (Figure 6a, orange line)  
813    increases from its pre-industrial value of 1512 Tg N/yr to 1639 Tg N/yr for the present day since  
814    the increasing C input from increasing GPP requires higher N input to maintain preferred  
815    minimum C:N ratio of plant tissues. However, since mineral N pools decrease in size over the  
816    historical period in this simulation (Figures 5e and 5f), the total plant N uptake (Figure 6b)  
817    reduces. Passive plant N uptake is directly proportional to pool sizes of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> and  
818    therefore it reduces in response to increasing CO<sub>2</sub>. Active plant N uptake, which compensates for  
819    insufficient passive N uptake compared to the N demand, also eventually starts to decline as it  
820    also depends on mineral N pool sizes. The eventual result of increased C supply and reduced N  
821    supply is an increase in the C:N ratio of all plant components and litter (Figure 7). The  
822    preindustrial total N uptake of around 960 Tg N/yr (Figure 6b) is lower than the preindustrial N  
823    demand (1512 Tg N/yr, Figure 6a) despite the sum of global NH<sub>4</sub> and NO<sub>3</sub> pool sizes being around  
824    4000 Tg N (Figures 5e and 5f). This is because of the mismatch between where the pools are high  
825    and where the vegetation actually grows and the fact that plant N uptake is limited by its rate.  
826    As a result, in our model, even in the preindustrial era vegetation is N limited.

827       Figure 8 shows the net mineralization flux (the net transfer of mineralized N from litter  
828    and humus pools to the mineral N pools as a result of the decomposition of organic matter),  
829    nitrification (N flux from NH<sub>4</sub><sup>+</sup> to the NO<sub>3</sub><sup>-</sup> pool), and the gaseous and leaching losses from the  
830    mineral pools. The net mineralization flux reduces in the CO<sub>2</sub>-only simulation (Figure 8a, orange  
831    line) as N gets locked up in the soil organic matter. A reduction in the NH<sub>4</sub><sup>+</sup> pool size in response  
832    to increasing CO<sub>2</sub> also yields a reduction in the nitrification flux over the historical period (Figure

833 8b, orange line) since nitrification depends on the  $\text{NH}_4^+$  pool size (equation 19). Finally, leaching  
834 from the  $\text{NO}_3^-$  pool (Figure 8c),  $\text{NH}_3$  volatilization (Figure 8d), and the gaseous losses associated  
835 with nitrification from the  $\text{NH}_4^+$  pool (Figure 8e) and denitrification from the  $\text{NO}_3^-$  pool (Figure 8f)  
836 all reduce in response to reduction in pool sizes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in the CO<sub>2</sub>-only simulation.

837 **5.2.2 Response to changing climate**

838 The perturbation due to climate change alone over the historical period in the CLIM-only  
839 simulation (magenta coloured lines in Figures 4 to 8) is smaller than that due to increasing CO<sub>2</sub>.  
840 In Figure 4a, changes in climate over the historical period increase GPP slightly by 3.60 Pg C yr<sup>-1</sup>  
841 which in turn slightly increases vegetation (including leaf) C mass (Figure 4b,c). The litter and soil  
842 carbon mass (Figure 4d), however, decrease slightly due to increased decomposition rates  
843 associated with increasing temperature (see Figure A2b). Both the increase in BNF due to  
844 increasing temperature (magenta line in Figure 2a), and the reduction in litter and soil N mass  
845 (Figure 5c) due to increasing decomposition and higher net N mineralization (Figure 8a, magenta  
846 line), make more N available. This results in a slight increase in vegetation and leaf N mass  
847 (Figures 5a and 5b) and the  $\text{NH}_4^+$  (Figure 5e) pool which is the primary mineral pool in soils under  
848 vegetated regions. The global  $\text{NO}_3^-$  pool, in contrast, decreases in the CLIM-only simulation  
849 (Figure 5f) with the reduction primarily occurring in arid regions where the  $\text{NO}_3^-$  amounts are very  
850 large (see Figure 9 that shows the geographical distribution of the primary C and N pools). The  
851 geographical distribution of  $\text{NH}_4^+$  (Figure 9a) generally follows the geographical distribution of  
852 BNF, but with higher values in areas where cropland exists and where N deposition is high. The  
853 geographical distribution of  $\text{NO}_3^-$  (Figure 9b) generally shows lower values than  $\text{NH}_4^+$  except in  
854 the desert regions where lack of denitrification leads to a large buildup of the  $\text{NO}_3^-$  pool (as

855 explained earlier in section 3.4.2). Although Figure 9 shows the geographical distribution of  
856 mineral N pools from the FULL simulation, the geographical distribution of pools are broadly  
857 similar between different simulations with obvious differences such as lack of hot spots of N  
858 deposition and fertilizer input in simulations in which these forcings stay at their pre-industrial  
859 levels. Figure 9 also shows the simulated geographical distribution of C and N pools in the  
860 vegetation and soil organic matter. The increase in GPP due to changing climate increases the N  
861 demand (Figure 6a, magenta line) but unlike the CO2-only simulation, the plant N uptake  
862 increases since the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools increase in size over the vegetated area in response to  
863 increased mineralization (Figure 8a, magenta line) and increased BNF (Figure 3a, magenta line).  
864 The increase in plant N uptake comes from the increase in passive plant N uptake (Figure 6c)  
865 while the active plant N uptake reduces (Figure 6d). Active and passive plant N uptakes are  
866 inversely correlated. This is by design since active plant N uptake increases when passive plant N  
867 uptake reduces and vice-versa, although eventually both depend on the size of available mineral  
868 N pools. Enhancement of plant N uptake due to changes in climate, despite increases in GPP  
869 associated with a small increase in  $V_{\text{cmax}}$  (Figure 5d), leads to a small reduction in the C:N ratio of  
870 all plant tissues (Figure 7). The litter C:N, in contrast, shows a small increase since not all N makes  
871 its way to the litter as a specified fraction of 0.54 (Table A1) leaf N is resorbed from deciduous  
872 trees leaves prior to leaf fall (Figure 7e). Although the leaf C:N ratio decreases in the CLIM only  
873 simulation, in response to increased BNF and increased mineralization, this decrease is not large  
874 enough to overcome the effect of resorption and as a result the C:N litter increases.

875           Finally, the small increase in pool sizes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  leads to a small increase in  
876   leaching, volatilization, and gaseous losses associated with nitrification and denitrification (Figure  
877   8).

878   **5.2.3 Response to N deposition**

879           The simulated response of GPP to changes in N deposition (brown line) over the historical  
880   period is smaller than that for  $\text{CO}_2$  and climate (Figure 4a). The small increase in GPP of 2.0 Pg C  
881    $\text{yr}^{-1}$  leads to commensurately small increases in vegetation (Figure 4b) and litter plus soil (Figure  
882   4d) C mass. Vegetation and leaf N mass (Figure 5a,b) also increase in response to N deposition  
883   and so do mineral pools of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  (Figure 5e,f). The increase in GPP in the simulation with  
884   N deposition results from an increase in  $V_{\text{cmax}}$  rates (Figure 5d) associated with an increase in leaf  
885   N amount (Figure 5b). N demand increases marginally and so does plant N uptake in response to  
886   N deposition (Figure 6). As would be intuitively expected, the C:N ratio of the whole plant, its  
887   components of leaves, stem, and root, and litter decreases slightly in response to N deposition  
888   (Figure 7). Net N mineralization, nitrification, leaching, volatilization, and gaseous losses  
889   associated with nitrification and denitrification all increase in response to N deposition (Figure  
890   8).

891   **5.2.4 Response to LUC and fertilizer input**

892           The simulated response to LUC, which reflects an increase in crop area, and increased  
893   fertilizer deposition rates over the historical period is shown by dark green lines in Figures 4  
894   through 8. The increase in fertilizer input is a much bigger perturbation to the N cycle system  
895   than N deposition. Figure 2 shows that at the global scale the fertilizer inputs increase from 0 to

896 ~92 Tg N/yr over the historical period, while the combined  $\text{NH}_4^+$  and  $\text{NO}_3^-$  N deposition rate  
897 increases from around 20 to 65 Tg N/yr. In addition, because of higher per unit area BNF rates  
898 over crop area than natural vegetation, the increase in crop area in this simulation leads to an  
899 increase in anthropogenic BNF from about 20 to 56 Tg N/yr over the historical period. All together  
900 increasing crop area and fertilizer inputs imply an additional ~130 Tg N/yr being input into the  
901 terrestrial N cycle at the present day since the pre-industrial period, compared to an increase of  
902 only 45 Tg N/yr for the N deposition forcing.

903 The global increase in fertilizer input over the historical period leads to higher  $\text{NH}_4^+$  and  
904  $\text{NO}_3^-$  pools (Figures 5e and 5f). Although both fertilizer and BNF contribute to the  $\text{NH}_4^+$  pool, the  
905  $\text{NO}_3^-$  pool also increases through the nitrification flux (Figure 8b). An increase in crop area over  
906 the historical period results in deforestation of natural vegetation that reduces vegetation  
907 biomass (Figure 4b). However, soil carbon mass also decreases (Figure 4d) despite higher litter  
908 inputs. This is because a higher soil decomposition rate is assumed over cropland areas to  
909 simulate soil carbon loss as empirical measurements of soil carbon show over deforested areas  
910 which are converted to croplands (Wei et al., 2014). Fertilizer application only occurs over crop  
911 areas which increases the  $V_{\text{cmax}}$  rates for crops and, as expected, this yields an increase in globally-  
912 averaged  $V_{\text{cmax}}$  (Figure 5d). A corresponding large increase in leaf N amount (Figure 5b) is,  
913 however, not seen because vegetation (and therefore leaf) N (Figure 5a,b) is also lost through  
914 deforestation. In addition,  $V_{\text{cmax}}$  is essentially a flux (expressed per unit leaf area) that is averaged  
915 over the whole year while leaf and vegetation N pools are sampled at the end of each year and  
916 all crops in the northern hemisphere above 30° N are harvested before the year end. Vegetation  
917 N mass, in fact, decreases in conjunction with vegetation C mass (Figure 4b). Plant N demand

918 reduces (Figure 6a) and plant N uptake increases (Figure 6b) driven by crop PFTs in response to  
919 fertilizer input, as would be intuitively expected. The increase in plant N uptake comes from the  
920 increase in passive N uptake, in response to increases in pool sizes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  over crop  
921 areas, while active plant N uptake decreases since passive uptake can more than keep up with  
922 the demand over cropland area. While the C:N ratio of vegetation biomass decreases over  
923 cropland area in response to fertilizer input (not shown) this is not seen in the globally-averaged  
924 C:N ratio of vegetation (Figure 7a) and its components because C and N are also lost through  
925 deforestation and the fact that crop biomass is harvested. The C:N of the global litter pool,  
926 however, decreases in response to litter from crops which gets rich in N as fertilizer application  
927 rates increase. Finally, in Figure 8, global net N mineralization, nitrification, leaching,  
928 volatilization, and gaseous losses associated with nitrification and denitrification all increase by  
929 a large amount in response to an increase in fertilizer input.

930 **5.2.5 Response to all forcings**

931 We can now evaluate and understand the simulated response of the FULL simulation to  
932 all forcings (red line in Figures 4 through 8). The increase in GPP in the FULL simulation (14.5 Pg  
933 C/yr) in Figure 4a over the historical period is driven by GPP increase associated with increase in  
934  $\text{CO}_2$  (7.5 Pg C/yr), changing climate (3.6 Pg C/yr), and N deposition (2.0 Pg C/yr). The increases  
935 associated with these individual forcings add up to 13.1 Pg C/yr indicating that synergistic effects  
936 between forcings contribute to the additional 1.4 Pg C/yr increase in GPP. The changes in  
937 vegetation and soil plus litter carbon mass (Figures 4b and 4d) in the FULL simulation are similarly  
938 driven by these three factors but, in addition, LUC contributes to decreases in vegetation and soil  
939 carbon mass as natural vegetation is deforested to accommodate for increases in crop area.

