22 **Abstract**

23

24 For the assessment of evapotranspiration, near-surface airborne thermography offers new opportunities  
25 for studies with high numbers of spatial replicates and in a fine spatial resolution. We tested drone-based  
26 thermography and the subsequent application of three energy balance models (DATTUTDUT, TSEB-PT,  
27 DTD) using the widely accepted eddy covariance technique as a reference method. The study site was a  
28 mature oil palm plantation in lowland Sumatra, Indonesia. For the 61 flight missions, latent heat flux  
29 estimates of the DATTUTDUT model with measured net radiation agreed well with eddy covariance  
30 measurements ( $r^2=0.85$ ; MAE=47; RMSE=60) across variable weather conditions and daytimes.  
31 Confidence intervals for slope and intercept of a model II Deming regression suggest no difference  
32 between drone-based and eddy covariance method, thus indicating interchangeability. TSEB-PT and  
33 DTD yielded agreeable results, but all three models are sensitive to the configuration of the net radiation  
34 assessment. Overall, we conclude that drone-based thermography with energy-balance modeling is a  
35 reliable method complementing available methods for evapotranspiration studies. It offers promising,  
36 additional opportunities for fine grain and spatially explicit studies.

37

## 38 **1 Introduction**

39

40 Evapotranspiration (ET) is a central flux in the hydrological cycle on a regional and on a global scale.  
41 Terrestrial ET consumes almost two-thirds of terrestrial precipitation (Oki and Kanae, 2006). There is an  
42 interest in better understanding ET and its drivers as climate change is expected to increase atmospheric  
43 evaporative demand and droughts are predicted to become more severe and frequent in the future  
44 (Prudhomme et al., 2014). ET is also strongly affected by land-cover and land-use changes, which are  
45 currently very pronounced in tropical regions (Hansen et al., 2013).

46

47 The eddy covariance technique (EC) is a widely accepted and well-established method to quantify ET at  
48 the stand scale (Baldocchi et al., 2001; Fisher et al., 2017). It results in a single latent heat flux (LE) value  
49 integrated over the footprint of the EC tower at a given time that can be converted to an ET estimate. A  
50 spatial fine grain attribution of different surface patches to this overall ET value is generally not possible.  
51 The EC method is costly and labor intensive, and therefore, a relatively low number of spatial replicates  
52 within a given region and among its different ecosystems are typically available. The EC method also has  
53 certain constraints regarding topography, atmospheric turbulence and landscape heterogeneity (Göckede  
54 et al., 2008).

55

56 A complementary approach for assessing LE at larger spatial scales is the use of remotely sensed land  
57 surface temperatures (LST) as boundary conditions for energy balance modeling and subsequent  
58 conversion to ET (Brenner et al., 2017; Guzinski et al., 2014; Hoffmann et al., 2016; Ortega-Farías et al.,  
59 2016; Xia et al., 2016). Transpiration from leaf surfaces leads to evaporative cooling of the canopy; LSTs,  
60 along with air temperature, can thus be used as a reliable indicator of plant water use, both in monocultures  
61 and in spatially highly heterogeneous systems such as natural forests (Lapidot et al., 2019). Compared to  
62 the EC method, this approach can potentially increase the number of spatial replicates within and among  
63 ecosystems and is also applicable in challenging terrain. Remotely sensed LSTs are regarded as good  
64 indicators for plant water use, stress and transpiration (Jones and Vaughan, 2010). One approach to obtain  
65 LST data is the use of satellite-based observations (Allen et al., 2007; Bastiaanssen et al., 1998; Ershadi  
66 et al., 2013). However, the spatial resolution of satellite data such as Landsat TM, ASTER, MODIS or  
67 AVHRR ranges from 90 m to 1 km, limiting the distinction of plant canopies and soil (Berni et al., 2009).  
68 A higher temporal resolution of satellite-based thermal infrared (TIR) observations is usually associated  
69 with a lower spatial resolution, and TIR data from satellites in both high spatial and high temporal  
70 resolution are not yet available (Brenner et al., 2017). Additionally, clouds are barriers for thermal  
71 radiation and therefore have a strong effect on the quality and availability of satellite-based TIR  
72 observations (Guzinski et al., 2013). This is of particular importance in regions with frequent cloud cover  
73 such as in tropical environments.

74

75 An alternative, recently emerging approach to measure LSTs is the use of drones. Radiometric TIR  
76 sensors for LST recording have become light-weight and affordable, and drones are now capable of  
77 carrying adequate payloads for reasonable timespans. Near-surface thermography-based studies allow  
78 temporal resolutions in flexible, e.g. hourly time steps and a spatial resolution in the decimeter scale or  
79 finer. Drone-based TIR recording and subsequent modeling of LE with energy balance models has  
80 previously shown promising results for short grass and crop vegetation in Central Europe (Brenner et al.,  
81 2018; Hoffmann et al., 2016). However, remote sensing of LST from drones is challenging and involves  
82 careful planning. Recording LST close to the surface results in a high resolution but reduces the area  
83 covered in a certain time span compared to surveying from a higher altitude. Increasing flight altitude  
84 reduces spatial resolution of LST images and thus increases the averaging of surface temperatures from  
85 individual canopies, soil patches and branches from neighboring canopies into a single pixel (Still et al.,  
86 2019). Further, air humidity can have a major effect on measurement accuracy as water vapor does not  
87 only attenuate the signals from the surface of interest to the sensor, but also emits its own thermal radiation  
88 (Still et al., 2019).

89  
90 Different energy balance models are available to compute LE from LST and subsequently calculate ET.  
91 In the one-source energy balance model DATTUTDUT (Deriving Atmosphere Turbulent Transport  
92 Useful To Dummies Using Temperature) (Timmermans et al., 2015) fluxes are estimated by relating  
93 single pixel temperatures to local temperature extremes. Two-source energy balance models such as  
94 TSEB (Two-Source Energy Balance) (Norman et al., 1995) and DTD (Dual Temperature Difference)  
95 (Norman et al., 2000) divide measured LSTs into a vegetation and a soil fraction. Several adaptations of  
96 these models were developed; the TSEB-PT model as described in Hoffmann et al. (2016), uses the  
97 Priestley-Taylor coefficient (PT) to determine canopy H flux and subsequently calculate the other  
98 fractions from the surface energy balance. TSEB-PT is based on the temperature difference between LST  
99 and air temperature (Norman et al., 1995). Expanding this concept, DTD uses a dual-temperature  
100 difference from an additional early morning set of measurements to account for biases in remotely sensed  
101 LSTs (Hoffmann et al., 2016; Norman et al., 2000). Crucial in applying such energy balance models is  
102 how the net radiation ( $R_n$ ) is implemented. In the original formulation of the DATTUTDUT model  $R_n$  is  
103 fully modeled, assuming a range of prerequisites and environmental conditions (Timmermans et al.,  
104 2015). TSEB-PT and DTD models use measured short and long-wave radiation to estimate  $R_n$  as a sum  
105 of in- and outgoing long- and short-wave radiation (Norman et al., 1995, 2000). Using airplanes or drones  
106 to record LSTs, the three models previously showed promising results for grass and crop surfaces in  
107 temperate and subtropical regions (Brenner et al., 2017, 2018; Hoffmann et al., 2016; Xia et al., 2016).  
108 However, to our knowledge, a comprehensive method comparison considering potential errors in both a  
109 reference method (e.g. the EC technique) and novel drone-based approaches is not yet available. Since  
110 full method comparisons based on model II regression require a sample size of at least  $n=60$  data pairs  
111 (Legendre and Legendre, 2003), many previous studies with smaller sample sizes were constrained to

