Abstract. Dimethyl sulfide and volatile organic compounds (VOCs) are important for atmospheric chemistry. The emissions of biogenically derived organic gases, including dimethyl sulfide and especially isoprene, are not well constrained in the Southern Ocean. Due to a paucity of measurements, 15 the role of the ocean in the atmospheric budgets of atmospheric methanol, acetone and acetaldehyde is even more poorly known. In order to quantify the air-sea fluxes of these gases, we measured their seawater concentrations and air mixing ratios in the Atlantic sector of the Southern Ocean, along a ~11000 km long transect at approximately 60° S in Feb-Apr 2019. Concentrations, oceanic saturations and estimated fluxes of five simultaneously sampled gases (dimethyl sulfide, isoprene, methanol, 20 acetone and acetaldehyde) are presented here. Campaign mean ($\pm 1\sigma$) surface water concentrations of dimethyl sulfide, isoprene, methanol, acetone and acetaldehyde were 2.60 (± 3.94), 0.0133 (± 0.0063), 67 (± 35), 5.5 (± 2.5) and 2.6 (± 2.7) nmol dm⁻³ respectively. In this dataset, seawater isoprene and methanol concentrations correlated positively. Furthermore, seawater acetone, methanol and isoprene concentrations were found to correlate negatively with the fugacity of carbon dioxide, possibly due to a 25 common biological origin. Campaign mean ($\pm 1\sigma$) air mixing ratios of dimethyl sulfide, isoprene, methanol, acetone and acetaldehyde were 0.17 (± 0.08), 0.053 (± 0.034), 0.17 (± 0.08), 0.081 (± 0.031) and 0.049 (± 0.040) ppbv. We observed diel changes in averaged acetaldehyde concentrations in seawater and ambient air (and to a lesser degree also for acetone and isoprene), which suggest light-driven production. Campaign mean ($\pm 1\sigma$) fluxes of 4.3 (± 7.4) $\mu\text{mol m}^{-2} \text{d}^{-1}$ DMS and 0.028 (± 0.021)

30 $\mu\text{mol m}^{-2} \text{d}^{-1}$ isoprene are determined where a positive flux indicates from the ocean to the atmosphere. Methanol was largely undersaturated in the surface ocean with a mean ($\pm 1\sigma$) net flux of $-2.4 (\pm 4.7) \mu\text{mol m}^{-2} \text{d}^{-1}$, but also had a few occasional episodes of outgassing. This section of the Southern Ocean was found to be a source and a sink for acetone and acetaldehyde this time of the year, depending on location, resulting in a mean net flux of $-0.55 (\pm 1.15) \mu\text{mol m}^{-2} \text{d}^{-1}$ for acetone and $-0.28 (\pm 1.22) \mu\text{mol m}^{-2} \text{d}^{-1}$ for acetaldehyde. The data collected here will be important for constraining the air-sea exchange, cycling, and atmospheric impact of these gases, especially over the Southern Ocean.

1 Introduction

Dimethyl sulfide is a key source of secondary aerosol in the global atmosphere, likely influencing cloud formation and the albedo of the planet (Charlson et al., 1987; Lana et al., 2011). Isoprene is particularly relevant for studies of atmospheric chemistry due to its extremely fast reaction with OH (Medeiros et al., 2018). Additionally, isoprene might also contribute to particle formation in the marine atmosphere (Arnold et al., 2009; Claeys, 2004). Oxygenated volatile organic compounds (OVOCs), such as methanol, acetone and acetaldehyde, are present ubiquitously throughout the atmosphere (Heald et al., 2008). Methanol, acetone and acetaldehyde are important for the oxidative capacity of the remote marine atmosphere (Lewis et al., 2005) and are suspected to play a role in particle formation and growth (Blando and Turpin, 2000). Acetone and acetaldehyde can react with NO_x to produce peroxyacetyl nitrate (PAN) (Atkinson, 2000). PAN can decompose over the ocean and represent a source of NO_x to the remote marine atmosphere, potentially leading to ozone production (Lee et al., 2012).