940 Vegetation and leaf N mass (Figures 5a and 5b) decrease in the FULL simulation driven primarily  
941 by the response to increasing CO<sub>2</sub> (orange line compared to the red line) while changes in litter  
942 and soil N mass are affected variably by all forcings (Figure 5c). Changes in V<sub>cmax</sub> (Figure 5d) are  
943 similarly affected by all forcings: increasing CO<sub>2</sub> leads to a decrease in globally-averaged V<sub>cmax</sub>  
944 values while changes in climate, N deposition, and fertilizer inputs lead to increases in V<sub>cmax</sub>  
945 values with the net result being a small decrease over the historical period. The increase in global  
946 NH<sub>4</sub><sup>+</sup> mass in the FULL simulation is driven primarily by the increase in fertilizer input (Figure 5e,  
947 red versus green line) while the changes in NO<sub>3</sub><sup>-</sup> mass are primarily the result of changes in  
948 climate (Figure 5f, magenta line) which causes a decrease in NO<sub>3</sub><sup>-</sup> mass from about 1940 to 1970  
949 and N deposition and fertilizer input (Figure 5f, green and brown lines) which contribute to the  
950 increase in NO<sub>3</sub><sup>-</sup> mass later on in the historical period. The increase in N demand (Figure 6a) over  
951 the historical period is also driven primarily by the increase in atmospheric CO<sub>2</sub>. Plant N uptake  
952 (Figure 6b) decreases in response to increasing CO<sub>2</sub> but increases in response to changes in  
953 climate, N deposition, and fertilizer inputs such that the net change over the historical is a small  
954 decrease. The increase in the C:N ratio of vegetation and its components (leaves, stem, and root)  
955 is driven primarily by an increase in atmospheric CO<sub>2</sub> (Figure 7a, red versus orange line). Litter  
956 C:N in the FULL simulation, in contrast, does not change substantially over the historical period  
957 in a globally-averaged sense as the increase in the C:N ratio of litter associated with an increase  
958 in atmospheric CO<sub>2</sub> is mostly compensated by the decrease associated with an increase in N  
959 deposition and fertilizer application. The simulated change in global net N mineralization (Figure  
960 8a) in the FULL simulation, over the historical period, is small since the decrease in net N  
961 mineralization due to increasing CO<sub>2</sub> (orange line) is compensated by the increase caused by

962 changes in climate, N deposition, and fertilizer inputs (magenta, brown, and green lines  
963 respectively). The remaining fluxes of nitrification,  $\text{NO}_3^-$  leaching,  $\text{NH}_3$  volatilization, and gaseous  
964 losses associated with nitrification and denitrification in the FULL simulation (Figure 8) are all  
965 strongly influenced by fertilizer input (green line compared to red line).

966 Table 2 compares simulated values of all primary N pools and fluxes from the FULL  
967 simulation with other modelling and quasi observation-based studies. Simulated values are  
968 averaged over the 1998-2017 period. Where available, time-periods for other modelling and  
969 quasi observation-based studies to which estimates correspond are also noted. For the most part  
970 simulated pools and fluxes lie within the range of existing studies with the exception of  $\text{N}_2$  and  
971 NO emissions that are somewhat higher.

972 **5.2.6 Response to all forcings except LUC**

973 The FULL-no-LUC simulation includes all forcings except LUC (blue line in Figures 4  
974 through 8) and corroborates several of the points mentioned above. In this simulation crop area  
975 stays at its 1850 value. Figure 2b (blue line) shows increasing global fertilizer input in this  
976 simulation despite crop area staying at its 1850 value since fertilizer application rates per unit  
977 area increase over the historical period. In the absence of the LUC, vegetation C mass (Figure 4b)  
978 and soil plus litter C (Figure 4d) and N (Figure 5c) are higher in the FULL-no-LUC compared to the  
979 FULL simulation. N demand (Figure 6a) is slightly higher in FULL-no LUC than in FULL simulation  
980 because there is more standing vegetation biomass that is responding to increasing  $\text{CO}_2$ . The  
981 increase in volatilization, leaching, and gaseous losses associated with nitrification and  
982 denitrification (Figures 8c-8f) are all primarily caused by increased fertilizer input over the

983 specified 1850 crop area. The increase in N losses associated with these processes, over the  
984 historical period, is much lower in the FULL-no-LUC simulation than in the FULL simulation since  
985 crop area stays at its 1850 values.

986 **5.3 Comparison of FULL and ORIGINAL simulations**

987 We now compare the results from the FULL simulation that includes the N cycle with that  
988 from the ORIGINAL simulation that does not include the N cycle. Both simulations are driven with  
989 all forcings over the historical period. Figure 4a shows that the global GPP values in the FULL (red  
990 line) and ORIGINAL (purple line) simulations are quite similar although the rate of increase of GPP  
991 in the FULL simulation is slightly higher than in the ORIGINAL simulation. As a result, simulated  
992 global vegetation biomass is somewhat higher in the FULL simulation (Figure 4b). The simulated  
993 global litter and soil carbon mass (Figure 4d) is, however, lower in the FULL simulation (1073 Pg  
994 C) compared to the ORIGINAL simulation (1142 Pg C) and this decrease mainly comes from a  
995 decrease at higher latitudes (not shown) due to a decrease in GPP (Figure 10a). The lower GPP in  
996 the FULL simulation, combined with the slow decomposition at cold high latitudes, results in a  
997 lower equilibrium for litter and soil carbon compared with the ORIGINAL simulation. Litter mass  
998 contributes about 80 Pg C to the total dead carbon mass. Overall both estimates of 1073 Pg C  
999 and 1142 Pg C are somewhat lower than the bulk density corrected estimate of 1230 Pg C based  
1000 on the Harmonized World Soil Database (HWSD) v.1.2 (Köchy et al., 2015). One reason for this is  
1001 that CLASSIC does not yet represent permafrost related soil C processes.

1002 Figure 10a shows that the zonal distribution of GPP from the FULL and ORIGINAL  
1003 simulations, for the 1998-2017 period, compares reasonably well to the observation-based

1004 estimate from Beer et al. (2010). The FULL simulation has slightly lower productivity at high-  
1005 latitudes than the ORIGINAL simulation, as mentioned above. Overall, however, the inclusion of  
1006 the N cycle does not change the zonal distribution of GPP in the model substantially, which is  
1007 determined primarily by the geographical distribution of climate. Figure 10b compares the zonal  
1008 distribution of GPP from the pre-industrial simulation (corresponding to 1850s) from the FULL  
1009 and FULL-with-no-implicit-P-limitation simulations to illustrate the high GPP in the tropics where  
1010 P and not N limitation affects GPP and the reason for choosing a lower value of  $\Gamma_1$  in equation  
1011 (31) for the broadleaf evergreen tree PFT.

1012 The global GPP in the ORIGINAL and FULL simulations averaged over the period 1998-  
1013 2017 (120.0 and 120.4 PgC/yr, respectively) are around 15% lower compared to that in the ORIG-  
1014 UNCONST simulation (142 PgC/yr), as shown in Figure 4a, yielding a global downregulation factor  
1015 of about 0.85. Figure 10c shows how downregulation works in the ORIGINAL and FULL  
1016 simulations in a zonally-averaged sense. Ratios of annual GPP averaged over the 1998-2017  
1017 period from the ORIGINAL versus ORIG-UNCONST simulations, and FULL versus ORIG-UNCONST  
1018 simulations were first calculated for each grid cell and then zonally-averaged over the land grid  
1019 cells. Ratios can be misleading especially for grid cells with low values, for example, in the desert  
1020 regions. In addition, these ratios also depend on the specified  $V_{cmax}$  values in the ORIG-UNCONST  
1021 simulation. In Figure 10c, the purple line for the ORIGINAL simulation exhibits values around 0.8  
1022 consistent with the global downregulation of around 0.85 and the fact that the same scalar  
1023 downregulation multiplier is used everywhere on the globe (equation 1). The red line for the FULL  
1024 simulation, however, indicates a pattern of higher downregulation at high-latitudes. The peaks  
1025 in red line, especially the one around 23°N (Sahara desert), are due to higher values in selected

1026 grid cells in dry and arid regions where the build-up of  $\text{NO}_3^-$  in the soil (due to reduced  
1027 denitrification) increases  $V_{\text{cmax}}$  and thus GPP in the run with N cycle leading to higher ratios  
1028 although the absolute GPP values still remain low.

1029 Figure 11a compares globally-summed net atmosphere-land  $\text{CO}_2$  flux from the FULL,  
1030 FULL-no-LUC, and ORIGINAL simulations with quasi observation-based estimates from the 2019  
1031 Global Carbon Project (Friedlingstein et al., 2019). There are two kinds of estimates in Figure 11a  
1032 from Friedlingstein et al. (2019): the first is the net atmosphere-land  $\text{CO}_2$  flux for the decades  
1033 spanning the 1960s to the 2000s which are shown as rectangular boxes with their corresponding  
1034 mean values and ranges, and the second is the terrestrial sink from 1959 to 2018 (dark yellow  
1035 line). Positive values indicate a sink of carbon over land and negative values a source. The  
1036 difference between the net atmosphere-land  $\text{CO}_2$  flux and the terrestrial sink is that the  
1037 terrestrial sink minus the LUC emissions yields the net atmosphere-land  $\text{CO}_2$  flux. The  
1038 atmosphere-land  $\text{CO}_2$  flux from the FULL-no-LUC simulation (blue line) is directly comparable to  
1039 the terrestrial sink since 1959, since the FULL-no-LUC simulation includes no LUC, and shows that  
1040 the simulated terrestrial sink compares fairly well to the estimates from Friedlingstein et al.  
1041 (2019). Averaged over the period 1959-2017, the modelled and Global Carbon Project values are  
1042 2.0 and 2.1 Pg C/yr, respectively. The net atmosphere-land  $\text{CO}_2$  flux from the FULL simulation  
1043 mostly lies within the uncertainty range for the five decades considered, although it is on the  
1044 higher side compared to estimates from Friedlingstein et al. (2019). The reason for this is that  
1045 LUC emissions in CLASSIC are much lower than observation-based estimates, as discussed below  
1046 in context of Figure 11c. CLASSIC simulates LUC emissions only in response to changes in crop  
1047 area whereas changes in pasture area and wood harvesting also contribute to LUC emissions. The

1048 net-atmosphere land CO<sub>2</sub> flux from the ORIGINAL simulation compares better with the estimates  
1049 from Friedlingstein et al. (2019), than the FULL simulation, because the photosynthesis down-  
1050 regulation parameter in the ORIGINAL simulation has been adjusted despite discrepancies in  
1051 simulated LUC processes.

1052 Figure 11b compares the zonal distribution of simulated net atmosphere-land CO<sub>2</sub> flux  
1053 from the FULL and ORIGINAL simulations with the model-mean and range from the terrestrial  
1054 ecosystem models that participated in the 2019 TRENDY model intercomparison and contributed  
1055 results to 2019 Global Carbon Project (Friedlingstein et al., 2019). The carbon sink simulated by  
1056 CLASSIC in the northern hemisphere is broadly comparable to the model-mean estimate from  
1057 the TRENDY models. However, in the tropics CLASSIC simulates a much stronger sink than the  
1058 model-mean, likely because of its lower LUC emissions.

#### 1059 **5.4 Contribution of forcings to land C sink and sources**

1060 Figure 11c shows cumulative net atmosphere-land CO<sub>2</sub> flux for the 1850-2017 period from  
1061 the six primary simulations with N cycle. These simulations facilitate the attribution of carbon  
1062 uptake and release over the historical period to various forcings. The cumulative terrestrial sink  
1063 in the FULL-no-LUC simulation for the period 1850-2017 is simulated to be ~153 Pg C and this  
1064 compares reasonably well with the estimate of 185 ± 50 Pg C for the period 1850-2014 from Le  
1065 Quéré et al. (2018). Increase in CO<sub>2</sub> (~115 Pg C), change in climate (~3 Pg C), and N deposition  
1066 (~19 Pg C) all contribute to this terrestrial sink. These three contributions add up to 137 Pg C so  
1067 the additional 16 Pg C is contributed by the synergistic effects between the three forcings.  
1068 Quantified in this way, the contribution of increasing CO<sub>2</sub> (115 out of 137 Pg C), climate change

1069 (3 out of 137 Pg C), and N deposition (19 out of 137 Pg C) to carbon uptake by land over the  
1070 historical period (1850-2017) is calculated to be 84%, 2%, and 14%, respectively. Cumulative LUC  
1071 emissions simulated for the period 1850-2017 by CLASSIC can be estimated using a negative  
1072 cumulative net-atmosphere-land CO<sub>2</sub> flux of ~66 Pg C from the LUC+FERT-only simulation or by  
1073 the differencing the FULL and FULL-no-LUC simulations (~71 Pg C). While LUC emissions are highly  
1074 uncertain, both of these estimates are much lower than the 195 ± 75 Pg C estimate from Le Quéré  
1075 et al. (2018).

1076 **6.0 Discussion and conclusions**

1077 The interactions between terrestrial C and N cycles are complex and our understanding  
1078 of these interactions, and their representation in models, is based on empirical observations of  
1079 various terrestrial ecosystem processes. In this paper, we have evaluated the response of these  
1080 interactions by perturbing the coupled C and N cycle processes in the CLASSIC model with one  
1081 forcing at a time over the historical period: 1) increase in CO<sub>2</sub>, 2) change in climate, 3) increase in  
1082 N deposition, and 4) LUC with increasing fertilizer input. These simulations are easier to interpret  
1083 and the model response can be evaluated against both our conceptual knowledge as well as  
1084 empirical observation-based data. Our assumption is that, if the model response to individual  
1085 forcings is realistic and consistent with expectations based on empirical observations then the  
1086 response of the model to all forcings combined will also be realistic and easier to interpret,  
1087 although we do expect and see synergistic effects between forcings.