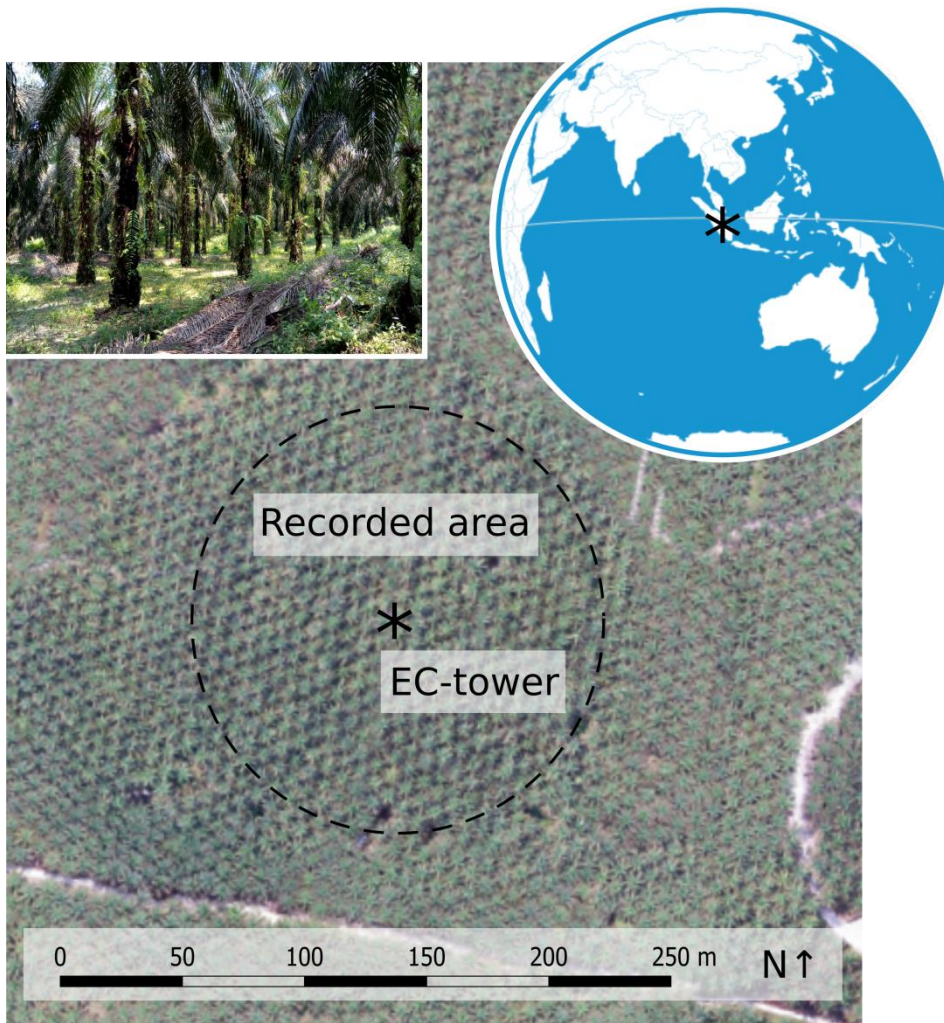

112 using error terms and correlation coefficients.

113  
114 The current study was conducted in the lowlands of Jambi province (Sumatra, Indonesia) where over the  
115 last decades, large areas of rainforest have been converted to rubber and oil palm plantations (Clough et  
116 al., 2016; Margono et al., 2012). This resulted in regional-scale changes in transpiration (Röll et al., 2019)  
117 and land surface warming (Sabajo et al., 2017). We assessed energy fluxes in a mature monoculture oil  
118 palm plantation and compared the LE estimates of drone-based methods with the established EC method  
119 as measured ground-based reference. Three energy-balance models (DATTUTDUT, TSEB-PT, DTD)  
120 were tested, each with three different configurations for the determination of  $R_n$  (fully modeling  $R_n$ ,  $R_n$   
121 estimates based on short-wave irradiance and measuring  $R_n$ ). The objectives of our study were to compare  
122 LE estimates from the drone-based methods to the EC technique, with a special focus on the detection of  
123 proportional and continuous errors among the methods and an evaluation of the model's prediction  
124 performance. The present study focuses on the comparison of different drone-based methods as a baseline  
125 for future ecological studies, rather than applying the methods to different land-use types.

## 126 127 **2 Methods**

### 128 129 **2.1 Study site**

130  
131 The study site is located in the lowlands of Jambi province (Sumatra, Indonesia) near the equator (E  
132 103.3914411, N -1.6929879, 76 m a.s.l.). Average annual air temperature in the region is 26.5°C and  
133 average annual precipitation is 2235 mm yr<sup>-1</sup> (Drescher et al., 2016). At the time of our measurement  
134 campaign in August 2017, the studied monoculture oil palm (*Elaeis guineensis*) plantation was 15 years  
135 old. Palm stem density was 140 palms ha<sup>-1</sup>, with an average palm height of 14.3 m and an average canopy  
136 radius of 4.5 m. Leaf area index (LAI) was estimated at 3.64 m<sup>2</sup> m<sup>-2</sup> (Fan et al., 2015) and canopy cover  
137 was estimated to be 90%. Plantation management included the removal of older and non-vital leaves from  
138 the oil palms, herbicide application to remove most understory plants and fertilization (196 kg N ha<sup>-1</sup> yr<sup>-</sup>  
139 <sup>1</sup>) (Meijide et al., 2017). The average annual oil palm yield is 27.7 Mg ha<sup>-1</sup>. An EC tower (22 m height)  
140 is situated in the center of the site with a fetch of up to 500 m in each direction (Meijide et al., 2017) (Fig.  
141 1).

142

143

145

146

## 2.2 Drone-based image acquisition

147

148

149

150

151

152

153

We used an octocopter drone (MK EASY Okto V3; HiSystems, Germany) equipped with a thermal and an RGB camera mounted in a stereo setup on a gimbal to ensure nadir perspective. The radiometric thermal camera was a FLIR Tau 2 640 (FLIR Systems, USA) attached to a TeAx Thermo-capture module (TeAx Technology, Germany). The sensor covers spectral bands ranging from 7.5 to 13.5  $\mu\text{m}$  with a relative thermal accuracy of 0.04 K and an absolute thermal accuracy of  $\pm 2$  K (FLIRSystems, USA). The RGB camera was based on an Omnivision OV12890 CMOS-Sensor (Omnivision, USA) with a 170° FOV

154 fish-eye lens. Instead of the mosaicking approaches applied in most of the mentioned previous studies,  
155 we used a single image recording concept as faster image acquisition allows for a denser temporal  
156 resolution of LSTs. To capture an area of 100 m radius around the EC tower in a single shot of the thermal  
157 camera, images were taken from 260 m altitude. Image corners were removed due to vignetting effects.  
158 During a consecutive five-day flight campaign in August 2017, 61 LST data sets and matching EC  
159 measurements were recorded. Flights were conducted between 9 am and 4 pm local time, in accordance  
160 with the 30 min intervals of the EC averaging cycles, resulting in 10 to 14 flights per day. All LSTs were  
161 measured using a fixed emissivity of one as the energy balance models would introduce specific soil and  
162 vegetation emissivities in the process.

163

## 164 **2.3 Energy balance models**

165

166 LSTs are recorded as 'snapshots' representing an instantaneous state of surface temperatures. Soil-  
167 Vegetation-Atmosphere Transfer (SVAT) models use these instantaneous observations of LST to solve  
168 the energy balance equation and estimate instantaneous fluxes. In our study the one-source energy balance  
169 model DATTUTDUT (Timmermans et al., 2015) and two two-source energy balance models, TSEB-PT  
170 (Norman et al., 1995) and DTD (Norman et al., 2000), were applied. For the TSEB-PT and DTD model  
171 directional radiometric temperatures are used and no further calculation of aerodynamic temperature by  
172 using an excess resistance term is needed (Hoffmann et al., 2016). Using drones, the proximity of the  
173 thermal camera to the surface is much closer compared to other typical carriers (such as satellites or  
174 planes) and hence atmospheric effects are supposed to have only a very minor effect. To use a uniform  
175 input for all the applied models, we used directional radiometric temperature recordings from the drone  
176 as input without applying further corrections. All models in this study use instantaneous land surface  
177 temperatures (LST) to solve the energy balance equation:

178

$$179 R_n = G + H + LE \quad (\text{eq. 1})$$

180

181 Where  $R_n$  is the net radiation,  $G$  is the ground heat flux and the turbulent fluxes  $H$  and  $LE$  represent  
182 sensible and latent heat flux, respectively.  $R_n$  is estimated by calculating the budget of incoming ( $\downarrow$ ) and  
183 outgoing ( $\uparrow$ ) long- ( $l$ ) and short-wave ( $s$ ) radiation:

184

$$185 R_n = R_{s\downarrow} + R_{s\uparrow} + R_{l\downarrow} + R_{l\uparrow} = (1 - \alpha) * R_{s\downarrow} + \epsilon_{\text{surf}} * \epsilon_{\text{atm}} * \sigma * T_{\text{air}}^4 - \epsilon_{\text{surf}} * \sigma * T(\theta)_{\text{surf}}^4 \quad (\text{eq. 2})$$

186

187 Where the short-wave component is calculated by multiplying incoming short-wave radiation  $R_{s\downarrow}$  [ $\text{W m}^{-2}$ ]  
188 with its absorption ratio deducted from the combined soil and vegetation albedo  $\alpha$ . This way, reflected  
189 outgoing short-wave radiation  $R_{s\uparrow}$  is subtracted from the energy balance. The long-wave radiation budget  
190 is calculated from surface (soil and vegetation) emissivity  $\epsilon_{\text{surf}}$  and atmospheric emissivity  $\epsilon_{\text{atm}}$ , the Stefan-

191 Boltzmann constant  $\sigma$  ( $5.6704 \cdot 10^{-8} \text{ W m}^{-2} \cdot \text{K}^{-4}$ ), air temperature  $T_{\text{air}}$  and radiometric land surface  
192 temperature  $T(\theta)_{\text{surf}}$  (both in K). The incoming long-wave radiation component is added to the budget and  
193 the outgoing long-wave radiation is component subtracted.

