8 **Abstract.** Recent Earth System Models predict a 10-20% decrease in particulate organic carbon export from the
9 surface ocean by the end of the 21st century due to global climate change. This decline is mainly caused by increased
10 stratification of the upper ocean, resulting in reduced shallow subsurface nutrient concentrations and a slower supply
11 of nutrients to the surface euphotic zone in low latitudes. These predictions, however, do not typically account for
12 associated changes in remineralization depths driven by sinking particle size. Here we combine satellite-derived export
13 and particle size maps with a simple 3-D global biogeochemical model that resolves dynamic particle size distributions
14 to investigate how shifts in particle size may buffer or amplify predicted changes in surface nutrient supply and
15 therefore export production. We show that higher export rates are empirically correlated with larger sinking particles
16 and presumably larger phytoplankton, particularly in tropical and subtropical regions. Incorporating these empirical
17 relationships into our global model shows that as circulation slows, a decrease in export is associated with a shift
18 toward smaller particles, which sink more slowly and are thus remineralized shallower. This shift towards shallower
19 remineralization in turn leads to greater recycling of nutrients in the upper water column and thus faster nutrient
20 recirculation into the euphotic zone. The end result is a boost in productivity and export that counteracts the initial
21 circulation-driven decreases. This negative feedback mechanism (termed the particle size-remineralization feedback)
22 slows export decline over the next century by ~14% globally (from -0.29 GtC/year to -0.25 GtC/year) and by ~20%
23 in the tropical and subtropical oceans, where export decreases are currently predicted to be greatest. Our findings
24 suggest that to more accurately predict changes in biological pump strength under a warming climate, Earth System
25 Models should include dynamic particle size-dependent remineralization depths.

26 1 Introduction

27 A key mechanism that controls the partitioning of carbon dioxide (CO₂) between the atmosphere and ocean
28 is the biological pump, in which CO₂ is fixed into phytoplankton organic matter via photosynthesis, and then exported
29 from the surface to the deep ocean as sinking particles (e.g., Ducklow et al., 2001). Decomposition of this particulate
30 organic carbon (POC) in the ocean interior maintains a reservoir of respired CO₂ that is sequestered out of contact
31 with the atmosphere, thus exerting an important control on long-term atmospheric CO₂ concentrations and global

32 climate (e.g., Martínez-García et al., 2014; Passow & Carlson, 2012; Sarmiento & Siegenthaler, 1992). Carbon
33 exported out of the surface euphotic zone also fuels the metabolism of organisms in the mesopelagic zone, sustaining
34 economically and socially important fisheries, as well as ecologically important zooplankton and micronekton
35 communities (e.g., Boyd et al., 2019; Friedland et al., 2012). POC export is also an important driver of dissolved
36 oxygen concentrations in the water column. Where sinking POC fluxes are particularly high and supply of oxygen via
37 physical transport is low, enhanced bacterial degradation of particles can deplete available oxygen and create hypoxic
38 or even suboxic conditions in which many organisms cannot survive (e.g., Deutsch et al., 2015; Deutsch et al., 2020;
39 Hofmann and Schellnhuber, 2009). Given the critical role of POC export in driving ocean carbon sequestration, the
40 global climate system, fisheries productivity, and dissolved oxygen availability, there is a growing need to better
41 understand how export will respond to future climate warming.

42 Recent Earth System Models (ESMs) that are part of the Coupled Model Intercomparison Project 5 (CMIP5)
43 predict decreases in global export production (defined as the sinking POC flux at 100m) of ~10-20% by 2100 (Bopp
44 et al., 2013; Cabré et al., 2015a) and ~30% by 2300 (Moore et al., 2018). In many of these models, primary production
45 and subsequent carbon export are largely limited by the physical supply of nutrients to the surface ocean, which is
46 predicted to slow with future warming (Cabré et al., 2015a; Fu et al., 2016; Laufkötter et al., 2015; Moore et al., 2018).
47 Mechanisms driving this nutrient supply slowdown include: (i) surface warming-induced stratification of the water
48 column, which will shoal winter mixed layers, limit vertical exchange, and “trap” nutrients in the ocean interior (Bopp
49 et al., 2013; Cabré et al., 2015a; Capotondi et al., 2012; Moore et al., 2018), and (ii) a weakening of the trade winds,
50 which will reduce upwelling rates and vertical nutrient supply in tropical oceans (Bopp et al., 2001; Collins et al.,
51 2010), as well as lateral Ekman-driven nutrient supply into the subtropics (Letscher et al., 2016).

52 Changes in the POC flux itself, however, also have the potential to modulate nutrient supply to the surface
53 ocean and therefore impact export. Because particles release nutrients when they decompose, the depth scale of
54 particle remineralization determines the proximity of these nutrients to the surface and their resupply rate to the
55 euphotic zone (Kwon et al., 2009; Yamanaka & Tajika, 1996). Shallow remineralization in mesopelagic waters,
56 especially above the permanent pycnocline, drives rapid nutrient recirculation to the surface; nutrients remineralized
57 in deeper waters, on the other hand, can take hundreds of years to re-emerge at the surface (Martin et al., 1987;
58 Matsumoto, 2007b). This raises the possibility of feedback loops in which changes in particle remineralization depth
59 might either dampen (negative feedback) or enhance (positive feedback) circulation-driven decreases in primary
60 production and export. For instance, increasing ocean temperatures may speed up bacterial remineralization rates
61 (Cavan et al., 2019; Cram et al., 2018; John et al., 2014; Laufkötter et al., 2017; Marsay et al., 2015; Matsumoto,
62 2007a) and enhance recycling of nutrients near the surface, which would dampen physically-driven decreases in
63 surface nutrient concentrations and result in a negative feedback on export. Oxygen concentrations, on the other hand,
64 are predicted to decrease with future warming (Bopp et al., 2002; Cabré et al., 2015b; Keeling et al., 2010; Long et
65 al., 2016; Matear & Hirst, 2003; Schmidtko et al., 2017) and slow bacterial remineralization and zooplankton-mediated
66 particle disaggregation rates (Cavan et al., 2017; Devol & Hartnett, 2001; Hartnett & Devol, 2003; Laufkötter et al.,
67 2017; Van Mooy et al., 2002). This would result in deeper particle remineralization and further exacerbate circulation-

68 driven nutrient supply decreases, leading to a positive feedback on export production. A decrease in mineral ballasting
69 and protection of particles with ocean acidification may also feedback negatively on export decreases by shoaling
70 remineralization depths (Hofmann and Schellnhuber, 2009).

71 Future changes in sinking particle size may also lead to strong feedbacks on export. Recent work has shown
72 that particle size, through its influence on sinking speed (Alldredge and Gotschalk, 1988; Smayda, 1971), plays a
73 paramount role in determining remineralization length scales and carbon transfer efficiency to depth (Cram et al.,
74 2018; Kriest & Oschlies, 2008; Weber et al., 2016). Potential mechanisms that could drive changing particle sizes
75 include changes in underlying phytoplankton community structure and organic matter packaging processes at higher
76 trophic levels. Whatever the mechanism, the direction and magnitude of the particle size-remineralization feedback in
77 a warming ocean will depend on how particle sizes change as export declines in the future. If the export decline is
78 associated with a shift towards larger organic particles that sink more quickly, remineralization depths will deepen
79 and further reduce surface nutrient supply and export in a positive feedback. If, on the other hand, export decreases
80 are associated with a shift towards smaller sinking particles, shallower remineralization will allow faster nutrient
81 recirculation to the surface and dampen stratification-driven decreases in nutrient supply and export in a negative
82 feedback.

83 Despite the potential importance of particle size, CMIP5 models do not resolve dynamic particle size
84 distributions and so cannot fully capture biological feedbacks driven by particle size (Laufkötter et al., 2016; Le Quéré
85 et al., 2005; Séférian et al, 2020). More complex models that resolve aggregation-disaggregation transformations
86 and/or particle size distributions have been developed (Gehlen et al., 2006; Jokulsdottir and Archer, 2016; Kriest &
87 Oschlies, 2008; Niemeyer et al., 2019; Schwinger et al., 2016), but have not been used to examine the interactions
88 between climate change, particle size, and export production. Furthermore, parameters and processes in most previous
89 models are not constrained by observations of particle size distributions or the relationships between particle size and
90 export.

91 Here we combine new data analyses and idealized model experiments to assess the potential impact of
92 feedbacks induced by dynamic particle size-dependent remineralization depths on future export changes. We use
93 remotely-sensed datasets to empirically constrain the relationship between export rates and sinking particle size, then
94 implement this relationship in a 3-D global biogeochemical model that resolves particle size distributions. Together,
95 these analyses reveal a *negative* particle size-remineralization (PSR) feedback effect on export, suggesting that ESMs
96 lacking these interactions may overestimate the decrease in ocean carbon export during the 21st century.

97 **2 Methods**

98 **2.1 Ocean biogeochemical and particle remineralization model**

99 **2.1.1 Model setup**

100 We quantified the PSR feedback using an idealized ocean biogeochemical model, which comprises a simple
101 nutrient cycle (DeVries et al., 2014) embedded within the observationally-constrained Ocean Circulation Inverse

102 Model (OCIM) (DeVries, 2014). OCIM assimilates passive and transient tracer data to generate an annual-mean
103 circulation that realistically reproduces water mass distributions and ventilation rates at 2-degree horizontal resolution
104 on 24 vertical layers. The circulation rates are stored in a transport matrix (A), that quantifies physical exchanges
105 between every grid cell in our model. Thus, all physical (advective and diffusive) fluxes of tracer X in our model are
106 represented by the matrix-vector product $A*[X]$. OCIM has previously been used successfully for high-fidelity
107 simulation of nutrients (DeVries, 2014) and oxygen (DeVries and Weber, 2017) and does not suffer from the equatorial
108 biases often evident in dynamical models with the same resolution. Nutrient cycling comprises phytoplankton
109 phosphate (PO_4^{3-}) uptake and export as sinking organic particles out of the surface ocean ($<75\text{m}$), particle
110 remineralization in the subsurface ($>75\text{m}$), and production and decomposition of dissolved organic phosphorus
111 (DeVries et al 2014). Nutrient concentrations in the ocean interior represent the sum of preformed nutrients,
112 transported from regions of incomplete utilization in the ocean surface, and the accumulated product of particulate
113 and dissolved organic matter remineralization.