1088 The simulated response of coupled C and N cycles in CLASSIC to increasing atmospheric  
1089 CO<sub>2</sub> is an increase in the C:N ratio of vegetation components due to an increase in their C content

1090 but also a decrease in their N content. This model response is conceptually consistent with a  
1091 meta-analysis of 75 field experiments of elevated CO<sub>2</sub> as reported in Cotrufo et al. (1998) who  
1092 find an average reduction in tissue N concentration of 14%. Most studies analyzed in the Cotrufo  
1093 et al. (1998) meta-analysis used ambient CO<sub>2</sub> of around 350 ppm and elevated CO<sub>2</sub> of around  
1094 650-700 ppm. In comparison, the plant N concentration in CLASSIC reduces by ~26% in response  
1095 to a gradual increase in atmospheric CO<sub>2</sub> from 285 ppm to 407 ppm (an increase of 122 ppm)  
1096 over the 1850-2017 period (whole plant C:N ratio increases from 142.6 to 194.1 in the CO<sub>2</sub>-only  
1097 simulation, Figure 7a). These two estimates cannot be compared directly - the majority (59%) of  
1098 Free-Air Carbon dioxide Enrichment (FACE) experiments last less than 3 years (Jones et al., 2014)  
1099 and the vegetation experiences a large CO<sub>2</sub> change of around 300-350 ppm while the duration of  
1100 our historical simulation is 167 years and the gradual increase in CO<sub>2</sub> of 122 ppm over the  
1101 historical period is much smaller.

1102 The response of our model to CO<sub>2</sub> increase over the historical period is also consistent  
1103 with the meta-analysis of McGuire et al. (1995) who report an average decrease in leaf N  
1104 concentration of 21% in response to elevated CO<sub>2</sub> based on 77 studies, which is the primary  
1105 reason for downregulation of photosynthetic capacity. The simulated decrease in leaf N  
1106 concentration in our study for the CO<sub>2</sub>-only experiment is around 27% (leaf C:N ratio increases  
1107 from 42.8 to 58.6 in the CO<sub>2</sub>-only simulation, Figure 7b). Although, the same caveats that apply  
1108 to the comparison with the Cotrufo et al. (1998) study also apply to this comparison. The  
1109 decrease in whole plant and leaf N concentrations in our results is conceptually consistent with  
1110 the meta-analyses of McGuire et al. (1995) and Cotrufo et al. (1998). The decrease in whole plant  
1111 N concentration in our CO<sub>2</sub>-only and FULL simulations is the result of an increase in both tissue

1112 C amount and a decrease in N amount. The decrease in tissue N amount is, in fact, necessary in  
1113 our modelling framework to induce the required downregulation of photosynthesis to simulate  
1114 the land carbon sink realistically over the historical period.

1115 The meta-analysis of Liang et al. (2016) reports an increase in above and belowground  
1116 plant N pools in response to elevated CO<sub>2</sub> associated with increase in BNF but since their results  
1117 are based on pool sizes they cannot be compared directly to the N concentration based results  
1118 from McGuire et al. (1995) and Cotrufo et al. (1998). Liang et al. (2016) also report results from  
1119 short-term ( $\leq 3$  years) and long-term (between 3 to 15 years) studies separately (their Figure 3).  
1120 They show that the increase in total plant and litter N pools become smaller for long-term studies.  
1121 Regardless, the difference in time scales of empirical studies and the real world is a caveat that  
1122 will always make it difficult to evaluate model results over long time scales.

1123 The response of C and N cycles to changes in climate in our model (in the CLIM-only  
1124 simulation) is also conceptually realistic. Globally, GPP increases in response to climate that  
1125 gradually gets warmer and wetter (see Figure A2) and as a result vegetation biomass increases.  
1126 Soil carbon mass, however, decreases (despite increase in NPP inputs) since warmer  
1127 temperatures also increase heterotrophic respiration (not shown). As a result of increased  
1128 decomposition of soil organic matter, net N mineralization increases and together with increased  
1129 BNF the overall C:N ratio of vegetation and leaves decreases, which leads to a  $V_{cmax}$  increase. The  
1130 small increase in  $V_{cmax}$ , due to increased mineralization, thus also contributes to an increase in  
1131 GPP over and above that due to a change in climate alone, and therefore compensates for the  
1132 amount of carbon lost due to increased soil organic matter decomposition associated with  
1133 warmer temperatures. This behaviour is consistent with land C cycle models showing a reduction

1134 in the absolute value of the strength of the carbon-climate feedback when they include coupling  
1135 of C and N cycles (Arora et al., 2020).

1136 The modelled differences in PFT specific values of  $V_{cmax}$ , in our framework, come through  
1137 differences in simulated values of leaf N amount ( $N_L$ ) that depend on BNF (given that BNF is the  
1138 primary natural source of N input into the coupled soil-vegetation system) but also differences  
1139 in mineralization that are governed by climate.  $N_L$  values, however, also depend on leaf  
1140 phenology, allocation of carbon and nitrogen, turnover rates, transpiration (which brings in N  
1141 through passive uptake), and almost every aspect of plant biogeochemistry which affects a PFT's  
1142 net primary productivity and therefore N demand. Modelled increases in GPP in response to N  
1143 deposition come through an increase in leaf N amount and therefore  $V_{cmax}$  values.

1144 Finally, changes in land use associated with an increase in crop area, and the associated  
1145 increase in fertilizer application rates lead to the largest increase in  $\text{NO}_3^-$  leaching,  $\text{NH}_3$   
1146 volatilization, and gaseous losses associated with nitrification and denitrification among all  
1147 forcings. Overall, the model response to perturbation by all individual forcings is realistic,  
1148 conceptually expected, and of the right sign (positive or negative) although it is difficult to  
1149 evaluate the magnitude of these responses in the absence of directly comparable observation-  
1150 based estimates.

1151 Despite the model responses to individual forcings that appear consistent with our  
1152 conceptual understanding of coupled C and N cycles, our modelling framework misses an  
1153 important feedback process that has been observed in the FACE and other experiments related  
1154 to changes in natural BNF. FACE sites and other empirical studies report an increase in natural

1155 BNF rates at elevated CO<sub>2</sub> (McGuire et al., 1995; Liang et al., 2016) and a decrease in natural BNF  
1156 rates when additional N is applied to soils (Salvagiotti et al., 2008; Ochoa-Hueso et al., 2013). On  
1157 a broad scale this is intuitively expected but the biological processes behind changes in BNF rates  
1158 remain largely unclear. A response can still be parameterized even if the underlying physical and  
1159 biological processes are not well understood. For instance, Goll et al. (2012) parameterize BNF as  
1160 an increasing and saturating function of NPP,  $BNF = 1.8 (1.0 - \exp(-0.003 NPP))$ . This  
1161 approach, however, does not account for the driver behind the increase in NPP - increasing  
1162 atmospheric CO<sub>2</sub>, change in environmental conditions (e.g., wetter and warmer conditions), or  
1163 increased N deposition. Clearly, increasing BNF if the NPP increase is due to N deposition is  
1164 inconsistent with empirical observations. Over the historical period an increase in atmospheric  
1165 CO<sub>2</sub> has been associated with an increase in N deposition so to some extent changes in BNF due  
1166 to both forcings will cancel each other. We realize the importance of changes in BNF, given it is  
1167 the single largest natural flux of N into the coupled soil-vegetation system yet highly uncertain,  
1168 and aim to address these issues in a future version of the model by exploring existing BNF  
1169 formulations. Meyerholt et al. (2016), for example, demonstrate the uncertainty arising from the  
1170 use of five different BNF parameterizations in the context of the O-CN model. They use  
1171 formulations that parameterize BNF as a function of 1) evapotranspiration, 2) NPP, 3) leaf C:N  
1172 ratio, that takes into account energy cost for N fixation (Fisher et al., 2010), 4) plant N demand,  
1173 and 5) an optimality-based approach that follows Rastetter et al. (2001) in which BNF only occurs  
1174 when the carbon cost of N fixation is lower than the carbon cost of root N uptake. The approach  
1175 used in our study is closest to the one that is based on evapotranspiration but makes the  
1176 distinction in BNF rates over natural and agricultural areas.

1177 The reduction of photosynthesis rates in response to N limitation is the most important  
1178 linkage between C and N cycles and yet it too is parameterized differently across models. Given  
1179 that leaf N amount and photosynthetic capacity are strongly correlated (Evans, 1989; Field and  
1180 Mooney, 1986; Garnier et al., 1999), photosynthesis downregulation due to N limitation reduces  
1181 photosynthetic capacity, and thus the GPP flux. Yet models reduce both NPP (Wiltshire et al.,  
1182 2020) and  $V_{cmax}$  rates, and thus GPP, (Zaehle and Friend, 2010; Wania et al., 2012; von Bloh et al.,  
1183 2018) in response to N limitation.  $V_{cmax}$  rates may themselves be parameterized as a function leaf  
1184 N amount directly (von Bloh et al., 2018; Zaehle and Friend, 2010) or leaf C:N ratio (Wania et al.,  
1185 2012). In this study, we have parameterized  $V_{cmax}$  rates as a function of leaf N amount (equation  
1186 31) since the use of leaf C:N ratio leads to an incorrect seasonal variation of  $V_{cmax}$ . If an increase  
1187 in leaf C:N ratio, as a result of increase in atmospheric CO<sub>2</sub>, leads to a decrease in  $V_{cmax}$  rates over  
1188 the historical period then it implies that  $V_{cmax}$  is inversely related to leaf C:N ratios. Since leaf C:N  
1189 ratio peak during the growing season (Li et al., 2017) this also implies  $V_{cmax}$  rates are lower during  
1190 the peak growing season than at its start and this is in contrast to observations that show an  
1191 increase in  $V_{cmax}$  during the growing season (e.g., see Fig. 1a of Bauerle et al. (2012)).

1192 Our framework assumes a constant C:N ratio of 13 for soil organic matter ( $C:N_H$ ), an  
1193 assumption also made in other models (e.g., Wania et al., 2012; Zhang et al., 2018). This  
1194 assumption is also broadly consistent with Zhao et al. (2019) who attempt to model C:N of soil  
1195 organic matter, among other soil properties, as a function of mean annual temperature and  
1196 precipitation using machine learning algorithms (their Figure 2h). It is difficult to currently  
1197 establish if increasing atmospheric CO<sub>2</sub> is changing  $C:N_H$  given the large heterogeneity in soil  
1198 organic C and N densities, and the difficulty in measuring small trends for such large global pools.

1199 A choice of a somewhat different value for all PFTs or had we chosen specified constant PFT-  
1200 dependent values of  $C:N_H$  is of relatively less importance in this context since the model is spun  
1201 to equilibrium for 1850 conditions anyway. It is the change in  $C:N_H$  over time that is of  
1202 importance. The assumption of constant  $C:N_H$  is the key to yielding a decrease in vegetation N  
1203 mass, and therefore leaf N mass and  $V_{cmax}$ , as  $CO_2$  increases, in our framework. Without a  
1204 decrease in  $V_{cmax}$  in our modelling framework, in response to elevated  $CO_2$ , we cannot achieve  
1205 the downregulation noted by McGuire et al. (1995) in their meta-analysis, and the simulated  
1206 carbon sink over the historical period would be greater than observed as noted above. It is  
1207 possible that we are simulating the reduction in leaf N mass, in response to elevated  $CO_2$ , for a  
1208 wrong reason in which case our model processes need to be revisited based on additional  
1209 empirical data. If our assumption of constant or extremely slowly changing  $C:N_H$  is indeed  
1210 severely unrealistic, this necessitates a point of caution that a realistic land carbon sink can be  
1211 simulated over the historical period with such an assumption.

1212 Related to this assumption is also the fact that we cannot make decomposition rates of  
1213 soil organic matter a function of its C:N ratio since it is assumed to be a constant. It is well known  
1214 that after climate, litter and soil organic matter decomposition rates are controlled by their C:N  
1215 ratio (Manzoni et al., 2008). Litter decomposition rates can still be made a function of its C:N ratio  
1216 and we aim to do this for a future model version.

1217 The work presented in this study of coupling C and N cycles in CLASSIC yields a framework  
1218 that we can build upon to make model processes more realistic, test the effect of various model  
1219 assumptions, parameterize existing processes in other ways, include additional processes, and  
1220 evaluate model response at FluxNet sites to constrain model parameters.

1221 **Appendix**

1222

1223 **A1. Budget equations for N pools**

1224 The rates of change of N in the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools (in  $\text{gN m}^{-2}$ ),  $N_{\text{NH}_4}$  and  $N_{\text{NO}_3}$ ,  
1225 respectively, are given by

1227

$$\frac{d N_{\text{NH}_4}}{dt} = B_{\text{NH}_4} + F_{\text{NH}_4} + P_{\text{NH}_4} + M_{D,\text{NH}_4} + M_{H,\text{NH}_4} - U_{\text{NH}_4} - (I_{\text{NO}_3} + I_{\text{N}_2\text{O}} + I_{\text{NO}}) - V_{\text{NH}_3} - O_{\text{NH}_4} \quad (\text{A1})$$

1226

1228

$$\frac{d N_{\text{NO}_3}}{dt} = P_{\text{NO}_3} + I_{\text{NO}_3} - L_{\text{NO}_3} - U_{\text{NO}_3} - (E_{\text{N}_2} + E_{\text{N}_2\text{O}} + E_{\text{NO}}) - O_{\text{NO}_3} \quad (\text{A2})$$

1229 and all fluxes are represented in units of  $\text{gN m}^{-2} \text{ day}^{-1}$ .  $B_{\text{NH}_4}$  is the rate of biological N fixation  
1230 which solely contributes to the  $\text{NH}_4^+$  pool,  $F_{\text{NH}_4}$  is the fertilizer input which is assumed to  
1231 contribute only to the  $\text{NH}_4^+$  pool, and  $P_{\text{NH}_4}$  and  $P_{\text{NO}_3}$  are atmospheric deposition rates that  
1232 contribute to the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools, respectively. Biological N fixation, fertilizer input, and  
1233 atmospheric deposition are the three routes through which N enters the coupled soil-vegetation  
1234 system.  $M_{D,\text{NH}_4}$  and  $M_{H,\text{NH}_4}$  are the mineralization flux from the litter and soil organic matter  
1235 pools, respectively, associated with their decomposition. We assume mineralization of humus  
1236 and litter pools only contributes to the  $\text{NH}_4^+$  pool.  $O_{\text{NH}_4}$  and  $O_{\text{NO}_3}$  indicate immobilization of N  
1237 from the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools, respectively, to the humus N pool which implies microbes (that  
1238 are not represented explicitly) are part of the humus pool. Combined together the terms  
1239 ( $M_{D,\text{NH}_4} + M_{H,\text{NH}_4} - O_{\text{NH}_4} - O_{\text{NO}_3}$ ) yield the net mineralization rate.  $V_{\text{NH}_3}$  is the rate of  
1240 ammonia ( $\text{NH}_3$ ) volatilization and  $L_{\text{NO}_3}$  is the leaching of N that occurs only from the  $\text{NO}_3^-$  pool.