### 194 195 2.3.3 DATTUTDUT 196

197 Key input for the DATTUTDUT model is a LST map from where the hottest and the 0.5% quantile of  
198 coldest pixels are extracted, assuming that hot pixels are a result of very little to no evapotranspiration  
199 and cold pixels origin in a high evapotranspiration rate (Timmermans et al., 2015). Fully modeled  $R_n$  is  
200 calculated based on down-welling short-wave radiation estimates calculated using sun-earth geometry to  
201 solve eq. 2. Surface albedo  $P_0$  is calculated as in Timmermans et al. (2015) based on the assumption that  
202 dense vegetation appears colder than rocks or soil in the thermal imagery (Brutsaert, 1982; Garratt, 1992):  
203

$$204 P_0 = 0.05 + ((T_0 - T_{\min}) / (T_{\max} - T_{\min})) * 0.2 \quad (\text{eq. 3})$$

205  
206 Down-welling shortwave radiation  $R_{s\downarrow}$  is calculated from the dimensionless atmospheric transmissivity  
207  $\tau$  and the exo-atmospheric shortwave radiation  $SW_{\text{exo}} = 1360 \text{ W m}^{-2}$  (Timmermans et al., 2015).  
208 Transmissivity  $\tau$  is calculated as described in Burridge and Gadd, A.J. (1977) using the solar elevation  
209 angle  $\alpha$  that was determined from the geographic position of our site and the coordinated universal time  
210 (UTC) of the measurements:

$$211 \tau = 0.6 + 0.2 * \sin(\alpha) \quad (\text{eq.4})$$

$$212 R_{s\downarrow} = \tau * SW_{\text{exo}} \quad (\text{eq. 5})$$

213  
214  
215  
216 Timmermans et al. (2015) suggest using a constant value of 0.7 for  $\tau$  and 0.8 atmospheric emissivity  
217 ( $\epsilon_{\text{atm}}$ ), but as our flight times range from 09:00 to 16:30h local time we decided to include the solar  
218 elevation angle as in eq. 4. Further, we used a constant surface emissivity ( $\epsilon_{\text{surf}}$ ) of 0.98 as recommended  
219 for vegetation dominated areas (Jones and Vaughan, 2010) and not 1.0 as simplified in the original  
220 formulation of the DATTUTDUT model. Air temperature  $T_{\text{air}}$  was calculated as the 0.5% quantile of the  
221 coldest pixels in the image.

222  
223 As the original DATTUTDUT formulation doesn't account for cloud cover, eq.5 is replaced by measured  
224 short-wave irradiance as in Brenner et al. (2018) for model runs with  $R_{n\_sw}$ . For model runs with  $R_{n\_mes}$   
225 eq. 2 was replaced by  $R_n$  measurements recorded at the EC-tower.  
226

227 The sum of the turbulent fluxes is calculated by subtracting  $G$  from  $R_n$ . The result is fractioned into its

228 components H and LE, using the evaporative fraction (EF) (Timmermans et al., 2015):

$$229 \quad EF = LE / (LE+H) = LE / (R_n - G) = (T_{\max} - T(\theta)_{\text{surf}}) / (T_{\max} - T_{\min}) \quad (\text{eq. 6})$$

231  
232 For our implementation of the DATTUTDUT model we used the QGIS3 plugin QWaterModel (Ellsäßer  
233 et al., 2020) that is provided with an easy-to-use graphical user interface.

### 234 TSEB-PT

235  
236 TSEB-PT calculates surface-energy budgets from the recorded LSTs splitting observations into a canopy  
237 and a soil fraction (Norman et al., 1995; Song et al., 2016; Xia et al., 2016). The model consists of two  
238 parts: First an initialization part where all parameters that do not depend on soil and canopy temperature  
239 partition and knowledge of atmospheric stability are computed. Afterwards an iterative part where the  
240 Monin-Obukhov length is stabilized and the fluxes are finally derived. To begin this process vegetation  
241 cover  $f_c(\theta)$  is computed as in (Campbell and Norman, 1998):

$$242 \quad f_c(\theta) = 1 - \exp((-0.5\Omega(\theta) * LAI) / (\cos(\theta))) \quad (\text{eq. 7})$$

243  
244 where LAI is leaf area index,  $\theta$  is the sun zenith angle and  $\Omega$  is a nadir view clumping factor to represent  
245 the cross-row structure in which the oil palm is planted (Kustas and Norman, 1999). Guzinski et al. (2014)  
246 suggest a maximum limit of 0.95 for  $f_c(\theta)$ , so that a small fraction of the soil is still visible and extreme  
247 magnitudes for soil temperature are avoided. Roughness parameters are calculated from vegetation height.  
248  $T_{\text{air}}$  was measured at the EC-tower,  $T(\theta)_{\text{surf}}$  was recorded with the drone both similar to descriptions in  
249 (Hoffmann et al., 2016). For the two-source energy balance models we used a canopy emissivity of 0.98  
250 and soil emissivity of 0.95. The emissivity values are based on averages for the 8-14  $\mu\text{m}$  spectrum taken  
251 from Jones and Vaughan, (2010). The TSEB-PT model requires additional in situ meteorological  
252 measurements of long- and short-wave radiation, wind speed, barometric pressure and relative humidity,  
253 which in our case were recorded at the EC tower. Further, measured data on LAI as well as surface and  
254 canopy albedo are required. The three resistances in the soil-canopy-atmosphere heat flux network, the  
255 aerodynamic resistance to heat transport (RA), the resistance to heat transport from the soil surface (RS)  
256 and the total boundary layer resistance of the leaf canopy (RX) are calculated as in (Norman et al., 1995,  
257 2000). Net radiation and the three resistances remain constant during the model runs. After finishing the  
258 computation of all constant parameters, the iterative part of the model starts assuming Monin-Obukhov  
259 length tends to infinity. In the first iteration  $R_n$  is partitioned into a soil and canopy fraction by calculating  
260 net radiation divergence  $\Delta R_n$  (Hoffmann et al., 2016; Norman et al., 2000):

$$261 \quad \Delta R_n = R_n * (1 - \exp((-K * LAI * \Omega) / \sqrt{2\cos(\theta_s)})) \quad (\text{eq. 8})$$

265

266 where K is an extinction coefficient that varies according to LAI (Hoffmann et al., 2016). We are aware  
267 of the fact, that the determination of K using LAI is disputed as other studies found no significant  
268 correlation of K and LAI (Zhang et al., 2014). With  $\Delta R_n$  known, sensible heat flux is then estimated using  
269 the Priestley-Taylor approximation following the approach by Hoffmann et al., (2016):

270

$$271 H_c = \Delta R_n * (1 - \alpha_{PT} * f_G * (D / (D + \gamma))) \quad (\text{eq. 9})$$

272

273  $\alpha_{PT}$  is the Priestley-Taylor coefficient and both  $\gamma$  the psychrometric constant and the slope of the saturation  
274 pressure curve D were calculated as in (Allen et al., 1998). Canopy temperature  $T_C$  was computed by  
275 summing up the results of the linear approximation in equation (A7) for  $T_{C,lin}$  and  $\Delta T_C$  from equation  
276 (A11) both from (Norman et al., 1995). Knowing canopy temperature  $T_C$  and the fraction of view covered  
277 by vegetation  $f_\theta$  as in (Hoffmann et al., 2016), soil temperature  $T_s$  can be calculated:

278

$$279 T_s = (T(\theta)_R^4 - f_\theta * T_C^4) / (1 - f_\theta)^{(1/4)} \quad (\text{eq. 10})$$

280

281 With soil and canopy temperatures and the resistances of the soil-canopy-atmosphere heat flux network  
282 known, fluxes can be calculated with equations (9), (10), (11) and (13) from Hoffmann et al. (2016). Total  
283 latent and sensible heat fluxes are calculated as the sums of canopy and soil fluxes. In the following  
284 iterations, a recalculation of Monin-Obukhov length takes place until a stable value is reached and the  
285 resulting fluxes are derived. For the model runs with  $Rn\_mod$  and  $Rn\_mes$  the model net radiation is  
286 forced accordingly.