114 Vertical particle fluxes are simulated by the 1-D mechanistic Particle Remineralization and Sinking Model
115 (PRiSM) (DeVries et al., 2014). PRiSM computes particle flux profiles as a function of particle size distribution at the
116 surface, microbial remineralization rate, and empirical relationships between particle size, mass, and sinking velocity.
117 These empirical relationships are in some cases derived from measurements of sinking phytoplankton and in other
118 cases from those of sinking particles or porous aggregates. PRiSM therefore implicitly assumes that phytoplankton
119 and smaller particles behave similarly as they sink down the water column.

120 Particle abundances in the ocean tend to follow a power-law distribution, with many more small particles
121 than large ones (Boss et al., 2001; Buonassissi and Dierssen, 2010; Cael and White, 2020; Sheldon et al., 1972; White
122 et al., 2015). Thus, PRiSM produces particles in the surface euphotic zone ($<75\text{m}$) following a power-law size
123 spectrum, in which the log of the particle number density declines linearly with the log of the particle diameter,
124 between the sizes of 20 and 2000 μm in diameter. Accordingly, the relative abundance of small and large particles is
125 controlled by the slope of the spectrum on a log-log scale (β): a shallower slope (small β) indicates a greater proportion
126 of large particles relative to small ones, while a steeper slope (large β) indicates a smaller proportion of large particles.
127 This surface particle size distribution slope is defined via specification of a global β map. Previous work with PRiSM
128 has demonstrated that spatial variations in annual mean β of the magnitude observed by satellite can lead to large
129 differences in particle fluxes at depth (Fig. S1; Fig. 1a-b; DeVries et al 2014).

130 Following export, the simulated particle size spectrum evolves through the water column due to
131 remineralization and size-dependent sinking. Remineralization is represented by first-order mass loss from particles,
132 such that each individual particle shrinks and sinks more slowly with depth. Because smaller, slower-sinking particles
133 reside for longer within any given depth interval and therefore have more time to remineralize, they are preferentially
134 lost from the particle population over depth. A constant rate of microbial respiration is used, optimized to fit global in
135 situ phosphate distributions (DeVries et al., 2014). There are therefore no temporal changes in bacterial respiration
136 due to warming, for example, which allows us to isolate changes in export that stem from the PSR feedback alone.
137 While PRiSM has recently been expanded to include temperature and oxygen effects on bacterial respiration and

138 remineralization (Cram et al., 2018), as well as to represent particle disaggregation (Bianchi & Weber et al., 2018),
139 here we use the original version described in DeVries et al. (2014), which can be solved analytically and has previously
140 undergone parameter optimization to best fit global phosphate distributions.

141 The model configuration and parameter values used here are outlined in Table S1. Further model details and
142 validation are described in DeVries et al. (2014). Here we extend the original PRiSM-enabled biogeochemical model
143 in DeVries et al. (2014) in two important ways:

- 144 1.) The original diagnostic nutrient uptake term (i.e., nutrient-restoring production) is replaced by the prognostic
145 organic matter production scheme developed by Weber and Deutsch (2012) with minor parameter updates
146 (see Table S2). This scheme calculates phytoplankton growth, in terms of PO_4^{3-} uptake, as a function of
147 observed annual-mean temperatures (Locarnini et al., 2010) and solar radiation levels (Rossow & Schiffer,
148 1999), along with modeled $[\text{PO}_4^{3-}]$. This formulation successfully reproduces the broad spatial patterns of
149 surface $[\text{PO}_4^{3-}]$ (Weber and Deutsch, 2012), suggesting that our model accurately captures the balance
150 between preformed and remineralized nutrients in the ocean interior. Of the organic phosphorus produced by
151 uptake in the euphotic zone, 10% is routed to dissolved organic matter, which circulates and degrades over
152 time, with the remainder being routed to particulate organic matter (Thornton, 2013). An empirical, spatially
153 variable relationship between particulate C-to-P ratios and phosphate concentrations (Galbraith & Martiny,
154 2015) is then used to convert particulate organic phosphorus fluxes into POC fluxes.
- 155 2.) We add the ability to enable or disable the PSR feedback by implementing an empirical relationship that links
156 changes in particle size spectrum slope (β) to changes in carbon export out of the surface ocean (<75 m) (see
157 Section 2.1.2).

158 2.1.2 Model representation of the PSR feedback

159 When the PSR feedback is disabled within our model, circulation-driven changes in the nutrient supply to
160 the euphotic zone (see Section 2.3) will lead to changes in POC export, but β (and therefore particle remineralization
161 depths) remains constant over time. With the PSR feedback enabled, any change in POC export is accompanied by a
162 change in β , the direction and magnitude of which is specified using the empirical relationships discussed in Section
163 2.2. We note that by design, this modeling approach makes no assumptions about the mechanisms driving shifts in the
164 particle size distribution, only that β changes in tandem with POC export, in a manner that is consistent with
165 observations. Mathematically, β is updated at a given grid point as follows between timesteps t and $t+1$:

$$166 \beta_{t+1} = \beta_t + \frac{d\beta_{sat}}{dE_{n,sat}} \frac{E_{t+1} - E_t}{E_t}, \quad (1)$$

167 where E is the modeled export rate and $\frac{d\beta_{sat}}{dE_{n,sat}}$ is the empirical, time-independent fractional change in satellite-derived
168 β (β_{sat}) per change in satellite-derived, time-mean normalized export ($E_{n,sat}$, defined as absolute export divided by time-
169 mean export calculated between 1997 and 2010 at a given grid point—see Section 2.2.2 for details).

170 To disable the feedback, $\frac{d\beta_{sat}}{dE_{n,sat}}$ is set equal to zero so that modeled β remains constant over time. To enable
171 the feedback, $\frac{d\beta_{sat}}{dE_{n,sat}}$ is set equal to the linear temporal regression coefficient between β_{sat} and $E_{n,sat}$, which is computed
172 from remotely-sensed time series of the two variables at each grid cell over the global ocean (Section 2.2). Thus, when
173 the feedback is enabled, changes in modeled β over time are dictated by the magnitude of modeled export change as
174 well as the strength and direction of the relationship between observed β and export, which can vary spatially.

175 **2.2 Empirical analyses of phytoplankton size, β , and export from satellite data**

176 Because the strength and direction of our modeled PSR feedback depends strongly on the observed
177 relationship between β and export ($\frac{d\beta_{sat}}{dE_{n,sat}}$ in Eq. (1)), we sought a robust empirical constraint on this relationship.
178 Sections 2.2.1 and 2.2.2 respectively describe the global satellite-derived time series maps of β and export used here.
179 Section 2.2.3 then describes how these monthly-mean β and export maps are used to compute a range of possible
180 global $\frac{d\beta_{sat}}{dE_{n,sat}}$ relationships.

181 **2.2.1 Global satellite-derived particle size distribution map**

182 Global 1/12°-by-1/12° monthly maps of β observed by the satellite Sea-viewing Wide Field-of-view Sensor
183 (SeaWiFS, in operation from September 1997 – December 2010) were downloaded from
184 <ftp://ftp.oceancolor.ucsb.edu/pub/org/oceancolor/MEaSURES/PSD/>. These β maps were derived from remotely-
185 sensed particulate backscattering measurements, which were previously validated with in situ near-surface Coulter
186 counter measurements (Kostadinov et al., 2009). To enable more efficient computation, we reduced the resolution of
187 the original monthly β maps to 1°-by-1° degree via spatial averaging. At this resolution, time-mean β ranges from
188 ~3.3 in coastal high-latitude regions (where high nutrient conditions favor larger phytoplankton) to ~5.3 in the
189 subtropics (where low macronutrient concentrations favor small phytoplankton) (Fig. 1a). Although β from
190 Kostadinov et al. (2009) is computed only over particle sizes ranging from 0.002 to 63 μm , we assume that the same
191 β continues to hold for larger particles up to 2000 μm (the largest particle size in PRiSM), as supported by prior
192 research (e.g., Durkin et al., 2015). Ideally, measurements of β would be computed over the same particle size range
193 as simulated in PRiSM (20–2000 μm); however, such a dataset was not readily available. Indeed, the Kostadinov et
194 al. (2009) observations of β were the only readily available measurements spanning long enough timescales, with high
195 enough spatiotemporal resolution to compute the relationships between β and POC export needed for this study.

196 **2.2.2 Global satellite-derived export maps**

197 POC export was computed as the product of net primary production (NPP) and the particle export ratio
198 (export/NPP, or e-ratio), both of which can be derived from satellite data. To create a range of plausible global monthly
199 export maps, we multiplied all possible permutations of three monthly NPP estimates and e-ratio algorithms, yielding
200 nine distinct monthly datasets of global export spanning >10 years (Fig. S2). All three sets of monthly satellite NPP

201 maps were downloaded from <http://sites.science.oregonstate.edu/ocean.productivity/> and derived from SeaWiFS
202 observations processed through the following algorithms: (i) the chlorophyll-based Vertically Generalized Production
203 Model (VGPM) (Behrenfeld & Falkowski, 1997); (ii) the Eppley-VGPM model (VGPME), containing a modified
204 relationship between temperature and production compared to the original VGPM (Carr et al., 2006); and (iii) the
205 Carbon-based Production Model (CbPM), which uses particulate backscatter-derived carbon rather than chlorophyll
206 to measure phytoplankton biomass (Behrenfeld et al., 2005). The three e-ratio algorithms we used were the ecosystem-
207 model based relationship of Laws et al., 2000, and the empirical relationships of Dunne et al. (2005) and Laws et al.
208 (2011). All three of these algorithms link e-ratio to SST and NPP. The in situ, statistically interpolated SST dataset
209 used here was NOAA’s Extended Reconstructed Sea Surface Temperature (ERSST) v3b, downloaded from
210 <https://www1.ncdc.noaa.gov/pub/data/cmb/ersst/v3b/netcdf/> (Smith et al., 2008). Euphotic zone depths needed to
211 compute D2005 e-ratios were derived from SeaWiFS-sensed chlorophyll concentrations (downloaded from the same
212 website as NPP) according to Equation 10 in Lee et al. (2007). As with β , all variables were computed and stored on
213 a 1°-by-1° degree grid over the entirety of the SeaWiFS period (September 1997 – December 2010, 160 months long).