1241 The positively charged ammonium ions are attracted to the negatively charged soil particles and  
 1242 as a result it is primarily the negatively charged nitrate ions that leach through the soil (Porporato  
 1243 et al., 2003; Xu-Ri and Prentice, 2008).  $U_{NH4}$  and  $U_{NO3}$  are uptakes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  by plants,  
 1244 respectively. The nitrification flux from  $\text{NH}_4^+$  to  $\text{NO}_3^-$  pool is represented by  $I_{NO3}$  which also results  
 1245 in the release of the nitrous oxide ( $\text{N}_2\text{O}$ ), a greenhouse gas, and nitric oxide (NO) through nitrifier  
 1246 denitrification represented by the terms  $I_{N2O}$  and  $I_{NO}$ , respectively. Finally,  $E_{N2}$ ,  $E_{N2O}$ , and  $E_{NO}$   
 1247 are the gaseous losses of  $\text{N}_2$  (nitrogen gas),  $\text{N}_2\text{O}$ , and NO from the  $\text{NO}_3^-$  pool associated with  
 1248 denitrification. N is thus lost through the soil-vegetation system via leaching in runoff and  
 1249 through gaseous losses of  $I_{N2O}$ ,  $I_{NO}$ ,  $E_{N2}$ ,  $E_{N2O}$ ,  $E_{NO}$ , and  $V_{NH3}$ .

1250 The structural and non-structural N pools in root are written as  $N_{R,S}$  and  $N_{R,NS}$ ,  
 1251 respectively, and similarly for stem ( $N_{S,S}$  and  $N_{S,NS}$ ) and leaves ( $N_{L,S}$  and  $N_{L,NS}$ ), and together the  
 1252 structural and non-structural pools make the total N pool in leaf ( $N_L = N_{L,S} + N_{L,NS}$ ), root ( $N_R =$   
 1253  $N_{R,S} + N_{R,NS}$ ), and stem ( $N_S = N_{S,S} + N_{S,NS}$ ) components. The rate change equation for  
 1254 structural and non-structural N pools in root are given by

$$1255 \quad \frac{dN_{R,NS}}{dt} = U_{NH4} + U_{NO3} + R_{L2R} - R_{R2L} - A_{R2L} - A_{R2S} - LF_{R,NS} - T_{R,NS2S} \quad (\text{A3})$$

$$1256 \quad \frac{dN_{R,S}}{dt} = T_{R,NS2S} - LF_{R,S} \quad (\text{A4})$$

1257 Similar to the uptake of carbon by leaves and its subsequent allocation to root and stem  
 1258 components, N is taken up by roots and then allocated to leaves and stem.  $A_{R2L}$  and  $A_{R2S}$   
 1259 represent the allocation of N from roots to leaves and stem, respectively. The terms  $R_{L2R}$  and  
 1260  $R_{R2L}$  represent the reallocation of N between the non-structural components of root and leaves.  
 1261  $R_{L2R}$  is the N reallocated from leaves to root representing resorption of a fraction of leaf N during

1262 leaf fall for deciduous tree PFTs.  $R_{R2L}$  indicates reallocation of N from roots to leaves (termed  
 1263 reallocation in Figure 2) at the time of leaf-out for deciduous tree PFTs. At times other than leaf-  
 1264 out and leaf-fall and for other PFTs these two terms are zero.  $T_{R,NS2S}$  is the one way transfer of  
 1265 N from the non-structural to the structural root pool, and similar to the carbon pools, once N is  
 1266 converted to its structural form it cannot be converted back to its non-structural form. Finally,  
 1267 the litterfall due to turnover of roots occurs from both the structural ( $LF_{R,S}$ ) and non-structural  
 1268 ( $LF_{R,NS}$ ) N pools.

1269 The rate change equations for non-structural and structural components of leaves are  
 1270 written as

$$1271 \frac{dN_{L,NS}}{dt} = A_{R2L} - R_{L2R} - R_{L2S} + R_{R2L} + R_{S2L} - LF_{L,NS} - T_{L,NS2S} \quad (A5)$$

$$1272 \frac{dN_{L,S}}{dt} = T_{L,NS2S} - LF_{L,S} \quad (A6)$$

1273 where  $T_{L,NS2S}$  is the one way transfer of N from the non-structural leaf component to its  
 1274 structural N pool and  $R_{S2L}$  indicates reallocation of N from stem to leaves (similar to  $R_{R2L}$ ) at the  
 1275 time of leaf out for deciduous tree PFTs. Litterfall occurs from both the structural ( $LF_{L,S}$ ) and non-  
 1276 structural ( $LF_{L,NS}$ ) N pools of leaves, and all other terms have been previously defined.

1277 Finally, the rate change equations for non-structural and structural components of stem  
 1278 are written as

$$1279 \frac{dN_{S,NS}}{dt} = A_{R2S} + R_{L2S} - R_{S2L} - LF_{S,NS} - T_{S,NS2S} \quad (A7)$$

$$1280 \frac{dN_{S,S}}{dt} = T_{S,NS2S} - LF_{S,S} \quad (A8)$$

1281 where  $LF_{S,NS}$  and  $LF_{S,S}$  represent stem litter from the non-structural and structural components,  
 1282  $T_{S,NS2S}$  is the one way transfer of N from the non-structural stem component to its structural N  
 1283 pool. All other terms have been previously defined.

1284 Adding equations (6) through (11) yields rate of change of N in the entire vegetation pool  
 1285 ( $N_V$ ) as

$$\frac{d N_V}{dt} = \frac{d N_{R,NS}}{dt} + \frac{d N_{R,S}}{dt} + \frac{d N_{L,NS}}{dt} + \frac{d N_{L,S}}{dt} + \frac{d N_{S,NS}}{dt} + \frac{d N_{S,S}}{dt} = \frac{d N_R}{dt} + \frac{d N_L}{dt} + \frac{d N_S}{dt}$$

1286

$$\begin{aligned} \frac{d N_V}{dt} &= U_{NH4} + U_{NO3} - LF_{R,NS} - LF_{R,S} - LF_{L,NS} - LF_{L,S} - LF_{S,NS} - LF_{S,S} \\ &= U_{NH4} + U_{NO3} - LF_R - LF_L - LF_S \end{aligned} \quad (A9)$$

1287 which indicates how the dynamically varying vegetation N pool is governed by mineral N uptake  
 1288 from the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  pools and litterfall from the structural and non-structural components of  
 1289 the leaves, stem, and root pools.  $LF_R$  is the total N litter generation from the root pool and sum  
 1290 of litter generation from its structural and non-structural components ( $LF_R = LF_{R,S} + LF_{R,NS}$ ),  
 1291 and similarly for the leaves ( $LF_L$ ) and the stem ( $LF_S$ ) pools.

1292 The rate change equations for the organic N pools in the litter ( $N_D$ ) and soil ( $N_H$ ) pools  
 1293 are written as follows.

$$\frac{d N_D}{dt} = LF_R + LF_L + LF_S - H_{N,D2H} - M_{D,NH4} \quad (A10)$$

$$\frac{d N_H}{dt} = H_{N,D2H} + O_{NH4} + O_{NO3} - M_{H,NH4} \quad (A11)$$

1296 where  $H_{N,D2H}$  is the transfer of humidified organic matter from litter to the soil organic matter  
 1297 pool, and all other terms have been previously defined.

1299

1300 **Acknowledgments**

1301 We are grateful and thank Joe Melton and Paul Bartlett for their comments on an earlier version  
1302 of this manuscript. We are grateful to one anonymous reviewer, and David Wårlind, for their  
1303 reviewer comments which greatly improved this manuscript. We also gratefully acknowledge  
1304 Sönke Zaehle, the handling editor for this paper, for his time and effort.

1305

1306 **Code/Data availability**

1307 Model code for the operational CLASSIC model can be obtained from  
1308 <https://gitlab.com/cccma/classic>. Changes made to the operational version to include N cycle  
1309 and the results shown here can be obtained from the second author.

1310

1311 **Author contributions**

1312 A.A. implemented the N cycle in the CLASSIC code, put together all the N cycle related input  
1313 data, and performed all the simulations. V.A. and A.A. wrote the manuscript.

1314

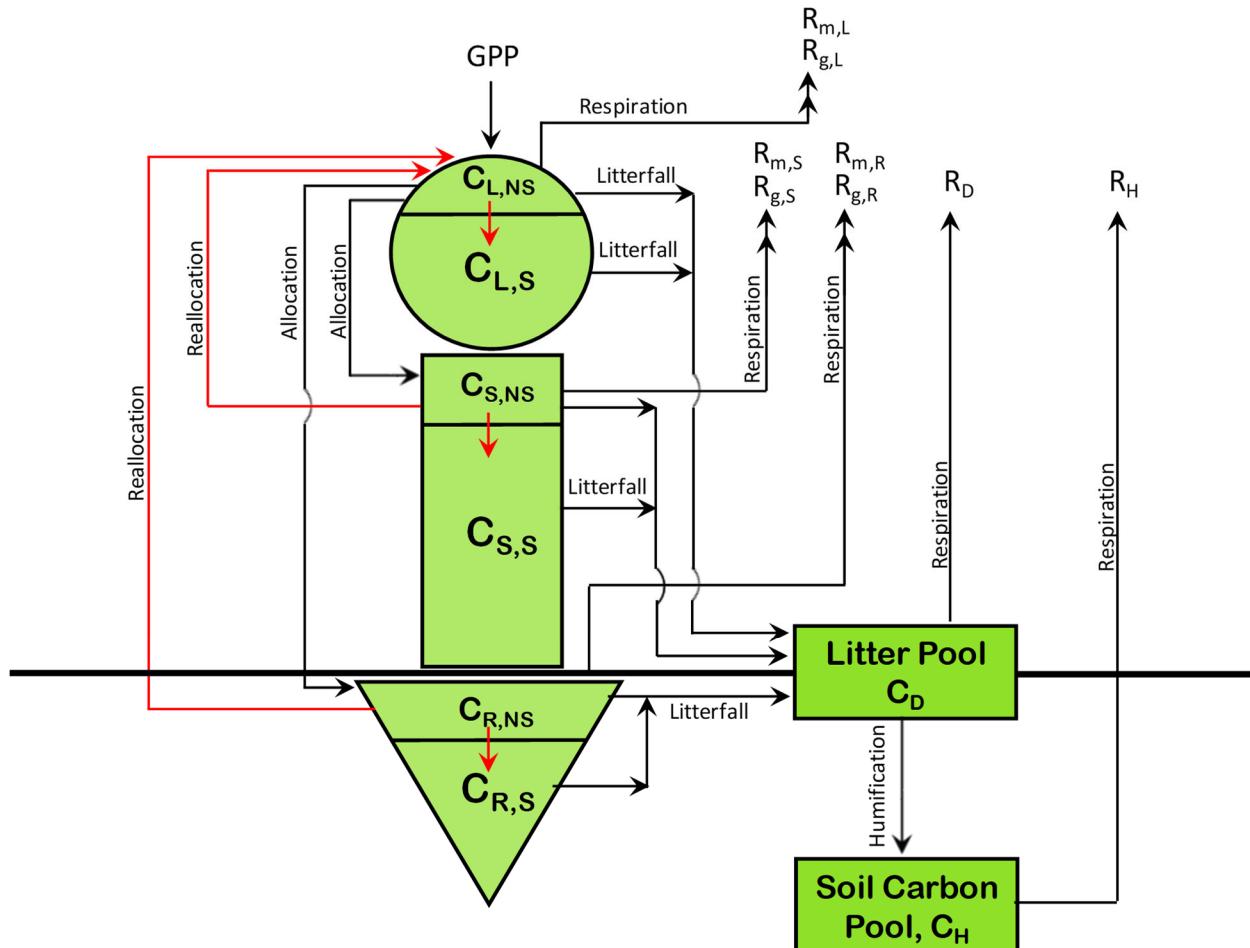

1315 **Competing interests**

1316 There are no competing interests.

1346

1347 **Table 1:** Historical simulations performed over the period 1851-2017 to evaluate the model's  
 1348 response to various forcings. All forcings are time varying. All forcings are also spatially explicit  
 1349 except atmospheric CO<sub>2</sub> for which a globally constant value is specified.