287

288 DTD

289

290 The Dual-Temperature-Difference (DTD) model works very similar to TSEB-PT and differs mainly in  
291 the way how sensible heat flux is calculated (Hoffmann et al., 2016). In the DTD model, the absolute  
292 temperatures of land surface and air (as used in the TSEB-PT) are supplemented with a second set of  
293 early morning reference measurements of LST and air temperature, thus creating a dual-temperature  
294 difference (Norman et al., 2000). The first observation is recorded in the early morning hours and the  
295 second observation is recorded later on the same day at any given time. We used two IRTs attached to the  
296 EC tower (see EC methodology Sect. 2.4 for details and Sect. 2.7 for the limitations) for the necessary  
297 early morning reference readings of absolute temperature and used the averaged LSTs to create a uniform  
298 map as input for the DTD model (similar as e.g. in Hoffmann et al. 2016). This relates measurements at  
299 any time during the day to measurements recorded in the morning, when fluxes are assumed to be  
300 minimal, and thereby accounts for measurement biases of LST (Anderson, 1997; Hoffmann et al., 2016).  
301 H flux is then calculated using the time-differential temperature and a series resistance network as it is

recommended for densely vegetated regions to consider interaction of soil and canopy fluxes (Guzinski et al., 2014; Li et al., 2005).

The actual amount of evapotranspired water ( $ET_w$ ) in  $mm\ h^{-1}$  was calculated as in (Timmermans et al., 2015):

$$ET_w = ((LE*t)/1000000)/(2.501-0.002361*(T_{air}-273.15)) \quad (eq.11)$$

Where  $LE$  is the latent heat flux in  $W\ m^{-2}$ ,  $t$  is the respective timespan in seconds and  $T_{air}$  is the air temperature in Kelvin.

## 2.4 Eddy covariance measurements

The micrometeorological tower is located in the center of the study site (Fig. 1). The EC technique was used to measure  $LE$  and  $H$  fluxes from high frequency (10 Hz) measurements of above-canopy water vapor concentration, sonic temperature, and 3-D wind components. The flux system consisted of a sonic anemometer (Metek uSonic-3 Scientific, Elmshorn, Germany) and a fast response open-path  $CO_2/H_2O$  infrared gas analyzer (Li-Cor7500A, LI-COR Inc. Lincoln, USA) installed at 22 m height. Meteorological variables were measured every 10 sec, averaged to 10 min means and stored on a DL16 Pro data logger (Thies Clima, Göttingen, Germany).  $R_n$  and its components were measured with a net radiometer (CNR4, Kipp & Zonen, Delft, The Netherlands) at 22 m height. Air temperature and relative humidity were measured with thermohygrometers (type 1.1025.55.000, Thies Clima, Göttingen, Germany) at 16.3 m height. Further, a wind direction sensor (Thies Clima, Göttingen, Germany) (22 m height) and 3-cup anemometers (Thies Clima, Göttingen, Germany) (18.5, 15.4, 13, and 2.3 m height) for wind speed measurements were installed on the tower. The two IRTs used in our study (IR100 Radiometer, Campbell Scientific Inc., Logan, USA) have a field-of-view (FOV) of 8-10°. Considering the distance from their fixed location on the tower to the average height of the oil palm canopy, they cover a circular area of 2.2  $m^2$ , over which they average the received thermal signal. The recorded canopy area comprises different functional parts of the canopy (e.g. leaflets, petioles). On average, we assumed a surface emissivity of 0.98 for the canopy area (Jones and Vaughan, 2010). We did not correct the values recorded with the IRTs for any other influences since the distance from the canopy surface to the sensors was only about 10 m. Ground heat flux was measured using heat flux plates (HFP01, Huxeflux, Delft, The Netherlands) at 10 cm depth. Additional soil moisture and temperature measurements (Trime-Pico 32, Imko, Ettlingen, Germany) above the heat flux plate at 5 cm depth were used to calculate heat flux at the soil surface. EC data recording, filtering and processing were carried out identical to the methodology described in Meijide et al. (2017) for the same study site. As the applied drone-based models all assume full energy balance closure, we used the Bowen ratio closure method (Pan et al., 2017; Twine et al., 2000) to compute full closure for the EC measurements. The Bowen ratio method was found to produce the most congruent

339 results in conjunction with drone-based latent heat flux estimates (Brenner et al., 2017) and was therefore  
340 applied in this study. The energy balance closure (EBC) of the reference EC measurements was 0.77 ( $r^2=$   
341 0.87), which is in line with EBC reported for other tall vegetation canopies (Stoy et al., 2013). Since the  
342 used energy balance models assume full EBC, we applied the so-called Bowen ratio closure method to  
343 the EC data (Pan et al., 2017). The method assumes that wind measurements miss some of the total  
344 covariance and dispersive fluxes. Therefore, underestimations of LE and H are carried over proportionally  
345 because of similarity among fluxes (Twine et al., 2000). The Bowen ratio closure method proportionally  
346 assigns the underestimated turbulent energy to LE and H fluxes to reach full EBC.  
347 EC data processing and quality checks were performed following the methodology described in (Meijide  
348 et al., 2017). Following (Mauder and Foken, 2006), flux estimates during low turbulence and thus stable  
349 atmospheric conditions were removed from the analysis; however, low turbulence mainly occurred during  
350 night hours and was not observed during the daytime drone flights. Generally, the EC method is associated  
351 with uncertainties of 5 - 20% (Foken, 2008). Further limitations are the high costs and quite specific  
352 requirements regarding size and terrain of the study site.

353

## 354 **2.6 Statistical analyses**

355

356 Both methods, the reference EC technique and the drone-based estimates, are associated with a certain  
357 degree of uncertainty. To account for the uncertainty in both, a model II Deming regression (Deming,  
358 1964) was applied for the analysis to consider uncertainties in both x and y variables (Cornbleet and  
359 Gochman, 1979; Glaister, 2001). We assumed that the error ratio ( $\sigma\epsilon^2/\sigma\delta^2$ ) of the variances ( $\sigma$ ) of errors  
360 on y ( $\epsilon_i$ ) and on x ( $\delta_i$ ) would not differ from 1 which is the standard procedure if both uncertainties are  
361 unknown (Legendre and Legendre, 2003). We used the interquartile range method with a factor  $k=1.5$  to  
362 remove outliers from the regression. A Durbin-Watson test was applied to test for correlation in error  
363 terms. We checked for heteroscedasticity visually and using a White test. Normal distribution of error  
364 terms was tested visually plotting standardized residuals vs. theoretical quantities and performing a  
365 Shapiro-Wilk test. Standard errors and confidence intervals for slope and intercept of the Deming  
366 regression were calculated using analytical methods (parametric) and the jackknife method (Armitage et  
367 al., 2001; Linnet, 1993). As further supporting indicators of model performance, we calculated the  
368 coefficients of determination ( $r^2$ ), the Mean Absolute Error (MAE), the Root Mean Square Error (RMSE)  
369 and slope and intercept from the Deming regression. Statistics such as  $r^2$  have their limitations in method  
370 comparison since they are designed to indicate how well the resulting model of the regression describes  
371 the outcome and are not necessarily a good measure for systematic bias between methods. However, they  
372 are used as a statistic in this study since they represent an additional indicator for interpretation. Linearity  
373 was checked visually plotting residuals vs. fitted values.

374 All modeling procedures and parts of the statistical analyses were computed using Python version 3.7.1  
375 (Python Software Foundation), involving the libraries NumPy 1.14.2, SciPy 1.1.0, pandas 0.23.1, scikit-

376 learn 0.19.1, gdal 2.3.2, Astropy 3.2.2 and tkinter 8.6. The Deming regression was computed using the  
377 MethComp and mcr v2.2.1 package (Manuilova et al., 2014) in R version 3.6.1 (R Development Core  
378 Team, 2019). Graphic representation was processed in Python using the Matplotlib 3.0.2 and Seaborn  
379 0.9.0 libraries.