214 In the following computations of $\frac{d\beta_{sat}}{dE_{n,sat}}$ (Section 2.2.3), we employed all nine sets of global monthly export
215 maps to propagate uncertainty into our assessment of the PSR feedback. When computing most-likely $\frac{d\beta_{sat}}{dE_{n,sat}}$ values,
216 we weighted the nine export map sets according to how well each map set’s annual mean export matches in situ
217 oxygen and mass balance-based observations (Emerson, 2014; Reuer et al., 2007) within each region defined here
218 (Table S3; see Weber et al. (2016) for derivation of weighting factors). Fig. 2 shows the weighted annual mean carbon
219 export flux over the nine map sets, as well as the regions used for weighting, which are delineated based on
220 biogeochemical characteristics such as sea surface temperature and surface phosphate concentrations (Weber et al.,
221 2016). The Atlantic and Pacific Oceans are divided into warm subtropics dominated by smaller picophytoplankton
222 (STA, STP), cold subarctic regions dominated by blooms of larger microphytoplankton in the north (NA, NP), and
223 cool tropical upwelling zones dominated by larger phytoplankton in the east (ETA, ETP). The Indian Ocean is kept
224 intact (IND), while the Southern Ocean is divided into the productive, diatom-dominated Subantarctic Zone (SAZ)
225 and the high-nutrient, low-chlorophyll Antarctic Zone (AAZ). The Indian Ocean region (IND) did not contain a
226 sufficient number of in situ observations of export to enable comparison to the satellite export maps, so all nine maps
227 are weighted equally there.

228 2.2.3 Regionally variable empirical β versus export relationships ($\frac{d\beta_{sat}}{dE_{n,sat}}$)

229 We quantified the empirical relationship between β and export individually for each grid cell by extracting
230 the monthly timeseries (September 1997 – December 2010) of β and normalized export (E_n) from the satellite products
231 described above, and then applying linear regression. This process produced a spatially variable, 1°-by-1° degree
232 global map of the best-fit linear slopes ($\frac{d\beta_{sat}}{dE_{n,sat}}$) relating β and E_n . To capture the range of plausible $\frac{d\beta_{sat}}{dE_{n,sat}}$ maps, we
233 repeated this process for each of the nine export products to generate nine distinct global $\frac{d\beta_{sat}}{dE_{n,sat}}$ maps (Fig. S3). To

234 smooth out small-scale noise and illuminate large-scale patterns in the β vs. export relationship, we spatially averaged
235 the $\frac{d\beta_{sat}}{dE_{n,sat}}$ slopes over the ocean biogeochemical regions defined in Fig. 2 (Fig. 3a). Finally, we set all grid points
236 within a given region equal to that region’s weighted (Table S3; Section 2.2.2) mean value (Fig. 3b) to generate the
237 final $\frac{d\beta_{sat}}{dE_{n,sat}}$ map used in our PSR feedback-on runs (Fig. 3c).

238 To quantify the sensitivity of $\frac{d\beta_{sat}}{dE_{n,sat}}$ to the choice of export map used, we computed upper and lower-bound
239 $\frac{d\beta_{sat}}{dE_{n,sat}}$ maps by adding and subtracting one standard deviation (error bars in Fig. 3b) to the weighted regional mean
240 $\frac{d\beta_{sat}}{dE_{n,sat}}$ values. Conducting PSR feedback-on runs using upper and lower-bound $\frac{d\beta_{sat}}{dE_{n,sat}}$ maps establishes the range of
241 PSR feedback strengths we can reasonably expect from our model forced with empirically-derived relationships.

242 2.3 Model runs to simulate future ocean warming and quantify the PSR feedback effect

243 To represent present-day conditions, we run a baseline simulation with modern-day circulation rates to steady
244 state. To simulate increased water column stratification and reduced vertical exchange due to warming in an idealized
245 way, we uniformly and instantaneously reduce circulation and diffusion rates by 10% throughout the ocean (i.e. we
246 multiply the tracer transport matrix A by 0.9, such that circulation patterns remain unchanged but the absolute
247 exchange rates between all grid cells are scaled down by 10%). For comparison, observations show that the Atlantic
248 meridional overturning circulation (AMOC) has weakened by about 15% since the mid-20th century due to
249 anthropogenic warming (Caesar et al., 2018), while ESMs project that AMOC will weaken by 11-34% over the 21st
250 century, depending on the chosen radiative forcing scenario (11% assumes the “high mitigation” RCP2.6 scenario,
251 while 34% assumes the “business-as-usual” RCP8.5 scenario) (Collins et al., 2019). A 10% decrease in circulation
252 rates is therefore a relatively conservative estimate of the effects of anthropogenic warming. Although modulation of
253 ocean circulation rates in response to climate change will be more complicated and variable than the uniform 10%
254 decrease applied here (e.g., Toggweiler and Russell, 2008), we seek only a simple, idealized way to approximate the
255 reduced surface nutrient supply that is expected in a warmer future ocean. Although we use a simplified representation
256 of future changes in ocean circulation, the exact same simplified representation is implemented in both PSR feedback-
257 on and -off simulations. We are thus isolating the effects of the PSR feedback from the effects of the circulation
258 change. It is therefore not unreasonable to assume that our calculated PSR feedback strength would be comparable to
259 that computed from a physical model with a more complex representation of future circulation changes, as long as
260 that model also applied identical circulation changes in PSR feedback-on and -off scenarios.

261 To quantify the impact of the global PSR feedback on export changes with future warming, we run the slower-
262 circulation rate simulation with and without the PSR feedback effect enabled. In feedback-off runs, β is set equal to
263 annual mean values (Fig. 1a) for the entire duration of the run. In feedback-on runs, β is initially set equal to annual
264 mean values, but is allowed to change according to Eq. (1), with $\frac{d\beta_{sat}}{dE_{n,sat}}$ defined as in Fig. 3c for the entire duration of

265 the run. Additional feedback-on runs were conducted using the upper and lower-bound $\frac{d\beta_{sat}}{dE_{n,sat}}$ maps (described in
266 Section 2.2.3).

267 All of the above described runs were also repeated with 10% faster circulation rates to determine whether the
268 PSR feedback strength is symmetrical with regard to the direction of circulation change. Within all runs, β is
269 constrained to realistically remain between 2 and 6.5 at all grid points, though these extremes are rarely reached. We
270 run all experimental simulations for 100 years (initializing with conditions from the end of the present-day spin-up)
271 to study near-future changes in export production and nutrient distributions, and to facilitate comparison with 100-
272 year changes projected by the state-of-the-art Earth System Models discussed above.

273 3 Results and Discussion

274 3.1 Empirically-derived, spatially-resolved β versus export relationships ($\frac{d\beta_{sat}}{dE_{n,sat}}$)

275 No matter which export datasets are used (Section 2.2), satellite-derived β and export are strongly negatively
276 correlated (Fig. 3; Fig. S3-4). The vast majority of variance in both β and export occurs over seasonal (rather than
277 interannual or longer) timescales, and therefore the coincident seasonal cycles of β and export account for much of
278 the relationship between the two variables (Fig. S3-4). Because β and export are negatively correlated, export tends to
279 be high when β is small (particles are large) and low when β is large (particles are small). These empirical findings
280 are in agreement with Cram et al. (2018), who observed that large particles tend to comprise a larger fraction of the
281 sinking flux where productivity and carbon export are high.

282 While our analysis does not provide mechanistic insights into the roots of the negative correlation between β
283 and export, a plausible explanation for the direction of this relationship is as follows. Low-nutrient conditions select
284 for small phytoplankton with high surface area-to-volume ratios, such that smaller phytoplankton are more abundant
285 in low-nutrient conditions (Litchman et al., 2007). In these nutrient-limited regions of the ocean, productivity and
286 export are also suppressed. Thus, nutrient availability controls both the export rate and the size structure of the
287 phytoplankton community over much of the ocean. Assuming that phytoplankton size in turn controls the size of
288 sinking particles, as suggested by past research (e.g., Guidi et al., 2007; Guidi et al., 2008; Guidi et al., 2009), the
289 availability of nutrients then ultimately controls sinking particle size as well. This potentially explains why small
290 particles (large β) are associated with reduced export rates and low-nutrient conditions, while large particles (small β)
291 are associated with increased export rates and high-nutrient conditions.

292 This line of reasoning may also explain why regions that are more nutrient-limited (i.e., the subtropics)
293 exhibit especially strong negative relationships between β and export (Fig. 3; Fig. S3-4); both β and export are likely
294 predominantly driven (in opposite directions) by surface nutrient supply in these areas. Where light or temperature
295 take over as the dominant factors limiting phytoplankton productivity, the relationships between β and export are
296 weakened, as in the higher-latitude regions (Fig. 3; Fig. S3-4). The counterintuitive weakly positive relationship
297 between β and export in the Subantarctic Zone (SAZ) of the Southern Ocean (Fig S5) is in line with findings from

298 Lam and Bishop (2007), who showed that in the Southern Ocean, areas with higher biomass and larger particles at the
299 surface were actually associated with lower rates of export out of the euphotic zone. In these diatom-dominated
300 regions, zooplankton may be more active and have higher particle grazing efficiencies, leading to faster attenuation
301 of particulate carbon fluxes with depth. The unique relationship between β and export in the SAZ is worth further
302 exploration, and may be further elucidated by NPP datasets that are specifically calibrated for the Southern Ocean
303 (e.g. Johnson et al., 2013), but is beyond the scope of the current study.