1350

| Simulation name  | Forcing that varies over the historical period  | N cycle  |
|--|---|--|
| <b><i>Primary simulations performed to evaluate N cycle response to various forcings</i></b> |   |  |
| 1. CO <sub>2</sub> -only   | Atmospheric CO <sub>2</sub> concentration   | Runs with N cycle  |
| 2. CLIM-only   | 1901-1925 meteorological data are used twice over the 1850-1900 period. For the 1901-2017 period, meteorological data for the correct year is used. |  |
| 3. LUC+FERT-only   | Land cover with increasing crop area, and fertilizer application rates over the crop area   |  |
| 4. N-DEP-only  | N deposition of ammonia and nitrate   |  |
| 5. FULL  | All forcings  |  |
| 6. FULL-no-LUC   | All forcings except increasing crop area  |  |
| <b><i>Other simulations</i></b>  |   |  |
| 7. ORIGINAL  | All forcings  | Runs without N cycle using the original model configuration. |
| 8. ORIG-UNCONST  | All forcings but with downregulation turned off   |  |
| 9. FULL-no-implicit-P-limitation   | All forcings but using same $\Gamma_1$ and $\Gamma_2$ globally  | Run with N cycle   |

1351

1352

1353

1354 **Table 2:** Comparison of simulated global N pools and fluxes, from the FULL simulation, with other  
 1355 modelling and quasi observation-based studies (references for which are noted as superscripts  
 1356 and listed below the table). The time-periods to which the other modelling and quasi  
 1357 observation-based estimates correspond are also noted, where available. The estimates are for  
 1358 land. Simulated fluxes and pool corresponds to the period 1997-2018.

1359

| N pool and fluxes                      |                                      | This study (1998-2017) | Other model and quasi observation-based estimates |

1360

1361

1362

1363

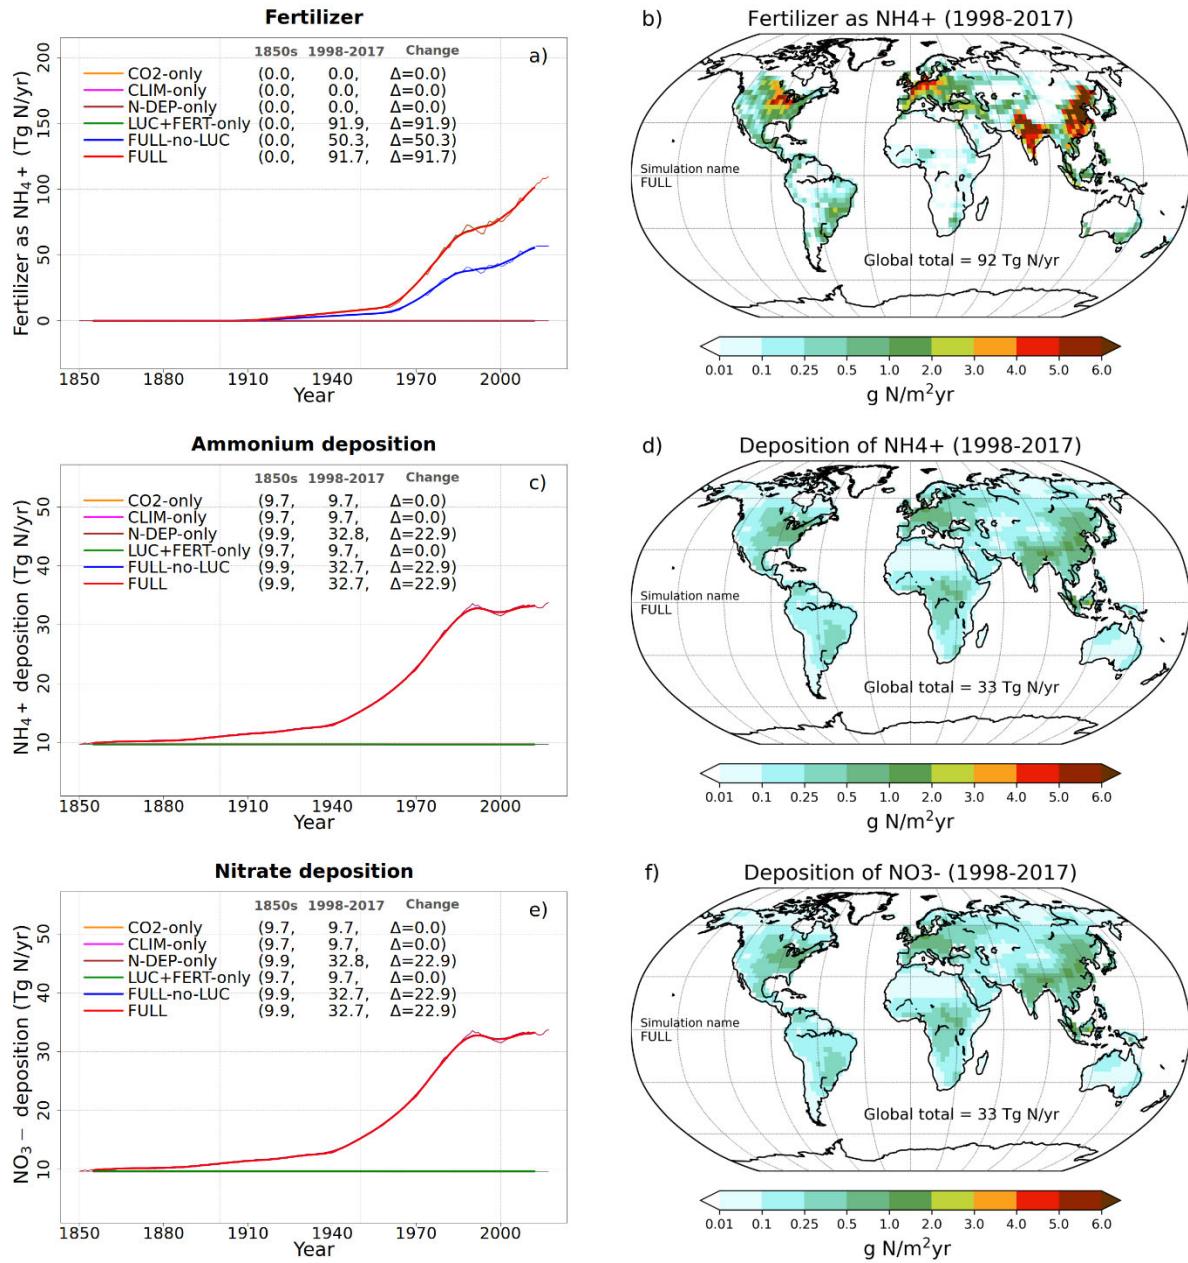

1364

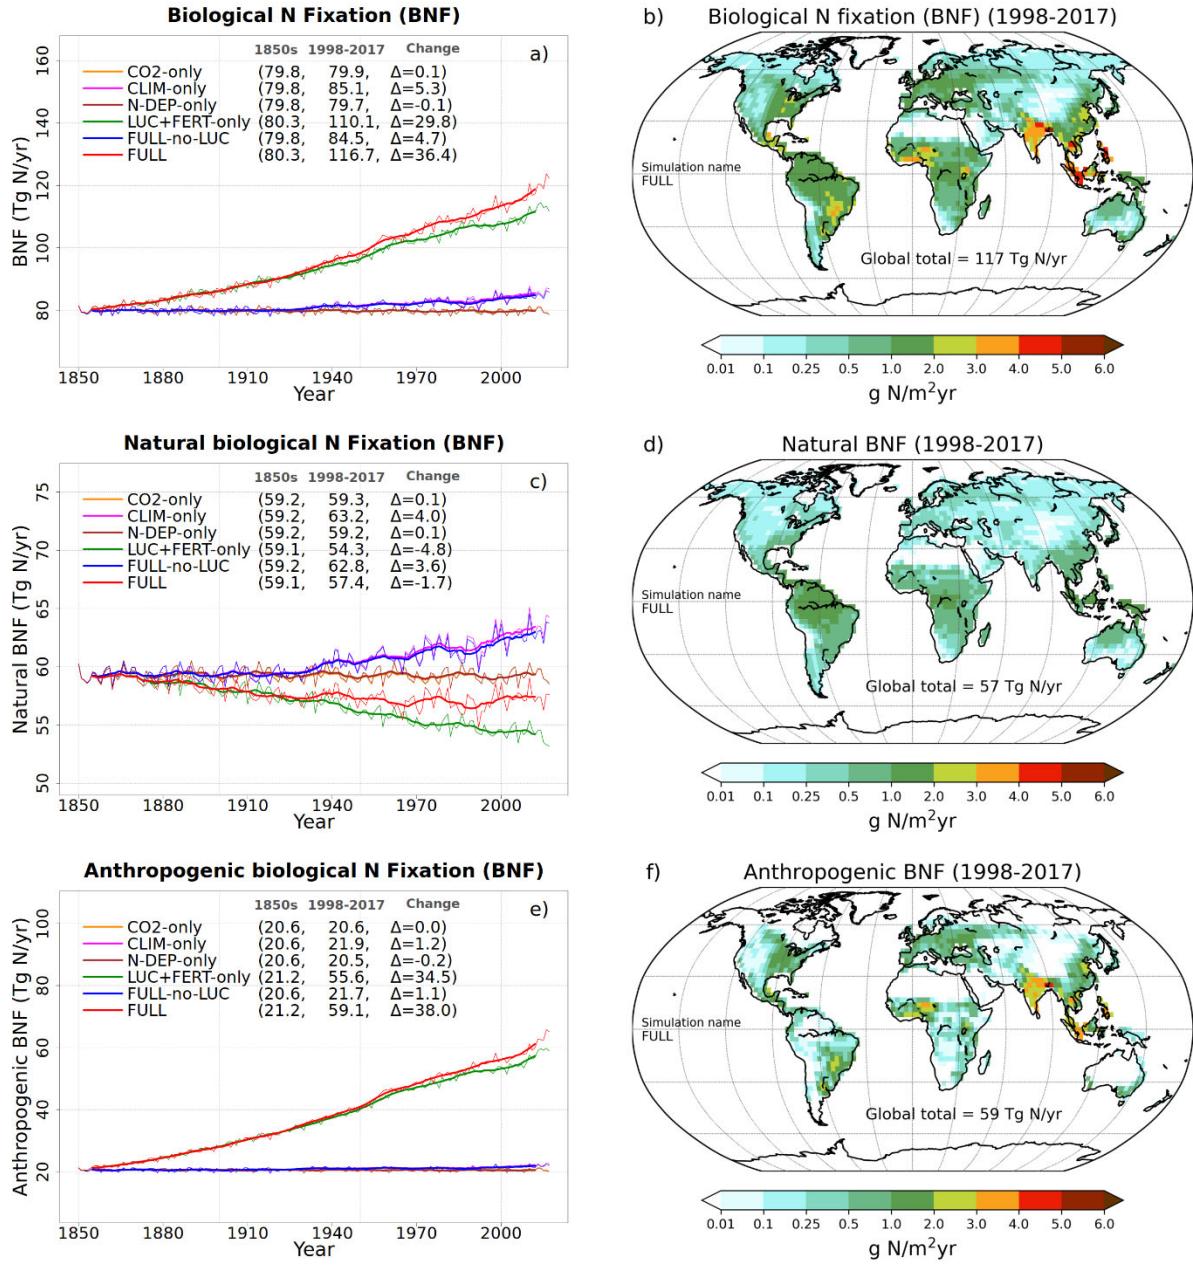

1365 Figure 1: The structure of CLASSIC model used in this study. The eight prognostic carbon pools  
1366 are shown in green colour and carbon fluxes in red colour. The ten prognostic nitrogen pools are  
1367 shown in orange colour and nitrogen fluxes are shown in blue colour.