380

## 381 **2.7 Dataset characteristics**

382

383 The dataset offers a comparatively high number of replicates from 61 drone recording flights and the  
384 corresponding eddy covariance measurements enabling a method comparison which requires at least  $n=60$   
385 observations (Legendre and Legendre, 2003). The data was recorded in a 30 min frequency, to facilitate  
386 the analysis of daily courses of evapotranspiration behavior creating a trade-off situation of more flights  
387 per day with shorter flight times per flight. Because flight times were so short, only a smaller footprint  
388 with a radius of 100 m around the eddy covariance station was covered, while the footprint recorded with  
389 the eddy covariance system ranged up to a 500 m radius around the tower. Therefore, the reduced area of  
390 the drone recorded LST maps is often smaller than the extent of the eddy covariance footprint. We have  
391 several reasons to assume that this doesn't cause major problems for the comparison though: the study  
392 area is very homogenous with an elevation difference of 5 m in the eddy covariance footprint and the  
393 biosphere is strongly dominated by only one species (oil palm). The plantation is very well managed, so  
394 that all oil palm canopies are alive, no oil palms have died and only dry leaves are removed. A further  
395 limitation of the dataset is the lack of morning or night LST measurements that could not be recorded  
396 with the drone due to security concerns and limited access to the plantation at night. This doesn't affect  
397 the procedure of the DATTUTDUT and TSEB-PT model, but morning measurements are an important  
398 factor for the DTD model. We were able to record night and morning measurements with two stationary  
399 infrared thermometers (IRTs) that were attached to the tower. As for the DTD model, morning and later  
400 recordings should ideally be recorded with the same camera. To check whether the two IRTs measure  
401 similar temperatures compared to drone recorded LSTs, we extracted a total of 122 'IRT-footprint-sized'  
402 (i.e.  $\sim 2.2 \text{ m}^2$ ) LST footprints from the drone-recorded maps. A correlation of both temperature  
403 measurements revealed a small deviation of the measured temperatures resulting in a mean absolute error  
404 (MAE) and root mean squared error (RMSE) of 1.59 and 2.15 K respectively. Since LST measurements  
405 are subject to a certain degree of uncertainty and thermal cameras usually have a measurement error of  
406 up to  $\pm 1^\circ\text{C}$  (Aubrecht et al., 2016) we decided to use the morning measurements from the tower IRTs as  
407 input for the morning temperature reference. The implementation of the DTD model is therefore strictly  
408 experimental and has to be interpreted with the uncertainties of the morning measurements in mind.

### 3 Results

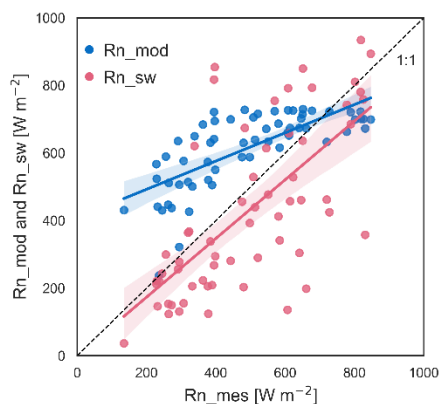

#### 3.1 Meteorology

During our 61 flight missions, cloudiness was variable from clear sky to full cloud cover; short-wave irradiance ranged from 204 to 1110 W m<sup>-2</sup>. The prevailing wind direction was from north-east, at an average wind speed of 1.7 m s<sup>-1</sup>. Canopy air temperature ranged from 22.5 to 32.3°C and relative humidity varied between 62 and 99%. Temperature differences between measured air temperature at 16.3m (top of canopy) and mean land surface temperatures ranged from 0.005K to a single peak of 8.689K for the single flights while the daily averaged differences ranged from 1.32K to 2.13K. The energy balance closure of the reference EC measurements was 0.77 ( $r^2 = 0.87$ ).

#### 3.2 Drone-based modeling methods vs. eddy covariance method

At the time of the drone flights, LE from the EC method ranged between 87 and 596 W m<sup>-2</sup> (mean: 337 W m<sup>-2</sup>) and eddy covariance-derived evapotranspiration was on average,  $0.43 \pm 0.21$  mm h<sup>-1</sup>, with peak evapotranspiration of up to 0.87 mm h<sup>-1</sup> during midday. Congruence of LE estimates with reference EC measurements differed among the three applied models and was further affected by the configuration of the R<sub>n</sub> assessment (Fig. 2). The assumptions for R<sub>n</sub>\_mod were not always met as cloud cover was present during several flights; consequently, the corresponding net radiation estimates were too high, leading to a substantial overestimation especially of smaller latent heat fluxes. The short-wave irradiance based R<sub>n</sub>\_sw configuration resulted in R<sub>n</sub> estimates that were by average very comparable with the measured net radiation R<sub>n</sub>\_mes but also showed a rather high variation (Fig. 2). Generally, error metrics were reduced and agreement was increased the more measurement-controlled the R<sub>n</sub> determination process was.

437

438

439 **Figure 2:** Measured net radiation ( $Rn\_mes$ ) plotted against fully modeled net radiation ( $Rn\_mod$ ) and net  
 440 radiation estimates based on short-short wave irradiance ( $Rn\_sw$ ).

441 DATTUTDUT LE estimates closely agreed with EC measurements around noon, but were higher in the  
 442 morning and afternoon hours, which is caused by overestimations of  $R_n$  from the  $Rn\_mod$  method (Fig.  
 443 3a). LE estimates from TSEB-PT were consistently higher than EC measurements, with particularly large  
 444 divergences around noon (Fig. 3a). The LE predictions from the DTD model in  $Rn\_mod$  configuration  
 445 were rather overestimated, especially around noon when compared with the EC reference measurements  
 446 (Fig. 3a). Models with  $Rn\_sw$  configuration produced LE estimates that matched LE from EC more  
 447 closely (Fig. 3b). DATTUTDUT computed similar or higher estimates of LE compared to the EC  
 448 measurements during noon but mostly underestimated LE fluxes in the morning and afternoon, while  
 449 TSEB-PT produced more congruent LE estimates for the morning and afternoon hours but also  
 450 overestimated LE fluxes especially during noon (Fig. 3b). The DTD model showed a very similar pattern  
 451 with overestimations of LE fluxes around noon and more accurate estimates for morning and afternoon  
 452 hours (Fig. 3b). Both two-source energy balance models with  $Rn\_sw$  configuration yielded comparably  
 453 accurate estimates during the morning and afternoon hours. With  $Rn\_mes$  configuration, DATTUTDUT  
 454 computed closely matching LE estimates at all times of day across the five-day measurement period,  
 455 while TSEB-PT and DTD consistently produced much higher estimates than EC around noon but  
 456 otherwise calculating mostly accurate results (Fig. 3c).