304 **3.2 An empirical negative global particle size-remineralization (PSR) feedback**

305 To determine how the empirically-derived relationships between β and export ultimately affect the direction
306 and strength of the PSR feedback effect on a global scale, we must first understand the effects of β on sinking particle
307 speeds and remineralization depths. Past work has broadly established a positive relationship between particle size
308 and sinking speed in the ocean (Alldredge and Gotschalk, 1988; Smayda, 1971; Iversen and Ploug, 2010)—although
309 there are exceptions to these rules (Cael and White, 2020; Laurenceau-Cornec et al., 2019), particularly in the Southern
310 Ocean (McDonnell and Buesseler, 2010). The characteristic depth scale of particle remineralization is proportional to
311 this sinking speed divided by a microbially-mediated remineralization rate (Kwon et al., 2009; McDonnell et al.,
312 2015). Here we define remineralization depth as the depth at which POC flux out of the euphotic zone is reduced by
313 a factor of e or 63% (i.e., the e -folding depth of the flux) (Fig. 1b). The dominance of smaller sinking particles in the
314 water column results in a shallower remineralization depth, as bacteria have more time to decompose these slow-
315 sinking particles into nutrients and CO₂ as they pass through the upper layers of the water column (Bach et al., 2016).
316 Together with the empirical relationships we found between POC export and particle size (Section 3.1), this points
317 towards a predominantly *negative* feedback loop that would dampen the response of POC export to physically-induced
318 changes in nutrient supply. In a warming and stratifying ocean, this hypothesized particle size-remineralization
319 feedback would theoretically proceed through the following steps at any given location, which are illustrated
320 schematically in Fig. 4:

321 1.) *Slower Circulation (SC)* – First, stratification of the water column and slowing trade winds with climate
322 warming will reduce shallow subsurface nutrient concentrations and vertical exchange/upwelling rates. This
323 slows nutrient supply into the euphotic zone, which in turn decreases phytoplankton productivity and
324 resultant export production (Fig. 4a, b, green arrows).

325 2.) *Ecological Effect (EE)* – A decrease in surface nutrient supply also selects for smaller phytoplankton, which
326 presumably leads to a larger proportion of small particles in the export flux. The net result of this ecological
327 effect (EE) (Fig. 4a, red arrow) is captured in a predominantly negative relationship between export and β
328 (Fig. 4c, red line). Constrained by this empirical relationship, changes in export and β under slowed
329 circulation (SC) must fall along the red line in Fig. 4c (“SC with EE” point). In the absence of the ecological
330 effect (i.e., phytoplankton/particle sizes are not affected by changes in the nutrient supply), there is no such
331 requirement and β would remain unchanged under a slowed circulation scenario (“SC without EE” point in
332 Fig. 4c).

333 3.) *Sinking Speed Effect (SSE)* – Smaller particles resulting from the ecological response to a reduced nutrient
334 supply would sink more slowly and therefore remineralize shallower in the water column. More regenerated
335 nutrients would then accumulate within shallower waters and thus recirculate more quickly to the surface. In
336 isolation, a shift to smaller particles would therefore ultimately lead to greater surface nutrient availability
337 and larger export rates (Fig. 4a, blue arrow), represented by the positive slope of the blue export-versus- β
338 line in Fig. 4d. In the presence of this sinking speed effect (SSE), changes in export and β under slowed
339 circulation must fall along the blue sinking speed-related export-versus- β line (Fig. 4d). In the absence of this
340 sinking speed effect (i.e., particle size does not affect sinking rates/remineralization depths), there is no such
341 requirement, and the initial stratification-induced export decrease would remain unaltered (“SC without SSE,
342 with EE” point in Fig. 4d).

343 Only in the presence of both the ecological and sinking speed effects does the PSR feedback function in full;
344 in this case, after circulation is slowed, export and β must reach a new steady-state at the intersection of the red and
345 blue lines (“SC with SSE and EE” yellow star in Fig. 4d). Thus, the overall decrease in POC export would be smaller
346 than predicted from decreased circulation rates and surface nutrient supply alone. That is, the net effect of
347 phytoplankton selection and particle size-dependent remineralization depths provide a negative feedback on, or
348 dampening of, changes in export, due to the empirically-derived negative relationship between β and export. While
349 we have assumed that phytoplankton community structure is the underlying mechanism linking POC export and
350 particle size, the PSR feedback would operate in the same direction discussed here if another mechanism were
351 ultimately responsible for the empirical negative relationship between these two factors. Though the above description
352 focuses on export decreases under decreased circulation rates, the PSR feedback would result in an analogous
353 dampening of export increases under increased circulation rates and surface nutrient supply.

354 **3.3 Predicted export changes in the presence of the global negative PSR feedback effect**

355 In this section, we discuss how predicted future changes in export production and mesopelagic POC flux
356 differ between biogeochemical model simulations with and without the PSR feedback effect applied globally. Sections
357 3.3.1 and 3.3.2/3.3.3 respectively examine resultant global and zonal/regional mean changes in export. Section 3.3.4
358 examines resultant global and zonal/regional mean changes in deeper POC fluxes.

359 **3.3.1 Predicted global mean export changes with and without the global PSR feedback**

360 To examine the global strength of the PSR feedback within our model under an idealized climate change
361 scenario, we compare global mean export changes over time in the PSR feedback-on and off runs after a 10% decrease
362 in circulation rates (Fig. 5, comparing slower circulation dashed and solid lines). In both the feedback-on and off
363 cases, instantaneously decreasing circulation rates reduces surface nutrient supply and immediately leads to a sharp
364 decrease in global mean export of $\sim 0.2 \text{ molC m}^{-2} \text{ yr}^{-1}$ from $3.54 \text{ molC m}^{-2} \text{ yr}^{-1}$. After this initial plunge, global mean
365 export declines by an additional $0.09 \text{ molC m}^{-2} \text{ yr}^{-1}$ over the next 100 years with the feedback off (for a total decrease

366 of $0.29 \text{ molC m}^{-2} \text{ yr}^{-1}$ or 8.1%), versus an additional $0.05 \text{ molC m}^{-2} \text{ yr}^{-1}$ with the feedback on (for a total decrease of
367 $0.25 \text{ molC m}^{-2} \text{ yr}^{-1}$ or 7.0%) (Fig. 5, slower circulation lines and bars).

368 Turning the PSR feedback on in our model reduced the total 100-year predicted decrease in export by $\sim 14\%$
369 relative to the PSR feedback-off scenario (the ratio of the solid-colored bar length to the full bar length below zero in
370 Fig. 5. At equilibrium (when global mean export stabilizes ~ 500 years after decreasing circulation rates), this feedback
371 effect increases to $\sim 16\%$. With the feedback turned on, particle sizes shrink and remineralization depths shoal in
372 response to an initial circulation-driven decrease in surface nutrient supply, thereby moderating this initial decrease
373 by keeping more recycled nutrients at the surface. In particular, global mean β increases by 0.03 (from 4.34 to 4.37)
374 under 10% decreased circulation rates after 100 years with the PSR feedback on (Fig. 6a,b), corresponding to a 17 m
375 global mean shoaling (from 595 to 578 m) of e-folding remineralization depths (Fig. 6b). The greatest regional mean
376 β increase of 0.06 occurs in the Indian Ocean (IND), resulting in a 41 m shoaling of remineralization depths there
377 (Fig. 6b). Results from runs employing upper and lower-bound $\frac{d\beta_{sat}}{dE_{n,sat}}$ maps (defined in Section 2.2.3, represented by
378 the error bars in Fig. 4b) lend further support to our findings and indicate that the modeled global PSR feedback effect
379 size is relatively insensitive to the choice of export maps used to compute $\frac{d\beta_{sat}}{dE_{n,sat}}$ (Fig 5, black error bars).

380 The PSR feedback also dampens the response of global-mean carbon export to an instantaneous *increase* in
381 ocean circulation rates (Fig. 5). One hundred years after circulation rates are increased by 10%, global mean carbon
382 export increases from $3.54 \text{ molC m}^{-2} \text{ yr}^{-1}$ by $0.28 \text{ molC m}^{-2} \text{ yr}^{-1}$ (8.0%) with the feedback off, whereas it increases by
383 $\sim 0.23 \text{ molC m}^{-2} \text{ yr}^{-1}$ (6.6%) with the feedback on (Fig. 5, faster circulation lines and bars). Thus, increasing circulation
384 rates by 10% with the PSR feedback on reduces the 100-year increase in export production by $\sim 18\%$ (the ratio of the
385 solid-colored bar length to the full bar length above zero in Fig. 5). At equilibrium, this feedback effect increases to
386 $\sim 20\%$. With the feedback turned on, particle sizes grow and remineralization depths deepen in response to an initial
387 circulation-driven increase in surface nutrient supply, thereby moderating this initial increase by transferring more
388 nutrients to deeper waters where they recirculate more slowly to the surface. In particular, global mean β decreases by
389 0.03 units (from 4.34 to 4.31) under 10% increased circulation rates, corresponding to a 20 m global mean deepening
390 (from 595 to 615 m) of e-folding remineralization depths (not shown). The greatest regional mean β decrease of 0.07
391 occurs in the Indian Ocean (IND), resulting in a 54 m shoaling of remineralization depths there. Compared with the
392 decreased circulation case, absolute changes in remineralization depths are slightly larger under increased circulation
393 rates because remineralization depth changes are more sensitive to variations in β when particles are larger (that is, at
394 smaller values of β). Because remineralization depth changes are greater under increased circulation rates, so too is
395 the global PSR feedback strength (14% with decreased circulation rates versus 18% with increased circulation rates).
396 Again, results from PSR feedback-on runs constrained by upper and lower-bound $\frac{d\beta_{sat}}{dE_{n,sat}}$ maps further support the
397 notion that the PSR feedback size is relatively insensitive to the choice of export maps used to compute $\frac{d\beta_{sat}}{dE_{n,sat}}$ (Fig 5,
398 error bars). Thus, the effect of the PSR feedback is to buffer changes in export production in response to any physical
399 perturbation in nutrient supply, regardless of the direction.

400 The strength of the PSR feedback also does not depend on the size of circulation rate changes. Indeed, we
 401 observed that PSR feedback strength remains constant whether circulation rates are increased/decreased by 10% or
 402 50%. Thus, the percentage difference in projected export change between PSR feedback on and off cases is relatively
 403 uniform even under quite different changes in circulation rates.