1368

1369

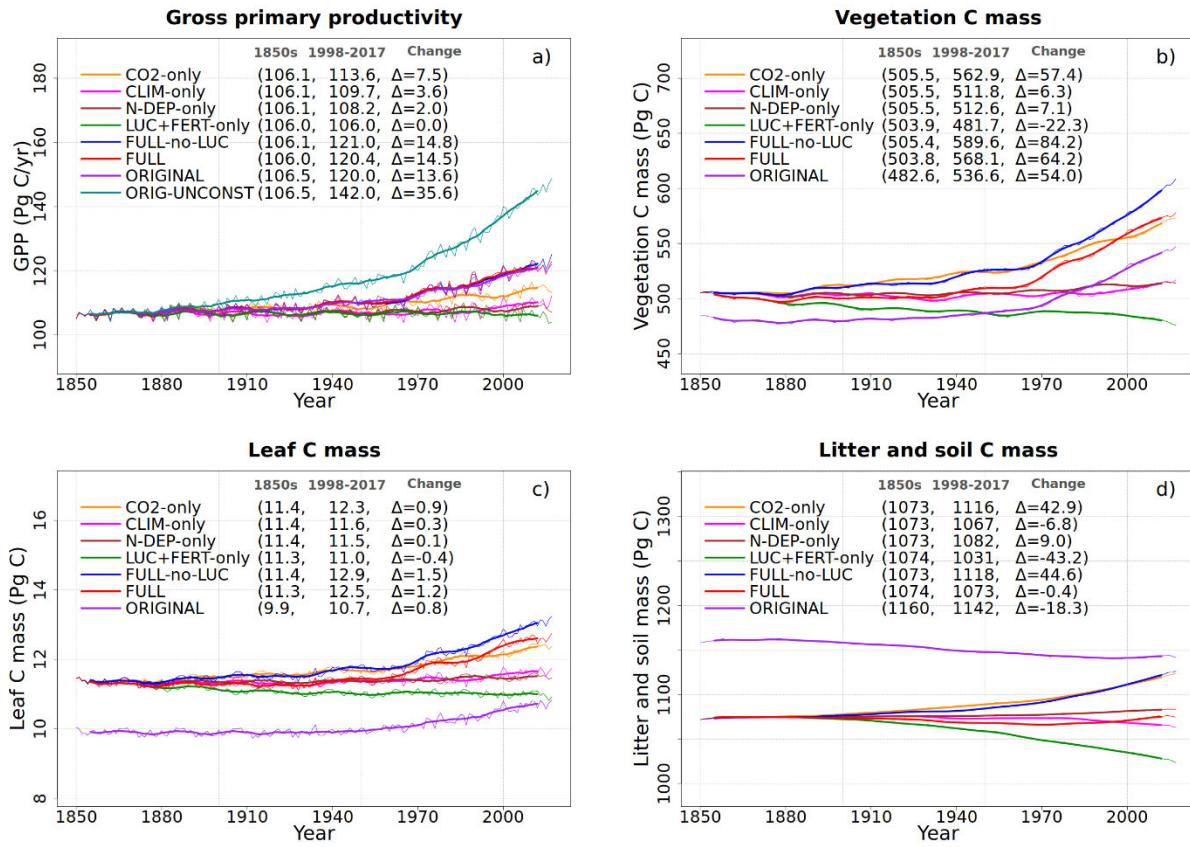

1370 Figure 2: Time series and geographical distribution of global annual values of externally specified  
 1371 N inputs. Fertilizer input (a, b), atmospheric deposition of ammonium (c, d) and atmospheric  
 1372 deposition of nitrate (e, f). The values in the parenthesis for legend entries in the time series plots  
 1373 show averages for the 1850s, the 1998-2017 period, and the change between these two periods.  
 1374 The thin lines in the time series plots show the annual values and the thick lines their 10-year  
 1375 moving average. The geographical plots show the average values over the last 20-years of the  
 1376 FULL simulation corresponding to the 1998-2017 period. Note that in the time series plots lines  
 1377 from some simulations are hidden behind lines from other simulations and this can be inferred  
 1378 from the legend entries which shows averages for the 1850s, the 1998-2017 period.

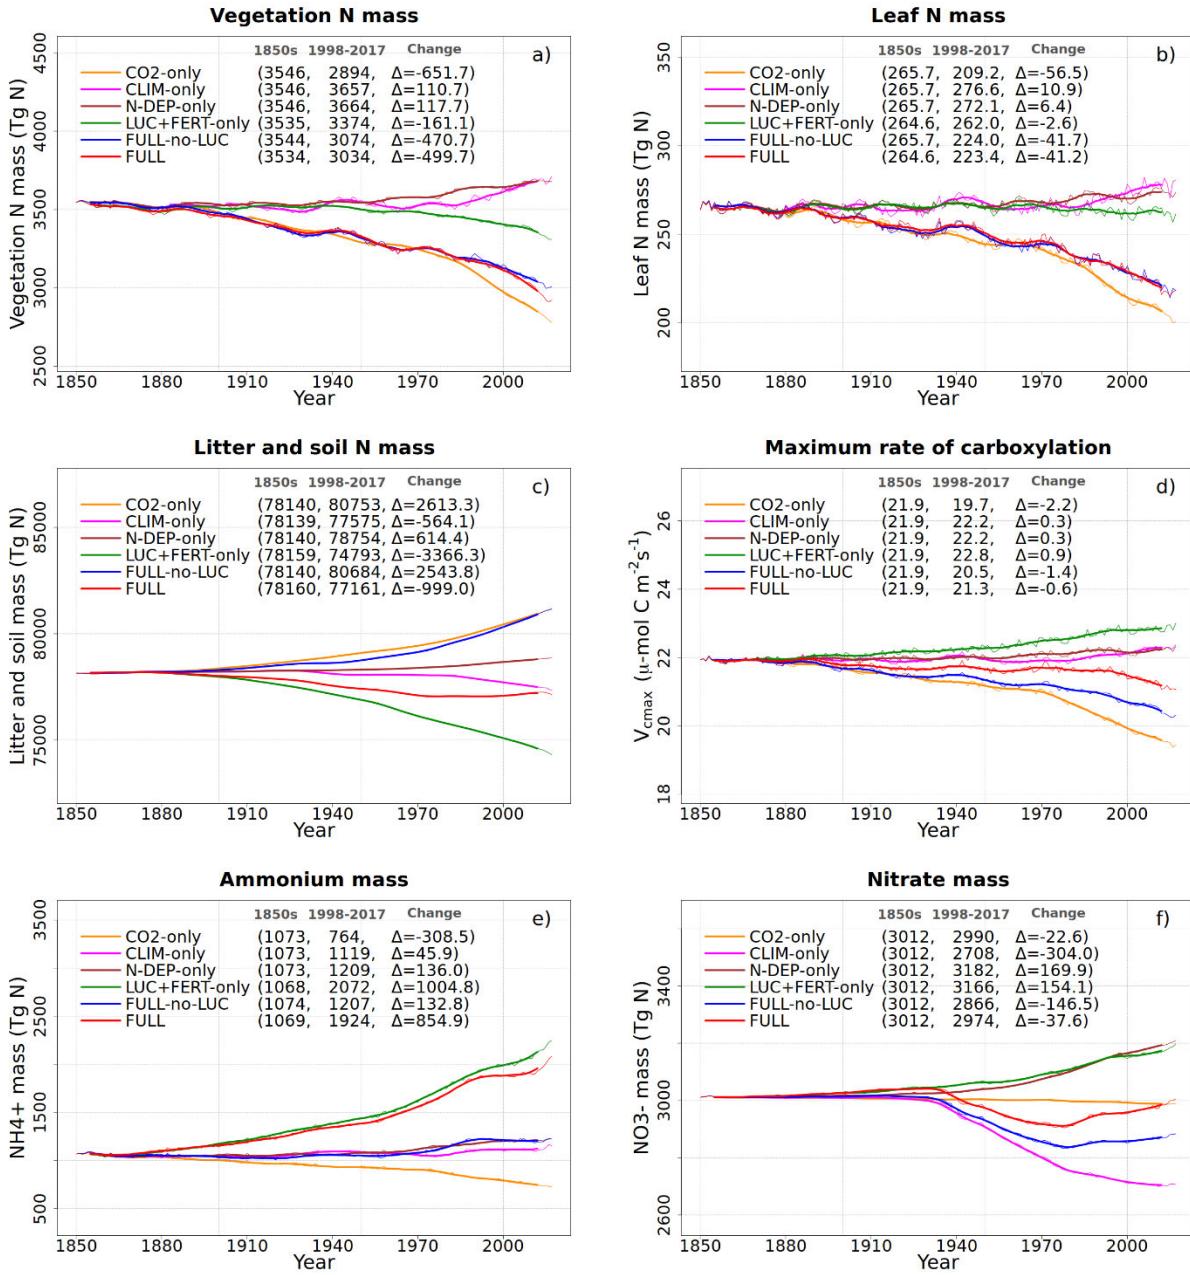

1379

1380 Figure 3: Time series and geographical distribution of annual values biological N fixation (BNF)  
 1381 (a,b) and its natural (c, d) and anthropogenic (e, f) components. The values in the parenthesis for  
 1382 legend entries in the time series plots show averages for the 1850s, the 1998-2017 period, and  
 1383 the change between these two periods. The thin lines in the time series plots show the annual  
 1384 values and the thick lines their 10-year moving average. The geographical plots show the average  
 1385 values over the last 20-years of the FULL simulation corresponding to the 1998-2017 period. Note  
 1386 that in the time series plots lines from some simulations are hidden behind lines from other  
 1387 simulations and this can be inferred from the legend entries which shows averages for the 1850s,  
 1388 the 1998-2017 period.

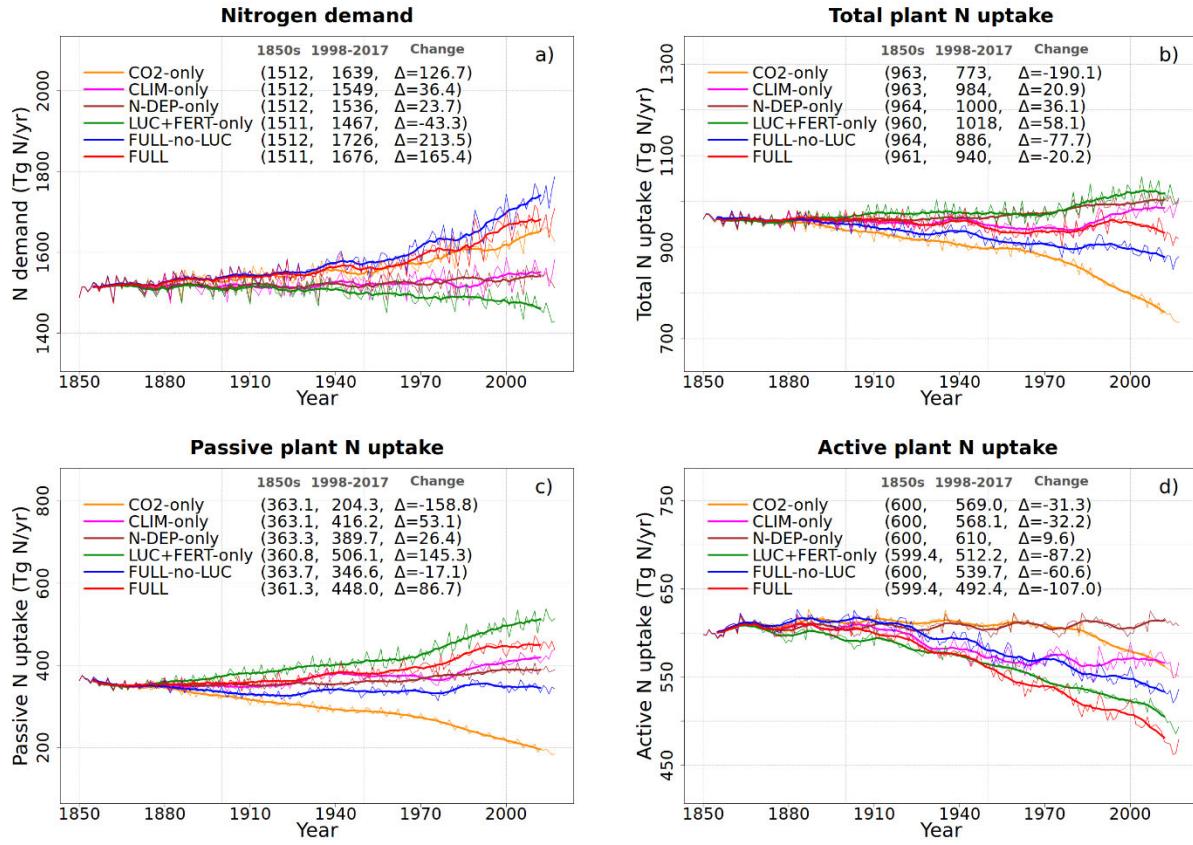

1391 Figure 4: Global annual values of gross primary productivity (a), vegetation carbon (b), leaf  
 1392 carbon (c), and litter and soil carbon (d) for the primary simulations performed. The values in  
 1393 the parenthesis for legend entries show averages for the 1850s, the 1998-2017 period, and the  
 1394 change between 1850s and 1998-2017 periods. The thin lines show the annual values and the  
 1395 thick lines their 10-year moving average.

1397

1398 Figure 5: Global annual values of N in vegetation (a), leaves (b), litter and soil organic matter (c)  
1399 pools,  $V_{cmax}$  (d), and ammonium (e), and nitrate (f) pools for the primary simulations performed.  
1400 The values in the parenthesis for legend entries show averages for the 1850s, the 1998-2017  
1401 period, and the change between 1850s and 1998-2017 periods. The thin lines show the annual  
1402 values and the thick lines their 10-year moving average.