457

458

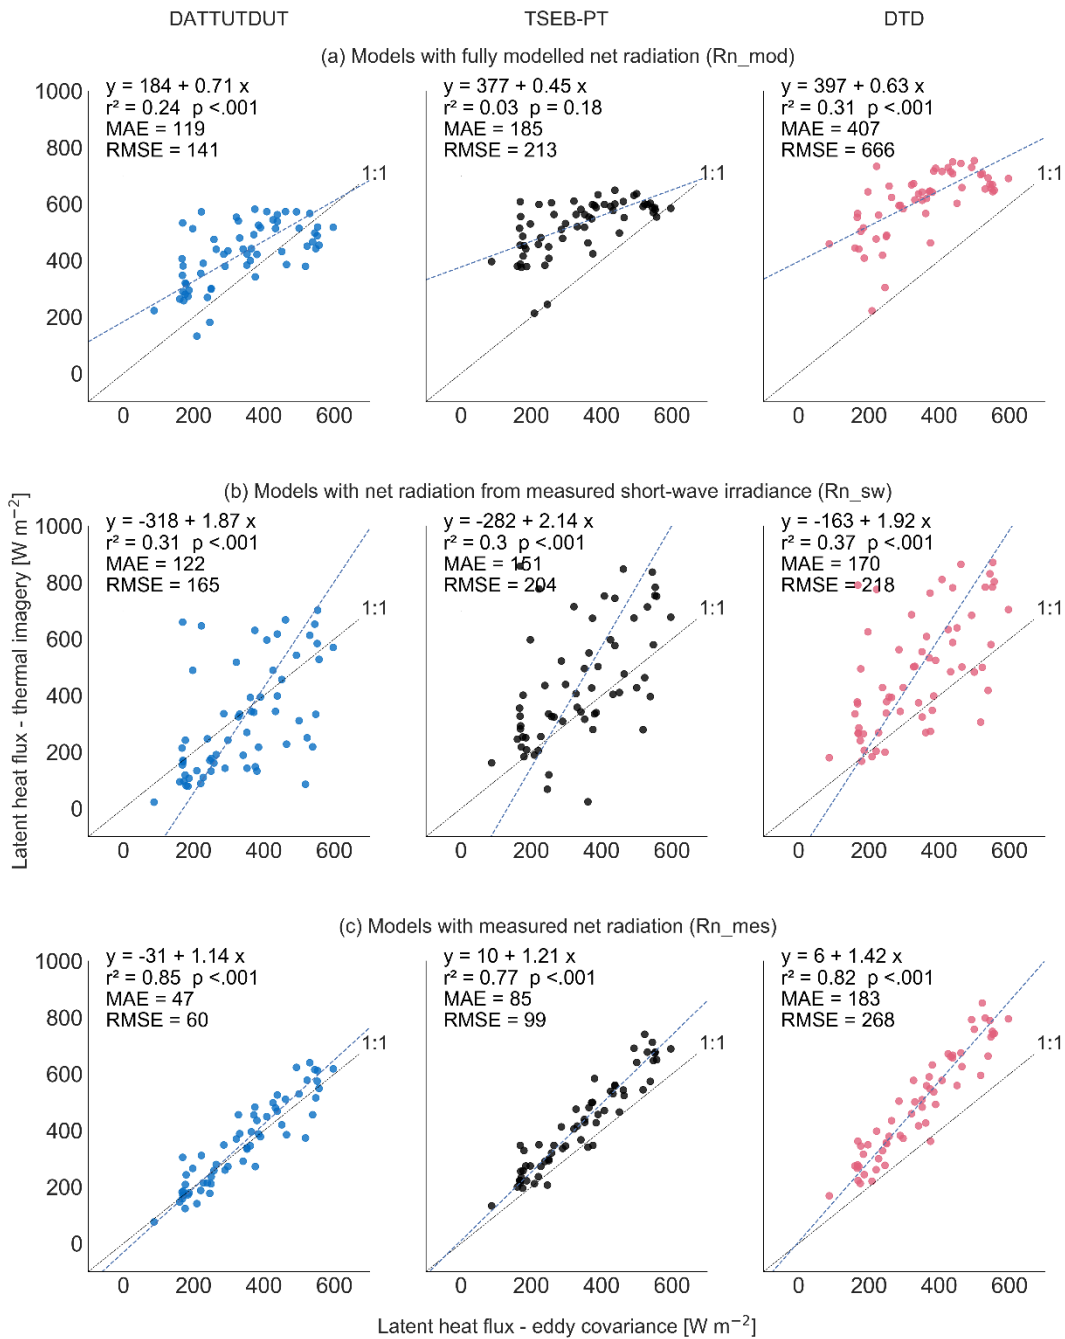

459 **Figure 3:** Latent heat flux (LE) from energy balance models (DATTUTDUT, TSEB-PT, DTD) and three  
 460 different configurations of net radiation ( $R_n$ ) determination ( $R_n$ \_mod,  $R_n$ \_sw,  $R_n$ \_mes) and eddy  
 461 covariance measurements (EC) over five consecutive days ( $n = 61$  flight missions).