404 3.3.2 Predicted zonal and regional mean export changes *without* the global PSR feedback

405 In our baseline simulation under current-day circulation rates, POC export covaries tightly throughout the
 406 low to mid-latitudes with nutrient concentrations in shallow subsurface waters beneath the euphotic zone, quantified
 407 here as $[PO_4]$ at 200m depth (P_{200m}) (Fig. 7a,b; Fig. 8a). South of $\sim 40^\circ S$ and north of $\sim 40^\circ N$, other factors such as light
 408 and/or temperature become limiting; as a result, export does not vary as tightly with P_{200m} in these higher-latitude
 409 regions. The spatial structure of the relationship between export and P_{200m} confirms that nutrient supply from
 410 subsurface layers is the primary driver of export rates throughout the nutrient-limited low- to mid-latitudes. Therefore,
 411 in these regions, the following balance approximately holds:

$$412 \text{Export} = E \approx wP_{200m}, \quad (2)$$

413 where w is the local upwards nutrient supply velocity, which represents the net effect of all vertical exchange
 414 processes, including diffusion, upwelling, entrainment, and mixing. This relationship between export, upwelling, and
 415 subsurface nutrient concentrations reflects the common assumption that at steady-state, export flux out of the euphotic
 416 zone must approximately balance the supply of nutrients into the euphotic zone by upwelling (e.g. Ducklow et al.,
 417 2001; Passow and Carlson, 2012). This balance can in turn be used to derive (via perturbation analysis) a simple,
 418 approximate diagnostic for understanding changes in export under altered circulation rates at any given location:

$$419 \Delta E = \Delta w * P_{200m,baseline} + w_{baseline} * \Delta P_{200m}, \quad (3)$$

420 where *baseline* denotes variables from the baseline simulation ran to steady-state with current-day circulation rates
 421 and Δ denotes change from the baseline simulation under altered circulation rates. (Note that we ignore the
 422 “perturbation product” term, $\Delta w * \Delta P_{200m}$, because it is negligible.)

423 Though Eqs. (2-3) are not mathematically equivalent to the full model solution, they explain much of the
 424 full model’s behavior and provide us with a tool to simplify, deconvolve, and better understand the different
 425 mechanisms leading to export changes. In particular, when ocean circulation is slowed, Eq. (3) allows us to identify
 426 two different contributions to the resultant reduction in export through the low to mid-latitudes. First, and most
 427 intuitively, when circulation rates are uniformly decreased, w is reduced across the entire ocean ($\Delta w < 0$) and the
 428 supply of “baseline” nutrients is curtailed. Second, a decrease in circulation rates also reduces phosphate
 429 concentrations throughout the shallow subsurface layer in the low to mid-latitudes ($\Delta P_{200m} < 0$) (solid lines and
 430 bars in Fig 7c,d; Fig. 8b). This decrease in P_{200m} is likely largely driven by enhanced biological nutrient utilization in
 431 the surface of the Southern Ocean in response to slower circulation, which is then propagated into the low to mid-
 432 latitude interior through Antarctic Intermediate and Subantarctic Mode Waters (e.g., Sarmiento et al., 2004; Marinov
 433 et al., 2006), as observed in future climate simulations by more complex ESMs (e.g., Moore et al., 2018).

434 Together, the decreases in shallow subsurface nutrient concentrations (P_{200m}) and vertical exchange rates (w)
 435 result in substantial reductions in export throughout most of the ocean under our decreased circulation simulations as
 436 dictated by Eq. (3), with the greatest reductions occurring in nutrient-limited areas. In the absence of the PSR feedback,
 437 the 10% decrease we imposed on circulation rates leads to 100-year zonal mean export decreases of $>15\%$ at 35°N
 438 and S and $\sim 10\%$ between 35°N and S (solid line in Fig. 7e). Regionally, the oligotrophic subtropics (especially the
 439 STP) exhibit the largest relative decreases in export ($\sim 10\text{-}13\%$), followed closely by the tropics (ETA, ETP) with
 440 export decreases around $8\text{-}10\%$ (solid bars in Fig. 7f). As expected, the decrease in export mirrors the pattern of ΔP_{200m}
 441 in low to mid-latitude regions due to a strong dependence of export on nutrient supply from the shallow subsurface
 442 here.

443 3.3.3 Predicted zonal and regional mean export changes *with* the global PSR feedback

444 As with the global mean (Section 3.3.1), we quantify zonal and regional mean PSR feedback strength as the
 445 difference in circulation-driven export change from baseline between the feedback-on and -off runs, normalized by
 446 the change from baseline in the feedback-off run. In other words, the PSR feedback strength is the percentage by
 447 which turning on the PSR feedback reduces (dampens) the response of carbon export to changes in ocean circulation
 448 (blue line and bars in Fig. 7g,h). Thus, the zonal mean feedback strength (blue line in Fig. 7g) is equal to the difference
 449 between the dashed and solid lines divided by the solid line in Fig. 7e, while the regional mean PSR feedback strength
 450 (blue bars in Fig. 7h) is equal to the length of the solid-colored portion of the bars divided by the entire length of the
 451 bars in Fig. 7f. The PSR feedback strength is greatest (most strongly damping) in the low to mid-latitudes and in the
 452 tropics (ETA, ETP) and subtropics (STA, STP, IND), with the feedback able to reduce zonal and regional mean export
 453 changes by up to 20% in these regions (blue lines and bars in Fig. 7g,h). To understand this spatial pattern, we combine
 454 Eq. (3) with our definition of PSR feedback strength to yield the following diagnostic, which can help separate out the
 455 various determinants of PSR feedback strength:

$$456 \text{ PSR feedback strength} = \frac{\Delta E_{on} - \Delta E_{off}}{\Delta E_{off}} \approx \frac{\frac{\Delta P_{200m,on} - \Delta P_{200m,off}}{P_{200m,baseline}}}{\frac{\Delta w}{w_{baseline}} + \frac{\Delta P_{200m,off}}{P_{200m,baseline}}}, \quad (4)$$

457 where *on/off* denotes whether the PSR feedback was turned on or off under the altered circulation rates. This
 458 expression reveals that the PSR feedback effect is strongest wherever activating the feedback leads to the greatest
 459 dampening of changes in P_{200m} , compared to the changes that occur in the feedback-off case. In the decreased
 460 circulation simulations ($\frac{\Delta w}{w_{baseline}} = -10\%$ everywhere), the low to mid-latitude regions display the greatest differences
 461 in P_{200m} changes between feedback-on and off runs (Fig. 7c,d; Fig. 8b-d); these regions undergo the greatest reductions
 462 in circulation-driven export change due to the PSR feedback (Fig. 7e,f) and thus exhibit the largest PSR feedback
 463 effects (blue lines and bars in Fig. 7g,h).

464 The degree to which the PSR feedback dampens P_{200m} changes is in turn driven by the strength of the
 465 relationship between β and export. The low to mid-latitudes exhibit the most negative $\frac{d\beta_{sat}}{dE_{n,sat}}$ values and therefore, the
 466 tightest coupling between β and export (Fig. 3c). In these regions, where macronutrient limitation is the dominant

467 constraint on productivity, a given circulation-driven decrease in surface nutrient supply causes a relatively large drop
468 in both export and phytoplankton/particle size (leading to an increase in β) in the presence of the PSR feedback. This
469 then allows significantly more nutrients to be recycled at the surface, resulting in greatly dampened decreases in P_{200m}
470 and subsequent export production.

471 Our simple diagnostic (Eq. (4), derived from Eqs. (2-3)) can explain PSR feedback strengths quite well over
472 much of the global ocean, as can be seen by comparing total feedback strengths (blue lines/bars in Fig. 7g,h) with our
473 diagnostic-derived feedback strengths (right-hand side of Eq. (4), represented by orange lines/bars in Fig. 7g,h), which
474 were calculated under the assumption that export is nearly equal to the supply of nutrients into the euphotic zone via
475 upwelling (Eq. (2)). In other words, Eqs. (2-4) are a good approximation to the full model solution where the orange
476 lines/bars lie relatively close to the blue lines/bars in Fig. 7g-h. However, new production can be fed by local upwelling
477 as well as lateral advection, such that changes in P_{200m} and vertical exchange rates alone (orange lines/bars in Fig.
478 7g,h) cannot perfectly predict all changes in export (blue lines/bars in Fig. 7g,h), especially in regions where lateral
479 advection plays a relatively large role in supplying nutrients to the surface.

480 3.3.4 Vertical reorganization of POC fluxes induced by the PSR feedback

481 Up to this point, the effect of the PSR feedback effect has been analyzed solely for carbon exported out of
482 the surface euphotic zone (<75 m depth here). We largely focus on export out of the bottom of the euphotic zone
483 rather than on POC fluxes at greater depths because export, by definition, is a measure of the total organic carbon
484 supply that feeds subsurface heterotrophic communities. Thus, the PSR feedback effect buffers the productivity of
485 mesopelagic communities as a whole by damping changes in export.

486 This buffering of the food supply does not occur uniformly through the water column, however. While
487 shallower particle remineralization helps maintain the nutrient supply to the surface and buffers the POC export rate,
488 it also means that fewer particles persist at depth. Indeed, the PSR feedback on export has the opposite effect on
489 POC fluxes in the lower mesopelagic zone (at 800 m depth, equivalent to 725 m below the bottom of the euphotic
490 zone, for example – Fig. 9a-b). This results in a vertical re-organization of particle fluxes, with more food available
491 in the upper mesopelagic and less in the lower mesopelagic when the PSR feedback is activated. In particular, by
492 350 m depth (225 m below the bottom of the euphotic zone), the PSR feedback effect on POC flux has changed sign
493 from negative to positive across all ocean regions except for the SAZ, AAZ, and NA (Fig. 9c). In regions where the
494 negative PSR feedback effect is strongest, vertical reorganization is more extreme and the sign of the PSR feedback
495 flips from negative to positive shallower in the water column. The PSR feedback effect becomes positive below
496 depths as shallow as 125, 148, 158, and 165 m (50, 73, 83, and 90 m below the euphotic zone) in the NP, ETP, STA,
497 and IND regions, respectively, for example (Fig. 9c).