1403

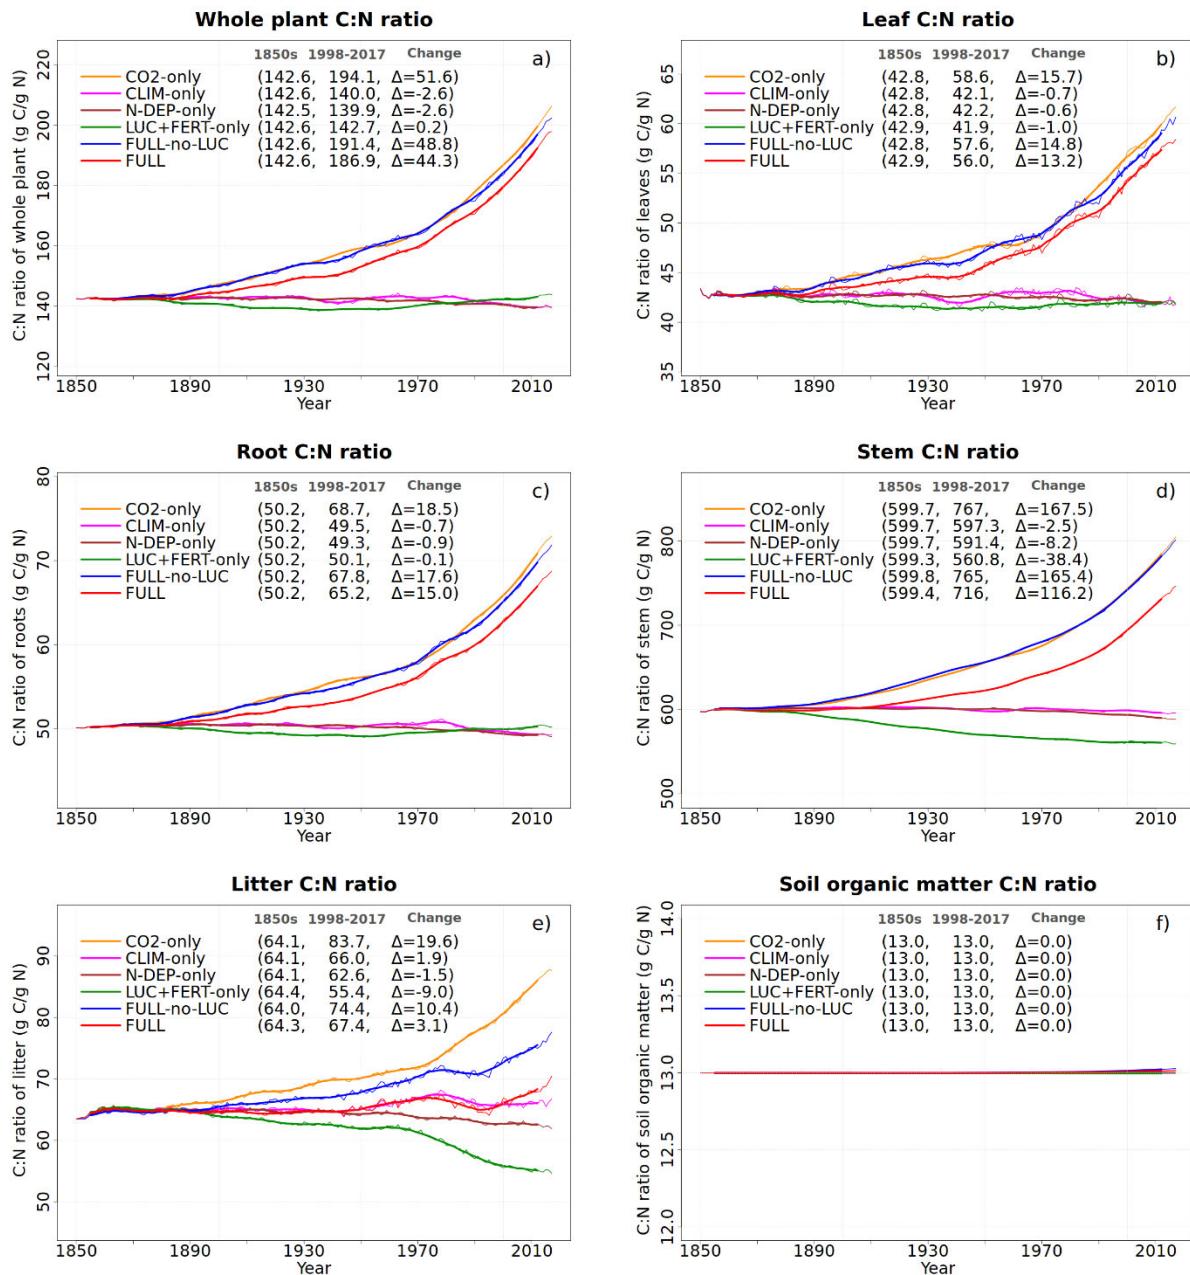

1404

1405

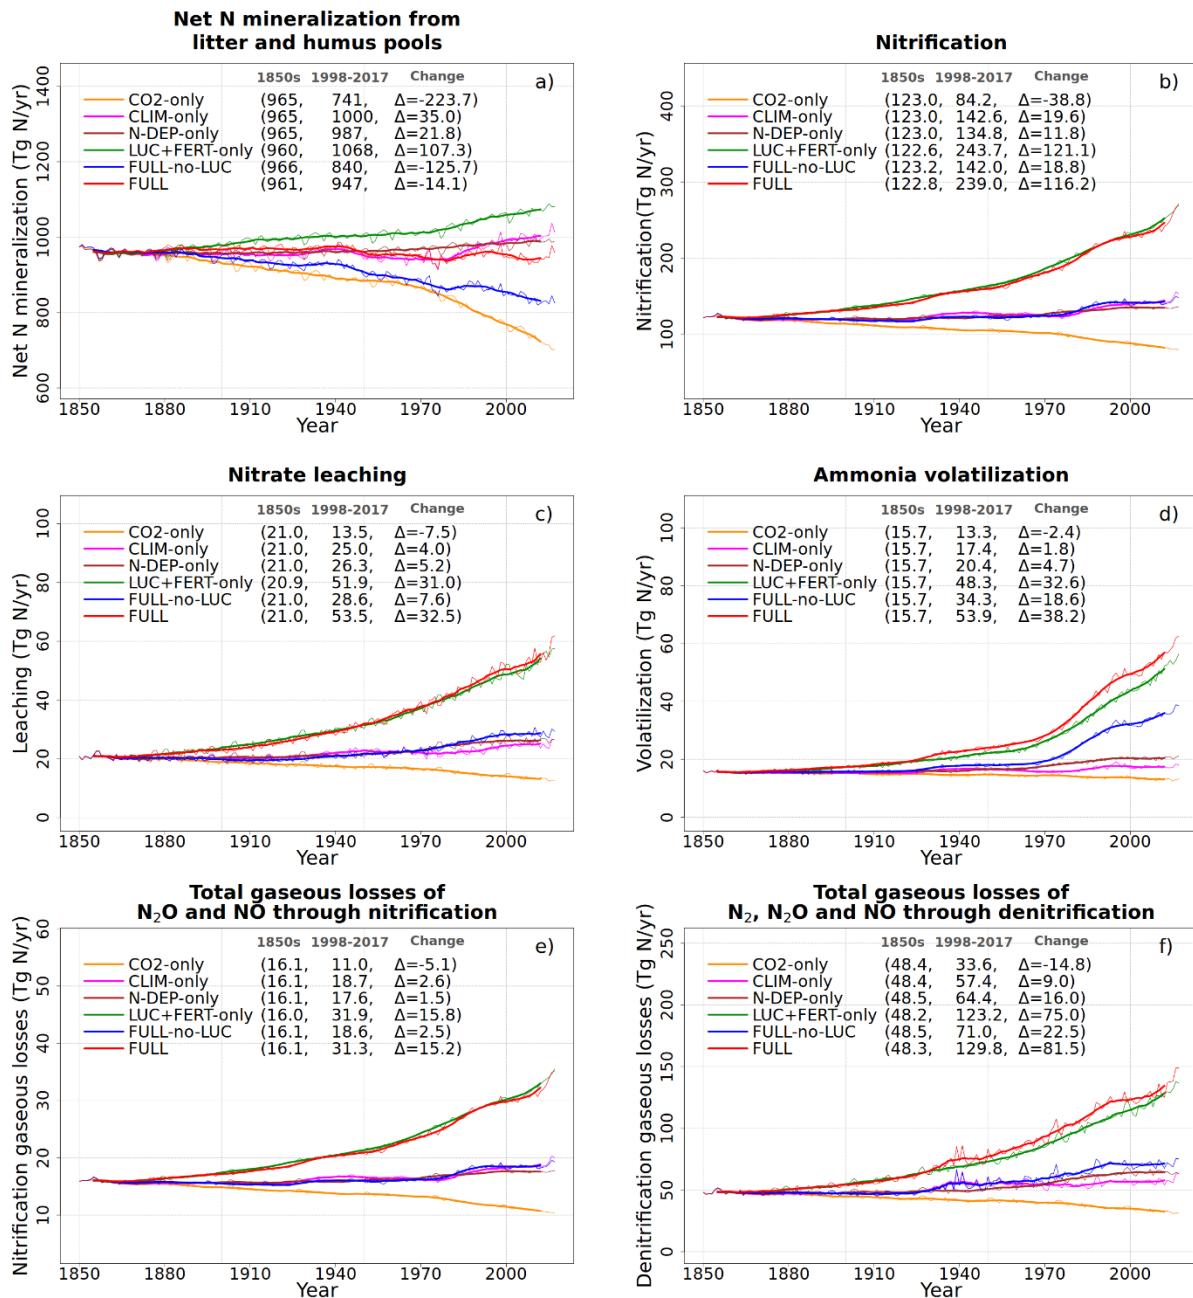

1406 Figure 6: Global annual values of N demand (a), total plant N uptake (b) and its split into passive  
 1407 (c) and active (d) components for the primary simulations performed. The values in the  
 1408 parenthesis for legend entries show averages for the 1850s, the 1998-2017 period, and the  
 1409 change between 1850s and 1998-2017 periods. The thin lines show the annual values and the  
 1410 thick lines their 10-year moving average.