462

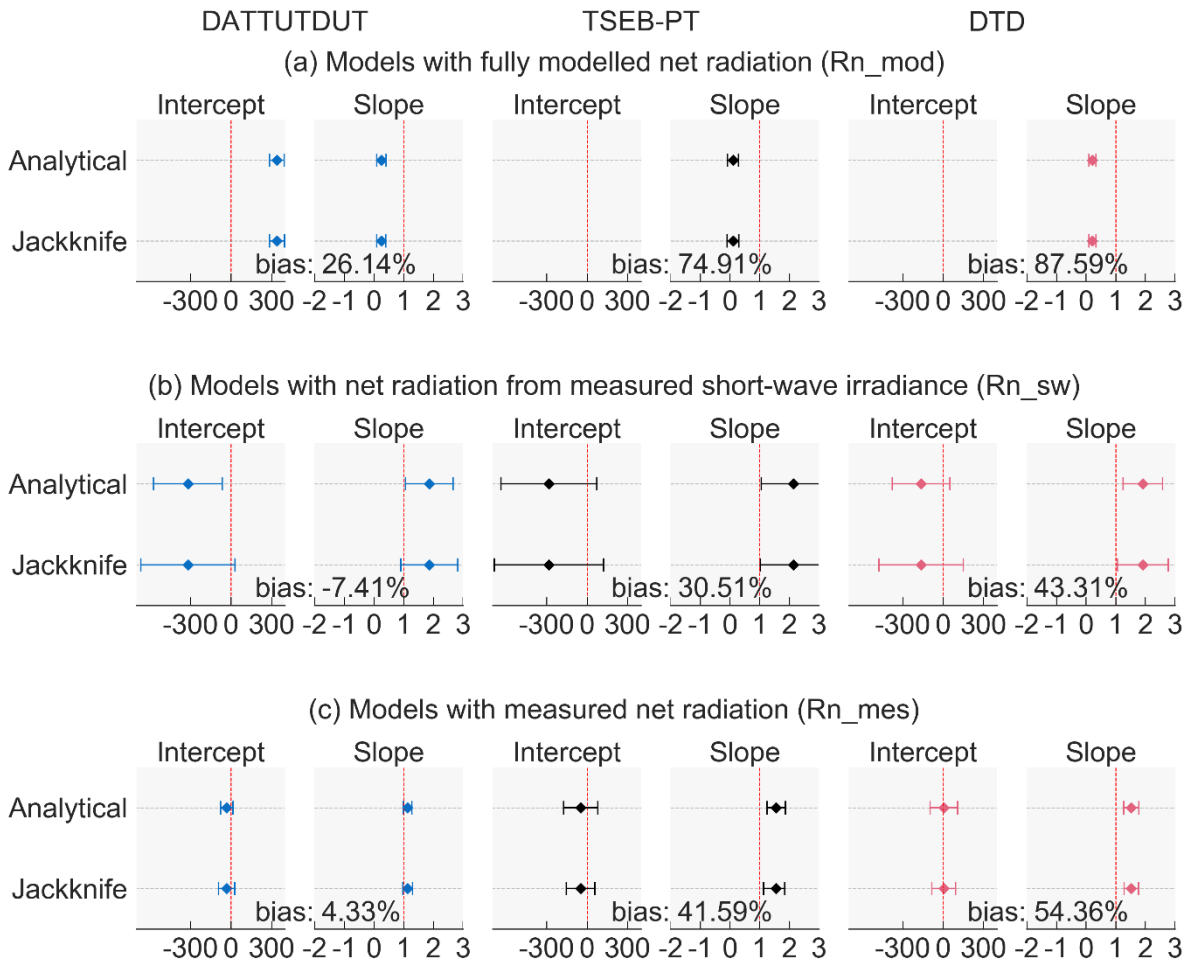

463 Across all daytimes and weather conditions (n=61 flight missions), congruence among drone-based LE  
464 estimates and reference EC measurements was highest for the DATTUTDUT model with Rn\_mes  
465 configuration ( $r^2=0.85$ ); MAE and RMSE were 47 and 60  $W m^{-2}$ , respectively (Fig. 4). To compare the  
466 model predictions and the eddy covariance measurements, we computed a Deming regression between  
467 both LE predictions from the models and LE estimates by the EC method. The methods are considered to  
468 be statistically interchangeable if the confidence intervals of the slope and intercept include one and zero  
469 respectively. If the confidence intervals for the intercept of the Deming regression include zero, there is  
470 no constant or continuous error between the two methods. If the confidence intervals for the intercept do  
471 not include zero, both methods differ by a constant amount, i.e. the new method has a continuous error  
472 compared to the reference method. In contrast, the confidence intervals of the slope of the Deming  
473 regression indicate whether there is a proportional error between the methods, which increases  
474 proportionally with the magnitude of the predicted value. Deming regression of the LE estimates of the  
475 DATTUTDUT model with Rn\_mes configuration showed no significant proportional or constant error  
476 compared to EC measurements as the values one and zero lay within the respective 99% confidence  
477 interval ranges of slope and intercept (Fig. 5). It is thus indicated that there is no significant difference  
478 between LE estimates from DATTUTDUT with Rn\_mes configuration and the EC technique. The TSEB-  
479 PT model in Rn\_mes configuration also showed no significant continuous errors but was subject to a  
480 minor proportional bias (Fig. 5c). The TSEB-PT model overestimated LE particularly around noon, when  
481 fluxes are very high (Fig. 3c and 4c). The DTD model also showed no continuous bias but indicated a  
482 proportional error in the analytical method and the Jackknife method (Fig. 5c). In the Rn\_sw  
483 configuration, only the DATTUTDUT model showed no significant proportional and continuous error of  
484 LE estimates compared to EC measurements (Fig. 5b). TSEB-PT and DTD model estimates showed no  
485 significant constant deviation from the EC measurements but were subject to a proportional error (Fig.  
486 4b and 5b). However, all confidence intervals for models with the Rn\_sw configuration were rather wide  
487 indicating a large level of uncertainty. All models in the Rn\_mod configuration showed significant  
488 proportional and constant errors or large biases compared to EC measurements, as well as very large  
489 confidence intervals Fig. 4a and 5a).

### 3.3 Spatial distribution of LE

For 9<sup>th</sup> of August 2017, 12.30 h, the DATTUDUT in Rn\_mes configuration suggested a mean of 526  $W m^{-2}$  (minimum of 0 on the corrugated iron roof of the EC tower system, maximum of 637  $W m^{-2}$ , coefficient of variation 7.53 %, for the analyzed 18,383 pixels) (Fig. 6), which translates to a mean ET of 0.778  $mm m^{-2} h^{-1}$ . Locally, i.e. in the center of oil palm crowns, high LE of  $> 400 W m^{-2}$  was observed, while LE from soil and ground vegetation areas between oil palm canopies was lower. The LE fluxes of

508 all pixels were almost normally distributed for the one-source energy balance model DATTUDUT (Fig.  
509 7), whereas the distribution of the two-source energy balance model TSEB-PT (for the same LST dataset)  
510 was more skewed, with more LE observations at the upper end of the range. The spatial LE estimates  
511 from the DTD model resulted in a similar distribution than from the TSEB-PT model (Fig. 7). Both  
512 distributions of the two-source energy balance models show gaps in the histogram, while the histogram  
513 of the DATTUTDUT model displays a more continuous distribution (Fig. 7)  
514

515

516 **Figure 6:** Spatial distribution of latent heat flux from drone-based thermography and subsequent energy  
517 balance modeling (DATTUTDUT with Rn\_mes configuration, 9 August 2017, 12.30 h).

518

519 **Figure 7:** Frequency distribution of latent heat flux for the model output images from the same thermal  
 520 image as shown in Fig. 5 (9 August 2017, 12.30 h). Absolute histogram bin size was set to  $16 \text{ W m}^{-2}$ , we  
 521 used 50 bins from 0 to  $800 \text{ W m}^{-2}$ .

## 522 4 Discussion

523

524 Our study indicates a high agreement between latent heat fluxes assessed by drone-based thermography  
 525 and the eddy covariance technique. However, the performance of the three applied energy balance models  
 526 differed among each other and among different configurations of net radiation assessments in the models  
 527 (Fig. 3 and 4). Model II Deming regression analyses and associated quality assessments suggest  
 528 interchangeability between the DATTUTDUT model in Rn\_mes configuration and the EC technique (Fig.  
 529 4 and 5). Applying this configuration, a fine grain spatial analysis of latent heat fluxes suggests relatively  
 530 low heterogeneity of LE in the studied tropical oil palm plantation (Fig. 6).

531

### 532 4.1 Drone-based LE modeling vs. eddy covariance measurements

533

534 The confidence intervals of slope and intercept of the Deming regression indicate that the one-source  
 535 energy balance model DATTUTDUT with Rn\_mes configuration is statistically interchangeable with the  
 536 established EC method for estimating LE fluxes. There are advantages and limitations to both methods.  
 537 For example, the DATTUTDUT model provides insights on the spatial distribution of LE fluxes within  
 538 the full extent of the available LST maps, whereas the EC technique averages the LE fluxes within its  
 539 footprint to a single value. On the other hand, the DATTUTDUT model is temporally limited to the  
 540 availability of LST maps, whereas the EC method can measure fluxes continuously over several years

541 once the equipment is in place. The DATTUTDUT model with Rn\_mes configuration further requires  
542 additional measurements of short- and long-wave radiation. In our study, these measurements were taken  
543 with the EC equipment, but future stand-alone drone approaches are possible by using on-board  
544 miniaturized radiation sensors (Castro Aguilar et al., 2015; Suomalainen et al., 2018). However, the  
545 accuracy of such on-board radiation sensors should first be tested against reference methods, e.g. visually  
546 by scatter or inter-comparison plots (Castro Aguilar et al., 2015; Suomalainen et al., 2018) or with a model  
547 II regression procedure evaluating the interchangeability of methods and measurements (Passing and  
548 Bablok, 1983). The two-source energy balance models TSEB-PT and DTD in the Rn\_mes configuration  
549 showed a very similar behavior. Both were found to have no continuous error when compared to the  
550 reference EC method. However, a small bias towards the overestimation of relatively high fluxes around  
551 noon was observed, which might be removed by improving the balance of e.g. vegetation parameters for  
552 oil palm.

553 All models with the Rn\_sw configuration showed a significant proportional error compared to EC  
554 measurements, which was mainly rooted in the high variance of the Rn\_sw configuration. The short-wave  
555 irradiance measurements used in this study were stored as 10 min averages that probably didn't represent  
556 the high level of irradiance variations in the tropical study area adequately. Previous studies have pointed  
557 out that R<sub>n</sub> derivation based on short-wave irradiance measurements is challenging as long-wave radiation  
558 budgets are often completely independent from their short-wave counterparts (Hoffmann et al. 2016).  
559 Estimation errors in long-wave radiation budgets have e.g. been reported to be related to high relative air  
560 humidity, when some of the original model assumptions are no longer met (Hoffmann et al., 2016). We  
561 observed a negative correlation ( $r^2 = 0.46$ ) between incoming long-wave irradiance and relative humidity  
562 and assume that the high relative humidity in our tropical study area may have affected the determination  
563 of R<sub>n</sub> when using the Rn\_sw configuration through inaccuracies in estimating long-wave radiation  
564 budgets, therefore causing the observed significant continuous errors. Since we recorded the data during  
565 very different daytimes and weather situations, the short-wave irradiance based approach might not be  
566 the most adequate mean of R<sub>n</sub> derivation. However, this approach can be very useful for measurements  
567 without the presence of clouds or high levels of relative humidity. We thus also consider the Rn\_sw  
568 configuration valuable for future research, particularly because measurements of incoming short-wave  
569 radiation are much easier to implement than assessing complete short- and long-wave radiation budgets  
570 as necessary for the Rn\_mes configuration. The application of the Rn\_sw configuration for a one-source  
571 energy balance model such as DATTUTDUT was also tested in two previous studies, with similar results  
572 to our study, i.e. a reduction of errors compared to its original formulation with fully modeled Rn\_mod  
573 (Brenner et al., 2018; Xia et al., 2016).

574 Lastly, the model configuration Rn\_mod did not produce accurate LE estimates for all three models, as  
575 many of the basic assumptions for fully modelled R<sub>n</sub> determination are not met in tropical environments  
576 such as our equatorial study area. As such, the sky is often cloudy, while haze frequently occurs during  
577 periods without rainfall. Even if no clouds are visible, relative humidity is often high, which interferes

578 with the clear-sky assumptions of the Rn\_mod configuration (Still et al., 2019).  
579 Among the three models applied in our study, the relatively simple DATTUTDUT model produced the  
580 most precise LE estimates compared to eddy covariance reference measurements. Similar conclusions  
581 were reached by Brenner et al. (2018), where DATTUTDUT marginally outperformed the more complex  
582 TSEB-PT model. On the other hand, contrasting observations were made by Xia et al. (2016) in vineyards  
583 with more extreme temperature divergences between soil and vegetation, where the TSEB-PT model  
584 produced more precise estimates of LE than the DATTUTDUT model. This was explained by the better  
585 physical representation of energy and radiative exchange in the TSEB-PT model. The authors further  
586 point out that  $R_n$  determination is not the only source of error in the DATTUTDUT model (Xia et al.,  
587 2016). In our study, the TSEB-PT model slightly outperformed the more complex DTD model in the  
588 Rn\_mes configuration regarding error terms. Limitations of the presented methods compared with the  
589 reference EC method however still exist. As such, the thermography-based recording process for land  
590 surface temperatures can be affected by water vapor, haze or dust, which increase atmospheric emissivity.  
591 Also, wind and turbulence cooling effects that compete with evaporative cooling are not captured in this  
592 approach.