498 A negative PSR feedback effect dampens predicted circulation-driven changes in global export out of the
499 euphotic zone, while a positive PSR feedback effect amplifies predicted changes in lower mesopelagic global POC
500 fluxes. It follows that global models without the PSR feedback effect would *overestimate* changes in export, but
501 *underestimate* changes in POC fluxes at deeper depths in a future warming/slowed circulation scenario. This vertical

502 reorganization of POC flux changes brought about by the PSR feedback effect, leading to greater-than-expected
503 fluxes in the upper mesopelagic and lower-than-expected fluxes in the lower mesopelagic under future warming, has
504 the potential to alter follow-on predictions of vertical ecological community organization as well. Importantly, the
505 net effect of the PSR feedback is still a buffering of the total food supply to subsurface heterotrophic communities,
506 however.

507 **3.4 Predicted export changes in the presence of regional PSR feedback effects**

508 In this section, we discuss each individual ocean region’s contribution to the global PSR feedback effect. To
509 isolate the PSR feedback effect coming from each region, we conduct a set of model runs in which we decrease the
510 circulation rate globally, but only activate the PSR feedback within one region at a time. In these feedback-on runs,
511 we set $\frac{d\beta_{sat}}{dE_{n,sat}}$ in Eq. (1) equal to zero at all grid points outside of the region we are isolating; within the isolated region,
512 we set $\frac{d\beta_{sat}}{dE_{n,sat}}$ equal to the corresponding empirically-derived value (as shown in Fig. 3b). These simulations are then
513 compared to the same feedback-off run discussed in Section 3.3 (i.e., no changes in β anywhere) to determine the
514 impact of enabling the feedback within one region at a time. Sections 3.4.1. and 3.4.2 respectively describe the global
515 and regional mean export changes resulting from this set of experiments.

516 **3.4.1 Predicted global mean export changes with and without regional PSR feedbacks**

517 Analysis of the regional feedback-on runs show that tropical (ETA, ETP) and subtropical (STA, STP, IND)
518 regions contribute most significantly to the global PSR feedback (Fig. 10). Turning the feedback on in the ETP alone,
519 for instance, leads to a 3.9% reduction in global mean export change compared to the feedback-off case (Fig. 10a –
520 row 7, last column); the ETP alone thus accounts for 38.6% of the global PSR feedback strength (Fig. 10b – row 7,
521 last column), while spanning only 10.3% of total ocean area. Turning the feedback on in the subtropical (STA, STP,
522 IND) and tropical (ETA, ETP) regions one at a time and then summing their individual contributions (11.7%, 11.6%,
523 22.3%, 13.3%, 38.6% respectively; Fig. 10b – last column) accounts for 97.5% of the global PSR feedback effect,
524 while all other regions (AAZ, SAZ, NA, NP) account for only a negligible fraction of the effect (or even act to decrease
525 the overall effect in the case of the SAZ) (Fig. 10b – last column). The dominant contributions of the
526 tropical/subtropical regions to the global PSR feedback can once again be understood via spatial patterns in $\frac{d\beta_{sat}}{dE_{n,sat}}$
527 (Fig. 3c), with large changes in β and remineralization depth associated with relatively small changes in export in the
528 nutrient-limited tropical/subtropical regions.

529 **3.4.2 Predicted regional mean export changes with and without regional PSR feedbacks**

530 The significant tropical/subtropical contribution to the PSR feedback can also be seen by examining export
531 changes within individual regions. Activating the PSR feedback in the STA, for example, dampens regional mean
532 export decreases within the STA, the ETA, and the NA by 7.7%, 3.1%, and 2.2%, respectively (Fig. 10a – row 3).
533 Turning on the feedback in the STP (Fig. 10a – row 4), ETA (Fig. 10a – row 6), or ETP (Fig. 10a – row 7) alone have

534 similarly large effects on surrounding regions. In contrast, activating the feedback within higher-latitude regions
535 (AAZ, SAZ, NA, NP) neither significantly moderates export decreases in any individual regions nor globally (Fig.
536 10a – rows 1-2, 8-9). The AAZ uniquely undergoes near-zero decreases in export for all runs with the feedback on or
537 off; PSR feedback strength here is therefore negligible (Fig. 10a,b – row 1).

538 When the PSR feedback is turned on within a given region, the effect is typically felt most strongly within
539 that same region, as would reasonably be expected given that export production and resultant remineralization are
540 spatially co-occurring (Fig. 10a,b – diagonal going from upper left to lower right corner). However, depending on the
541 local magnitude of $\frac{d\beta_{sat}}{dE_{n,sat}}$ compared to that of neighboring regions, as well as the connectivity of nutrient supplies
542 between them, there can be substantial PSR feedback effects originating from afar. For example, in the Pacific basin,
543 switching on the PSR feedback in the ETP has a stronger buffering effect on export in the STP region than switching
544 on the feedback in the STP itself (Fig. 10b – row 7, column 4). This is because the relationship between β and export
545 is much stronger in the ETP (with a regional mean $\frac{d\beta_{sat}}{dE_{n,sat}}$ of -0.40; see Fig. 3c) than in the STP (with a regional mean
546 $\frac{d\beta_{sat}}{dE_{n,sat}}$ of -0.18; see Fig. 3c), and because remineralized surface nutrients in the ETP are readily carried into the STP
547 by wind-driven Ekman transport. In this way, PSR feedback-driven buffering of surface nutrient supply changes
548 within the ETP indirectly buffers surface nutrient supply changes in the STP as well. This indirect effect also operates
549 in the reverse direction, in that activating the PSR feedback in the STP also has a relatively strong impact back on the
550 ETP (Fig. 10b – row 4, column 7). In this case, nutrients remineralized shallower in the STP thermocline are directed
551 along sloping isopycnals that eventually upwell into the ETP surface, thus buffering decreases in export there. The
552 STP also has a relatively large PSR feedback effect on the subpolar NP (Fig. 10b – row 4, column 9), due to the intense
553 flow of the Kuroshio Current, which carries surface nutrients from the STP northward.

554 Similar relationships hold in the Atlantic basin between the tropics, subtropics, and subpolar regions.
555 However, the PSR feedback effect of the ETA on the STA is smaller (Fig. 10b – row 6, column 3), while the effect of
556 the STA on the ETA is larger (Fig. 10b – row 3, column 6) compared to their Pacific counterparts, presumably due to
557 less pronounced Ekman divergence along the equatorial Atlantic. The STA's PSR feedback effect on the subpolar NA
558 (Fig. 10b – row 3, column 8) is also substantially more pronounced than the STP's effect on the NP, indicating a
559 stronger nutrient supply pathway between subtropical and subpolar gyres in the Atlantic Ocean via the Gulf Stream.

560 An interesting phenomenon that arises in the Southern Ocean is the negative (dampening) overall PSR
561 feedback effect on the SAZ (Fig. 10a – row 10, column 2), despite a positive (amplifying) local feedback effect (Fig.
562 10a,b – row 2, column 2) and relationship between β and export here (regional mean $\frac{d\beta_{sat}}{dE_{n,sat}}$ of +0.13; see Fig. 3c).
563 Additive negative (dampening) PSR feedback effects from surrounding regions (STA, STP, IND, ETA, ETP) (Fig.
564 10a,b – rows 3-7, column 2) overcome the small positive (amplifying) local feedback effect here (Fig. 10a,b – row 2,
565 column 2), such that the total feedback effect still reduces the magnitude of the regional mean export decrease by
566 1.2% compared to the feedback-off case (Fig. 10a – last row, column 2). Because the SAZ spans the entire width of
567 the ocean and touches every other basin, additional remineralized surface nutrients collected in the many connected

568 regions are quickly and easily circulated into the SAZ when the global PSR feedback is active, thus buffering larger
569 would-be decreases in export here.

570 **3.5 Comparison with CMIP5 models**

571 In the absence of the PSR feedback, our model predicts a 100-year global mean export decrease of 8.1%
572 ($0.29 \text{ molC m}^{-2} \text{ yr}^{-1}$). With the PSR feedback on, this export decrease is reduced to 7.0% ($0.25 \text{ molC m}^{-2} \text{ yr}^{-1}$).
573 Meanwhile, CMIP5 models project global mean export decreases of around 7-18% between 2090-2099 and 1990-
574 1999 under a “business-as-usual” radiative forcing scenario (RCP8.5), with an ensemble mean of 13% (Bopp et al.,
575 2013). Assuming that none of the CMIP5 models are currently able to simulate the PSR feedback, our results
576 therefore suggest that accounting for the feedback would alter the CMIP5 range of projections from a 7-18% to a 6-
577 15.5% decline in export, and the CMIP5 ensemble mean projection from a 13% to an 11% decline in export. Many
578 of the CMIP5 models may be capable of capturing some semblance of a PSR feedback effect, however, thus
579 necessitating smaller corrections.

580 All CMIP5 models simulate various processes that have the potential to change POC export fluxes in a
581 warming future ocean, including zooplankton grazing/fecal pellet formation, phytoplankton aggregation,
582 phytoplankton/zooplankton mortality, and variations in phytoplankton community structure (which provide the
583 source material for sinking particles) based on changing nutrient, temperature, and light conditions. However, 7 of
584 17 total CMIP5 models with ocean biogeochemistry simulate only one class or type of particulate organic matter
585 (Ilyina et al., 2013; Tjiputra et al., 2013; Tsujino et al., 2010; Watanabe et al., 2011; Zahariev et al., 2008), and
586 therefore cannot capture changes in the *nature* of sinking POC with future warming. The other 10 CMIP5 models
587 *can* simulate changes in the nature of sinking particulate organic matter with future warming, either through the
588 amount of associated ballasting (3 models) (Dunne et al., 2013; Moore et al., 2004) or through particle size (7
589 models).