1411

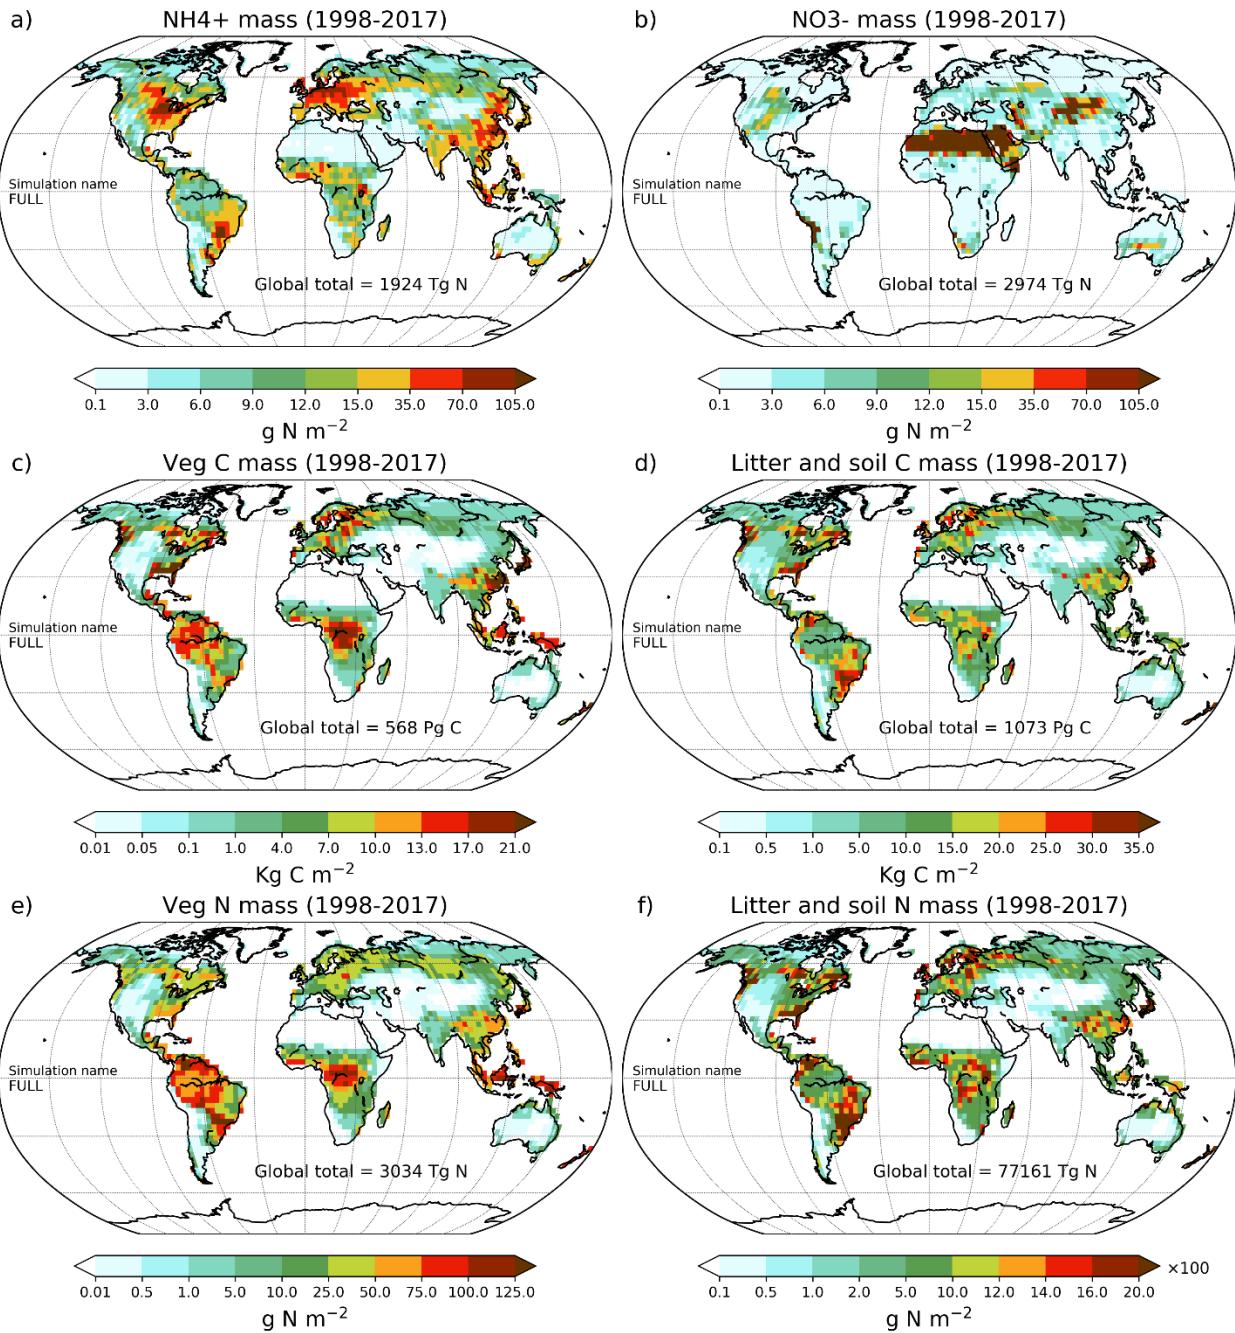

1412

1415 Figure 7: Global annual values of C:N ratios for whole plant (a), leaves (b) , root (c), stem (d),  
1416 litter (e) and soil organic matter (f) pools from the primary six simulations. The values in the  
1417 parenthesis for legend entries show averages for the 1850s, the 1998-2017 period, and the  
1418 change between 1850s and 1998-2017 periods. The thin lines show the annual values and the  
1419 thick lines their 10-year moving average.

1423 Figure 8: Global annual values of net mineralization (a), nitrification (b), NO<sub>3</sub>- leaching (c), NH<sub>3</sub>  
 1424 volatilization (d), and gaseous losses associated with nitrification (e) and denitrification (f) from  
 1425 the primary six simulations. The values in the parenthesis for legend entries show averages for  
 1426 the 1850s, the 1998-2017 period, and the change between 1850s and 1998-2017 periods. The  
 1427 thin lines show the annual values and the thick lines their 10-year moving average.

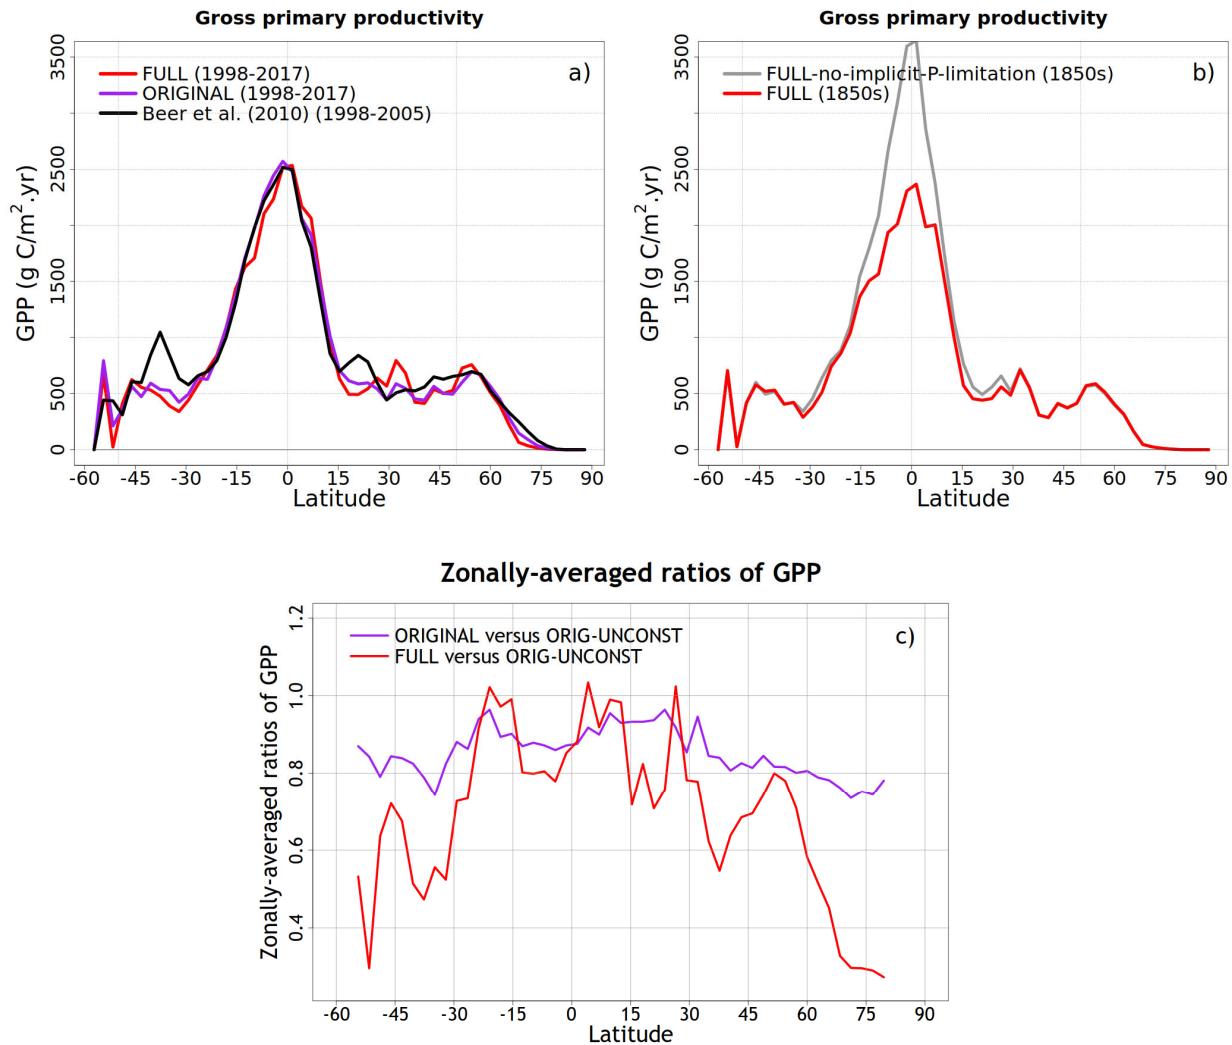

1429

1430 Figure 9: Geographical distribution of primary C and N pools. Ammonium (a), nitrate (b),  
 1431 vegetation C mass (c), litter and soil C mass (d), vegetation N mass (e), and litter and soil N mass  
 1432 (f). The global total values shown are averaged over the 1998-2017 period.

1433

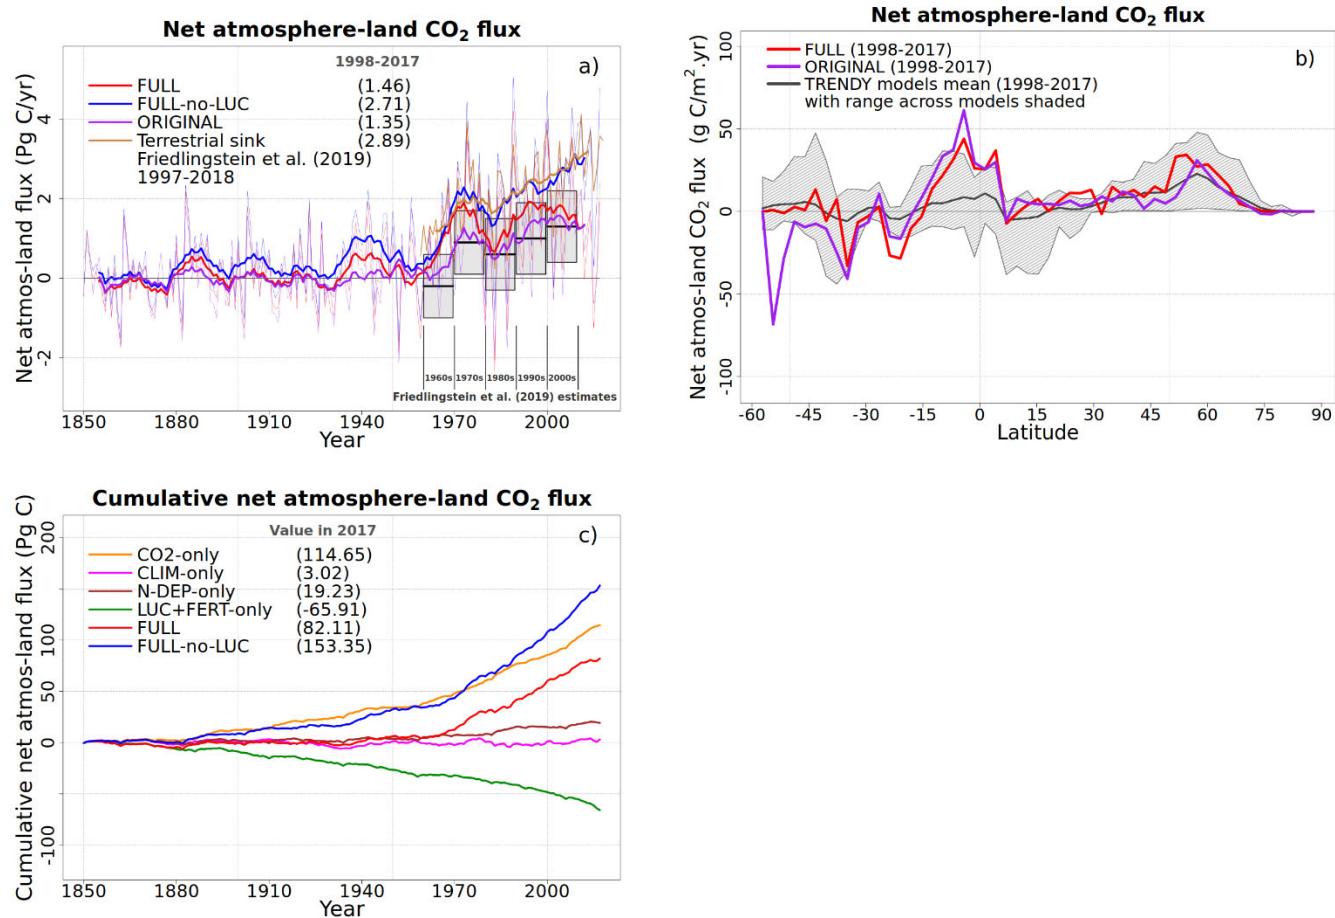

1434

1435

1436 Figure 10: Comparison of zonal distribution of gross primary productivity (GPP) and the effect of  
1437 GPP downregulation compared to the ORIG-UNCONST simulation. Panel (a) compares zonal  
1438 distribution of GPP from FULL and ORIGINAL simulations with observation-based estimate from  
1439 Beer et al. (2010) for the present day. Panel (b) compares the zonal distribution of GPP from the  
1440 pre-industrial simulation, corresponding to 1850 conditions, from the FULL and FULL-no-  
1441 implicit-P-limitation simulations to illustrate the effect of not reducing the  $\Gamma_1$  parameter for  
1442 calculating  $V_{cmax}$  for the broadleaf evergreen tree PFT that implicitly accounts for phosphorus  
1443 limitation. Panel (c) shows the zonally-averaged ratios of GPP from the ORIGINAL and FULL  
1444 simulations versus those from the ORIG-UNCONST simulations to illustrate how downregulation  
1445 acts in the ORIGINAL and FULL simulations.

1446

1449 Figure 11: Comparison of simulated net atmosphere-land  $\text{CO}_2$  flux from various simulations.  
 1450 Panel (a) compares globally-summed values of net atmosphere-land  $\text{CO}_2$  flux from FULL, FULL-  
 1451 no-LUC simulation, and ORIGINAL simulations with estimate of terrestrial sink (dark yellow line)  
 1452 and net atmosphere-land  $\text{CO}_2$  flux (grey bars) from Friedlingstein et al. (2019). The thin lines  
 1453 show the annual values and the thick lines their 10-year moving average. Panel (b) compares  
 1454 zonal distribution of net atmosphere-land  $\text{CO}_2$  flux from FULL and ORIGINAL simulations with  
 1455 the range from TRENDY models that contributed to the Friedlingstein et al. (2019) study. Panel  
 1456 (c) shows cumulative values of net atmosphere-land  $\text{CO}_2$  flux from the six primary simulations  
 1457 to investigate the contribution of each forcing to the cumulative land carbon sink over the  
 1458 historical period.