593  
594 We used the Bowen-ratio method to close the energy balance for the reference EC measurements. As  
595 reported by Xia et al. (2016), agreement between measured EC and modeled LE estimates could  
596 potentially be increased by using the residual method from Twine et al. (2000) for energy balance closure.  
597 Further potential improvements include the aerial sampling alignment with the EC measurement logging  
598 cycles. We compared snapshot measurements of LST to 30 min averages of EC measurements for the  
599 corresponding times in an environment where key variables such as solar irradiance can change very  
600 quickly. Better matching the measurement cycle duration may further improve agreement between the  
601 methods and was already suggested in a previous study (Brenner et al., 2018). Further, in our study the  
602 aerial-derived LST images represented only the center area of the (at times quite variable and large) EC  
603 footprint. Covering the whole potential area of the footprint in all directions could also increase agreement  
604 between the measurements, but would require even higher flight altitude or longer flight times to cover  
605 the whole area; both options would reduce the number of temporal replicates and increase errors from  
606 measurements and processing, but could nonetheless be viable approaches for other research questions.

607  
608 Only few previous studies have demonstrated applicability and limitations of estimating LE with the three  
609 energy balance models from non-satellite data. In these studies, LSTs were e.g. recorded from drones for  
610 European grasslands and croplands (Brenner et al., 2018; Hoffmann et al., 2016) and from drones or  
611 airplanes for taller vegetation including olive orchards and vineyards (Ortega-Farías et al., 2016; Xia et  
612 al., 2016). Our study adds to this an application of these models in a tropical environment, for higher  
613 vegetation (i.e. oil palm) and across variable daytimes and weather conditions. Generally, the equatorial  
614 study site was rather challenging due to high temperatures and humidity and frequent occurrence of haze,

615 as well as for logistical reasons. Additionally, many previous drone-based studies were conducted on  
616 grasslands (e.g. Brenner et al. 2017, 2018) or on low-growing crops such as wheat fields (Hoffmann et  
617 al., 2016), but not on crops with a rather complex canopy structure such as oil palm. On the other hand,  
618 our study site showed large temperature differences between soil and canopy, which simplified the  
619 distinguishing of each fraction. We further analyzed for the first time whether drone-data based models  
620 and EC measurements can be used interchangeably, as our large sample size of n=61 flights allowed for  
621 a method comparison based on a model II Deming regression (Legendre and Legendre, 2003). We  
622 conclude that this is the case for some models and configurations, above all for the DATTUTDUT with  
623 Rn\_mes configuration.

624

## 625 **4.2 Spatial distribution of latent heat fluxes**

626

627 A particular strength of drone-based thermal imagery is the high spatial resolution which allows for  
628 spatially explicit assessments of evapotranspiration, within and potentially also beyond the footprints of  
629 EC towers. The outlines of the single oil palm canopies are clearly visible in the LE flux map (Fig. 6),  
630 with the highest LE fluxes occurring in the center of the oil palm canopies. We assume that this spatial  
631 pattern is caused by an increased local LAI in the centers of the oil palm canopies, while leaf area density  
632 decreases towards the outer canopies. Further, the central areas of oil palm canopies are more exposed to  
633 sunlight and wind throughout most of the day, increasing their potential for (evapo)transpiration  
634 compared to canopy edges. Mixed pixel effects (among soil and canopy) likely also contribute to the  
635 observed lower LE fluxes towards the borders of oil palm canopies. Further contributing factors to higher  
636 LE fluxes in the centers of oil palm canopies could be leaf age (with younger leaves in the center) and  
637 additional ET from pockets in the axils of pruned leaves along the stem, which contain small water  
638 reservoirs and epiphytes (Meijide et al., 2017; Tarigan et al., 2018).

639

640 While the DATTUTDUT histogram shows only few pixel values of zero and most pixels closely  
641 distributed around the mean, the TSEB-PT and DTD histograms are much wider distributed and with a  
642 much more pronounced peak. For the DATTUTDUT model mean and median are very similar indicating  
643 close to zero skewness. Such a distribution tending towards unimodality is also considered typical for  
644 landscapes where ET is highly dominated by one species (Xia et al., 2016). Both, the TSEB-PT and the  
645 DTD model show a different, more skewed distribution of LE fluxes (for the same dataset of LST), with  
646 the median of the LE estimates located between the mean and the upper end of the LE flux range. We  
647 assume that this skewness is caused by the TSEB-PT and DTD models being more sensitive to dry  
648 surfaces and hence better represent the lower LE flux from dryer soil areas.

649

650 Drone-based methods have a large untapped potential for ecological applications, e.g. regarding  
651 ecohydrological optimization in land use systems and designing the climate-smart urban landscapes of

652 the future. We see great potential in the drone-based remote sensing applications presented in this study;  
653 especially when recent developments in drone-environment interaction, mobile edge computing  
654 (potentially on-board of the drone) and communication technologies such as LoRaWAN (Long Range  
655 Wide Area Network) or 5G are combined (Becerra, 2019; Marchese et al., 2019). Autonomous acquisition  
656 of LSTs over EC stations and the surrounding areas can be supplemented by on-board and ground sensors.  
657 Energy-balance models can then potentially be calculated using edge computing schemes on-board the  
658 drone to enable a dense temporal resolution of LST, flux and ET maps in almost real-time. This concept  
659 can e.g. be used for the attribution of fluxes in mixed species plant communities, the study of edge effects  
660 in landscapes, and further be adapted e.g. to detect water stress in agriculture and forests.

661

## 662 **5 Conclusions**

663

664 Drone-based thermography and subsequent energy balance modeling under certain configurations can be  
665 considered a highly reliable method for estimating latent heat flux and evapotranspiration; for some  
666 configurations statistical interchangeability is suggested with the established eddy covariance technique.  
667 They thus complement the asset of available methods for evapotranspiration studies by fine grain and  
668 spatially explicit assessments.

## **Data availability**

The final data used for the statistical tests were uploaded in Göttingen Research Online Data with a doi: <https://doi.org/10.25625/IOF18T>  
Raw thermal images, orthomosaics and terrain data, georeferenced rasters and model configurations are available upon request to the corresponding author.

## **Author Contribution**

The study was conceptualized by DH in cooperation with H (drone measurements) and AK in cooperation with TJ (eddy covariance measurements). FE led the writing of the paper with help from AR and DH supervised the work. FE collected and processed the drone data and CS the eddy covariance data. FE conducted data processing, model application, statistical analysis and production of plots in cooperation mainly with DH and AR. FE, DH and AR created a first version of the manuscript, which was further improved in a cooperation of all authors.

## **Competing interests**

The authors declare that they have no conflict of interest.

## **Acknowledgements**

This study was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – project number 192626868 – SFB 990 (subprojects A02 and A03) and the Ministry of Research, Technology and Higher Education (Ristekdikti). We thank Ristekdikti for providing the research permit for field work (No. 322/SIP/FRP/E5/Dit.KI/IX/2016, No. 329/SIP/FRP/E5/Dit.KI/IX/2016 and No. 28/EXT/SIP/FRP/E5/Dit.KI/VII/2017). We thank our field assistants Zulfi Kamal, Basri, Bayu and Darwis for great support during the field campaigns and Edgar Tunsch, Malte Puhan, Frank Tiedemann and Dietmar Fellert for their technical support. We also thank Perseroan Terbatas Perkebunan Nusantara VI, Batang Hari Unit (PTPN6) for giving us permission to conduct our research at the oil palm plantation. We thank Mr. Nieto for publishing the code for TSEB-PT and DTD (pyTSEB) on [www.github.com](http://www.github.com). Thanks to all ‘EFForTS’ colleagues and friends in Indonesia, Germany, and around the world.