590 Of the 7 models that simulate changes in particle size and could thus potentially capture the PSR feedback
591 effect, 3 of these models resolve two particle sizes (small and large) with different sinking speeds (3 m day^{-1} for the
592 small particles and $50 \text{ to } 200 \text{ m day}^{-1}$ for the large particles) (Aumont and Bopp, 2006). Another 2 of these 7 models
593 also resolve two size-based particle types (diatoms and detritus) with different sinking speeds (1 m day^{-1} for diatoms
594 and 10 m day^{-1} for detritus) (Totterdell, 2019). The final 2 of these 7 models simulate 5 different organic particle
595 sinking speeds based on size, 1 for each different phytoplankton type in the model (for a total of 4) and 1 for carbon
596 detritus (Romanou et al., 2013). In sum, out of the 17 CMIP5 models described here, only 7 resolve particles of
597 more than one size that sink down the water column at different speeds and therefore have the potential to capture
598 some part of the PSR feedback effect.

599 If all the CMIP5 models differed only in their resolution of sinking particle sizes, then we would expect the
600 7 models with more than one particle size to project the smallest decreases in export with future warming. In reality,
601 however, the models differ in too many other ways to isolate potential impacts of the PSR feedback when comparing
602 between them. For example, three of the models that resolve more than one sinking particle size (IPSL-CM5A-LR,

603 IPSL-CM5A-MR, and HadGEM2-ES) predict some of the largest decreases in export production by 2100 (Fig. 9b in
604 Bopp et al., 2013), contrary to what would be expected given the potential presence of a PSR feedback in these
605 models. Indeed, the models that can simulate changes in the nature of sinking particles project changes in export that
606 span the entire range of CMIP5 model predictions (Fig. 9b in Bopp et al., 2013). The reasons for these differences in
607 projected export decreases is difficult to disentangle and would require examining the effects of one mechanism at a
608 time on export in each model.

609 Simply representing differently sized particles also does not ensure that a model will adequately represent
610 the negative PSR feedback quantified in this study. To adequately represent the negative PSR feedback, a given
611 model would need to contain mechanisms that give rise to the same strong, empirically-derived relationships
612 between POC export and particle size that we specify here. Within the models that resolve particle size to some
613 degree, the relative proportion of large and small particles is determined by internal model dynamics and are not
614 prescribed empirically. Furthermore, these models do not resolve a particle size spectrum over a wide range of sizes
615 as is done here. Therefore, CMIP5 models that dynamically resolve 2-5 different particle size classes with different
616 sinking speeds might qualitatively reproduce the same feedback, but it is not clear whether the magnitude or even
617 the sign of the feedback would be accurately captured. We argue that our model, which resolves particle size spectra
618 over a wide range of sizes and employs empirical export/particle-size relationship constraints, is most likely to
619 accurately capture the true magnitude of the PSR feedback. We thus suggest that our study provides a reasonable
620 baseline against which more complex Earth System Models can assess their ability to reproduce particle size-
621 remineralization feedbacks.

622 3.6 Caveats and future work

623 The exact strength of the PSR feedback hinges on the empirical relationship between carbon export and
624 particle size, which may differ depending on the datasets used to constrain it. To address this uncertainty, we correlated
625 β against a range of different global export datasets and found that our results were relatively insensitive to the choice
626 of export dataset. Unfortunately, well-grounded alternative global and temporally-resolved datasets for β were not
627 readily available, so uncertainty in the PSR feedback strength due to uncertainties in observed β could not be quantified
628 here. Analysis of in situ Underwater Visual Profiler (UVP) data suggests that β may actually be smaller (thus particles,
629 larger) and less variable (Cram et al., 2018) than the backscatter-derived values (Kostadinov et al., 2009) used in this
630 study. This would potentially imply less variability in particle size-driven remineralization depths, weakening the PSR
631 feedback strength calculated here. On the other hand, differences in remineralization depths are greater at smaller
632 values of β (Fig. S1; Fig. 2 in Devries et al., 2014), such that any given increase in β associated with a decrease in
633 export would lead to greater shoaling of remineralization depths and a larger PSR feedback effect than calculated here.
634 More in situ observations of β are clearly needed to better resolve these competing effects. One potential explanation
635 for these β discrepancies is that the algorithm used to derive β from remotely-sensed particulate backscatter sometimes
636 misses the largest particles in high-productivity areas such as the Southern Ocean (Kostadinov et al., 2009). In addition
637 to the mechanisms proposed in Lam and Bishop (2007), this may partly explain why $\frac{d\beta_{sat}}{dE_{n,sat}}$ is weakly positive in the

638 Subantarctic Zone (SAZ); particles may actually get larger with increasing export here, but because they are already
639 quite large, the satellite β sensor/algorithm may not be able to capture the particles becoming any larger. The result
640 would be an underestimation of the negative (dampening) PSR feedback effect in this region.

641 Another caveat of our study is that very simple phytoplankton biology and growth dependent on only one
642 macronutrient was assumed. Furthermore, particle fragmentation—via processes such as zooplankton grazing,
643 microbial degradation, or ocean turbulence (e.g., Cavan et al., 2017; Briggs et al., 2020)—was not included in our
644 model, nor was particle aggregation—via processes such as Transparent Exopolymer Particles production (e.g.,
645 Passow, 2002; Mari et al., 2017) or fecal pellet generation (e.g., Steinberg et al., 2012; Turner, 2015 and references
646 therein). Despite the aforementioned shortcomings, the results presented here represent a reasonable first attempt to
647 quantify the strength of the PSR feedback effect on export changes within a global model. Future work should test the
648 PSR feedback effect in more complex models that better resolve phytoplankton/zooplankton biology, particle
649 dynamics, and/or circulation changes. These models could include particle aggregation-disaggregation with
650 prognostic sinking speeds (Gehlen et al., 2006), empirically-driven food-webs (Siegel et al., 2014), explicit
651 phytoplankton and grazers of different sizes (Buesseler & Boyd, 2009), and/or spatiotemporally-resolved circulation
652 changes that respond directly to atmospheric forcing.

653 Additionally, future work should analyze the downstream effects of the PSR feedback on climate-driven
654 projections of fisheries productivity, dissolved oxygen availability, and carbon sequestration in the deep ocean over
655 centennial to millennial timescales. A smaller-than-currently-projected decrease in surface nutrient supply and export
656 rates would be beneficial for maintaining fisheries, for example. On the other hand, predicted increases in deep ocean
657 carbon sequestration may be reduced by the PSR feedback. In particular, a decrease in circulation rates should enable
658 enhanced carbon sequestration, as nutrients and CO₂ collect in the deep ocean (Fig. 8), but the PSR feedback may
659 potentially moderate this increased sequestration effect by shoaling remineralization and forcing a shorter carbon
660 sequestration timescale. We focused solely on 100-year changes in POC export, to the exclusion of potential longer-
661 term changes in deep ocean carbon storage, because it is a critical energy source energy to the mesopelagic twilight
662 zone and therefore determines the productivity of heterotrophic communities, including commercial fisheries.
663 Furthermore, while changes in the biological pump may also drive changes in ocean carbon storage, these will manifest
664 over longer timescales than changes in export, and will likely be overwhelmed on short timescales by the effects of
665 anthropogenic CO₂ uptake and solubility-driven outgassing. A detailed exploration of changes in carbon storage is
666 therefore beyond the scope of the current paper, but could be a fruitful avenue for future work.

667 Other remineralization depth-related feedbacks induced by changes in temperature, oxygen, particle density,
668 and mineral ballasting (among others) not studied here may also be important for modulation of future changes in
669 carbon export and its downstream effects. Ensuring that the PSR and other remineralization feedbacks are adequately
670 represented in ESMs should be a priority of the modeling community to enable robust predictions of carbon export
671 fluxes in the future ocean.

672 4 Summary

673 In this study, we used remotely sensed data to show that sinking particle size is empirically correlated with
674 the rate of particulate organic carbon export out of the euphotic zone across the global ocean, such that larger particles
675 tend to dominate when export is high. This empirical relationship between particle size and export likely emerges due
676 to the dependence of both variables on surface nutrient supply. Indeed, nutrient limitation both curtails productivity
677 and selects for smaller phytoplankton that likely aggregate into smaller sinking particles (Litchman et al., 2007; Guidi
678 et al., 2007; 2008; 2009). A reduction in surface nutrient supply stemming from increased water column stratification
679 in a warming ocean (Bopp et al., 2013; Cabré et al., 2015a; Capotondi et al., 2012) should thus lead to a decrease in
680 global export production (Fig 4, green arrows; Fig. 5, slower circulation solid lines/bars) *and* sinking particle size (Fig
681 4a, red arrow; Fig. 4c-d, red line; Fig. 6b). Smaller particles in turn drive shallower nutrient remineralization and thus
682 faster resupply of those nutrients to the surface, dampening the initial circulation-driven change in export (Fig. 4a,
683 blue arrow; Fig. 4d, blue line; Fig. 5, slower circulation dashed lines/hatched bars; Fig. 6b; Fig. 7c-f; Fig. 8b-c).
684 Regardless of the mechanism linking export and particle size, implementing the empirical relationships between the
685 two in an idealized global biogeochemical model revealed the presence of a negative particle size-remineralization
686 feedback effect that moderates circulation-driven changes in export.

687 Many Earth System Models ignore the effects of nutrient supply on particle size and/or the effects of particle
688 size on remineralization depths. Within our model, including these effects reduces the magnitude of predicted 100-
689 year changes in global export production by ~14% (Fig. 5). This implies that in isolation of other mechanisms, ESMs
690 without the PSR feedback may be projecting 100-year climate-driven export decreases that are ~1.16 times too large.
691 Under a relatively extreme ESM-projected decrease of 18% by 2100 (Bopp et al., 2013), absolute global export would
692 be reduced by ~0.7-2.9 GtC/yr, assuming a present rate in the range of 4-16 GtC/yr (Boyd & Trull, 2007; DeVries &
693 Weber, 2017; Dunne et al., 2005, 2007; Falkowski et al., 1998; Henson et al., 2011; Laws et al., 2000; Siegel et al.,
694 2014; Yamanaka & Tajika, 1996); with the PSR feedback in effect, this predicted decrease would be reduced by ~14%
695 to ~0.6-2.3 GtC/yr.

696 The PSR feedback is strongest in low-latitude tropical and subtropical regions (moderating export changes
697 by up to 20%; Fig. 7g,h; Fig. 10), where ESMs also predict some of the largest future export decreases (Bopp et al.,
698 2013; Cabré et al., 2015a). Within these regions, primary and export production are highly nutrient-limited, such that
699 a given stratification-induced decrease in nutrient supply leads to relatively large decreases in export and sinking
700 particle size (Fig. 3), with correspondingly large effects on remineralization depth (Fig. 6) and surface nutrient
701 recycling. Because these regions exhibit the greatest projected decreases in export as well as the strongest PSR
702 feedback effects, spatial variations in projected export decrease may also be less pronounced than currently expected.

703 The PSR feedback operates on increases in surface nutrient supply as well. Under surface nutrient supply
704 increases, phytoplankton/particles grow larger and remineralization depths deepen, which sends more nutrients out of
705 the shallow subsurface and thereby moderates initial circulation-driven increases in export. This PSR feedback reduces
706 the magnitude of predicted 100-year changes in global export production by about 18% when circulation rates are
707 increased by 10% (Fig. 5, faster circulation dashed lines/hatched bars). In scenarios of global cooling (resulting in
708 water column destratification, enhanced mixing, and increased surface nutrient supply), centennial-scale projections

709 of export increase in models lacking the PSR feedback would therefore be >1.2 times too big, again with the largest
710 overestimates in the low to mid-latitude regions. The PSR feedback thus moderates export changes in response to any
711 physical perturbation to surface nutrient supply, whether driven by increasing or decreasing circulation rates.

712 **Code availability**

713 The MATLAB code required to make the figures generated here can be found at
714 <https://doi.org/10.5281/zenodo.4117382>.

715 **Data availability**

716 Data in the form of *.mat files required to make the figures generated here can be found at
717 <http://doi.org/10.5281/zenodo.3785724>.

718 **Author contribution**

719 SL and CD designed the model experiments. SL developed the model code and performed the simulations. SL
720 prepared the manuscript with contributions from all co-authors.

1029 **Figure Captions**

1030
 1031 **Figure 1. Global maps of annual mean (a) particle size distribution slope (β) measured by remotely-sensed particulate**
 1032 **backscatter and reproduced from Kostadinov et al. (2009) and (b) remineralization depth, defined as the depth at which**
 1033 **particulate flux out of the euphotic zone is decreased by a factor of e assuming β in (a) at the surface, calculated using a**
 1034 **particle remineralization and sinking model (PRiSM, described in Section 2.1.1). Larger values of β are associated with**
 1035 **smaller particles, while smaller values of β are associated with larger particles.**

1036
 1037 **Figure 2. Global map of regionally-weighted annual mean export, averaged over nine different export maps (detailed in**
 1038 **Section 2.2.2). Contours indicate biogeochemical regions used for weighting and spatial averaging.**

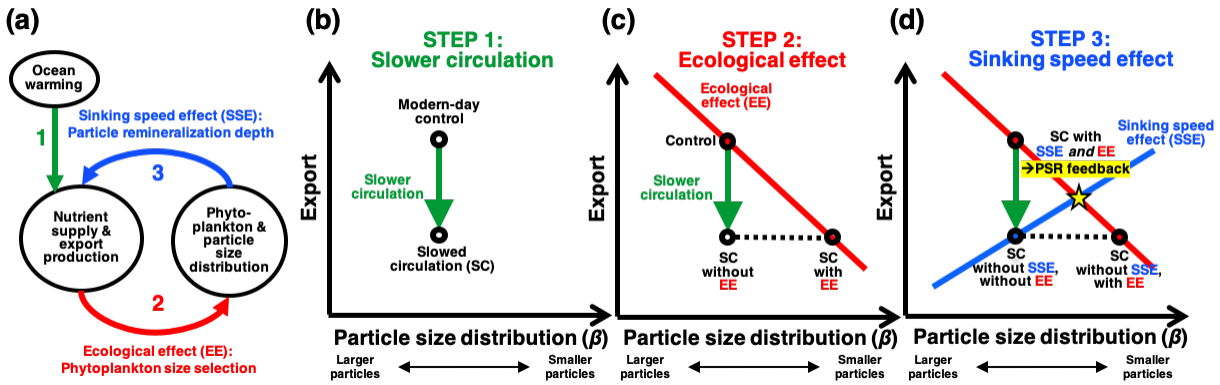

1039

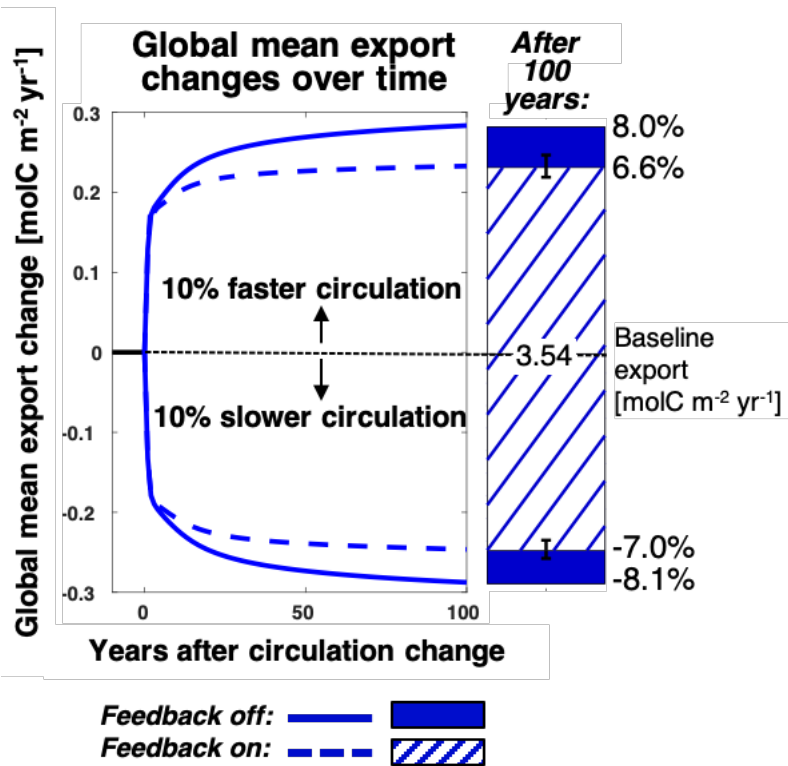

1040
1041
1042
1043

Figure 3. (a) All regional mean changes in particle size slope for a given change in time-mean normalized export, $\frac{d\beta_{sat}}{dE_{n,sat}}$ values (i.e., spatial averages of each map in Fig. S3 over regions shown in Fig. 2), colored by corresponding export map. Colorbar labels indicate the NPP and e-ratio algorithms used to generate the given export map (see Section 2.2.2 for full descriptions of the algorithms). NPP algorithm key: VGPM = the Vertically Generalized Production Model (VGPM)

1044 (Behrenfeld & Falkowski, 1997); VGPM = the Eppley-VGPM model (Carr et al., 2006); CbPM = the Carbon-based
 1045 Production Model (Behrenfeld et al., 2005). E-ratio algorithm key: L2000 = Laws et al. (2000); D2005 = Dunne et al. (2005);
 1046 L2011 = Laws et al. (2011). (b) Regionally-weighted mean $\frac{d\beta_{sat}}{dE_{n,sat}}$, averaged over the nine possibilities for each region shown
 1047 in Fig. 3a. Error bars represent one weighted standard deviation. (c) Global map of regionally variable $\frac{d\beta_{sat}}{dE_{n,sat}}$ used in model
 1048 runs with the PSR feedback on.

1049
 1050 Figure 4. (a) Schematic diagram of the particle size-reminerzalization (PSR) negative feedback on export production. A
 1051 change in circulation rates induced by climate change alters surface nutrient supply and subsequent export production
 1052 (green arrow). Changes in surface nutrient supply also drive changes in phytoplankton and resultant sinking particle sizes
 1053 (red arrow). Changes in sinking particle sizes in turn alter remineralization depth and consequently, surface nutrient supply
 1054 and export (blue arrow). (b) Schematic depicting decreased export production with decreases in circulation rates and
 1055 surface nutrient supply. (c) Schematic depicting a theoretical relationship between export and β , here termed the
 1056 phytoplankton size selection ecological effect (EE), in which smaller phytoplankton dominate in low-nutrient, low-export
 1057 conditions. (d) Schematic depicting all previous components of the PSR feedback, in addition to the crucial final component:
 1058 the particle remineralization depth sinking speed effect (SSE), in which smaller particles tend to get remineralized
 1059 shallower, leading to a greater recycled surface nutrient supply and therefore greater export.

1060

1061 Figure 5. Changes in global mean export over time from baseline conditions (current-day circulation, ran to steady-state)
 1062 after increasing or decreasing circulation rates by 10%. Dashed and solid lines represent runs with the PSR feedback turned
 1063 off and on, respectively. The bars on the right show absolute changes in global mean export from the baseline case 100 years
 1064 after changing circulation rates. Corresponding relative changes (calculated as absolute changes from the baseline over the
 1065 baseline mean) are listed in black. Global mean export in the baseline case is listed on the zero line. Hatched and solid
 1066 patterns represent runs with the PSR feedback turned off and on, respectively. The error bars represent export decreases
 1067 generated when employing the upper and lower-bound $\frac{d\beta_{\text{sat}}}{dE_{\text{n,sat}}}$ maps described in Section 2.2.3.

1101
1102

Figure 10. (a) Regional mean feedback strength due to the PSR negative feedback effect within each individual region. The y-axis denotes the single region (or the entire ocean in the case of “GLB” or “global”) within which the PSR feedback was turned on, while the x-axis denotes the region affected. A feedback strength above 0 indicates a negative PSR feedback effect (that is, a reduction in export change when the PSR feedback is applied). (b) Percent contribution of each individual region to each region’s total PSR feedback strength, computed as the regionally-derived feedback strength within an affected region divided by the globally-derived feedback strength in the same affected region (i.e., each given grid cell in (a) is divided by the corresponding column’s bottom-most grid cell).