50 The role of the oceans in the global budget of these volatile organic compounds (VOCs) is unclear. Using the latest global climatology of DMS, the global ocean is estimated to emit about 28 (Lana et al., 2011) to 20 Tg sulfur yr^{-1} (Land et al., 2014). The difference between these two estimates is mainly due to the use of different gas transfer velocity parameterisations. Lana et al. (2011) suggest that uncertainty in the distribution of seawater DMS concentration contributes to at least as much uncertainty to the global flux as the uncertainty in the gas transfer velocity. Further in situ concentration measurements, particularly in the Southern Ocean (Jarníková and Tortell, 2016), will reduce the uncertainty of this

estimate. Production of DMS in seawater is thought to involve bacterial degradation of DMSP as well as direct production of DMS by phytoplankton (Dani and Loreto, 2017). Only ~10 % of the DMS in the water column is lost due to emission to the atmosphere (Archer et al., 2002; Yang et al., 2013b). The largest sink of DMS in seawater is bacterial consumption (Kiene and Bates, 1990; Yang et al., 2013b). Global oceanic isoprene emissions have been estimated to be $0.31 \pm 0.08 \text{ Tg yr}^{-1}$ using seawater concentration data (bottom-up approach) and 1.9 Tg yr^{-1} using marine air mixing ratios and an atmospheric inversion model (top-down approach) (Arnold et al., 2009). Photochemical production of isoprene at the sea surface microlayer has been suggested to be a significant source of isoprene and could partly account for this discrepancy (Brüggemann et al., 2018; Ciuraru et al., 2015). However, the only direct flux measurement of isoprene over the ocean to date have found no evidence for an enhanced flux under increased light levels (Kim et al., 2017b). Isoprene is mainly produced in seawater by phytoplankton (Shaw et al., 2010) and the largest removal mechanism from the water column is emission to the atmosphere (Booge et al., 2018; Palmer and Shaw, 2005), probably followed by bacterial consumption (Booge et al., 2018). The lifetime of isoprene in seawater has been estimated as 7 (Palmer and Shaw, 2005) to 10 days (Booge et al., 2018).

Models indicate that over the Southern Ocean and globally, DMS (Tesdal et al., 2016) and isoprene (Carslaw et al., 2013) emissions are important for cloud formation and the albedo of the planet. The Southern Ocean is highly under-sampled for DMS and isoprene which increases errors when running global atmospheric models and using highly interpolated data from the Southern Ocean. To give an appreciation of the sensitivity of the models to these emissions, Woodhouse et al. (2013) calculate a 4-6 % change in global CCN for a 10 % change in DMS flux (relative to Kettle and Andreae (2000)) in the Atlantic sector of the Southern Ocean for December. Variations in CCN concentrations show clear seasonal trends with highest concentrations typically observed in austral summer (Kim et al., 2017a) thus suggesting, amongst others, a role of biological productivity in formation of CCN over the Southern Ocean.

Using satellite data, Stavrou et al. (2011) suggest that methanol is both absorbed (-48 Tg yr^{-1}) and emitted (42.7 Tg yr^{-1}) by the oceans, resulting in a net sink of -5 to -13 Tg yr^{-1} . Earlier atmospheric global budget by Millet et al. (2008) have used measurements of methanol in the atmosphere and have

85 estimated that the oceans represent a net sink of -16 Tg yr^{-1} , with a large oceanic source (85 Tg yr^{-1}) and
sink (-101 Tg yr^{-1}). Direct flux measurements during a transatlantic transect (Yang et al., 2013a) and in
the North Atlantic (Yang et al., 2014a) have found that the flux of methanol was consistently into the
ocean (Yang et al., 2013a). Based on those Atlantic observations, a net oceanic sink of -42 Tg yr^{-1}
90 globally has been extrapolated (Yang et al., 2013a), with the largest air-to-sea flux in regions downwind
of continental outflow. In a more recent study, Müller et al. (2016) estimate that the ocean emits 39 Tg
 yr^{-1} of methanol and absorb -46 to -66 Tg yr^{-1} . They admit that their ocean emissions likely represent an
overestimate (Müller et al., 2016). In seawater, methanol is thought to be predominantly produced by
phytoplankton (Mincer and Aicher, 2016) and consumed by bacteria with a lifetime of 10-26 days
(Dixon et al., 2013; Dixon and Nightingale, 2012). Methanol is a source of carbon and energy for
95 methylotrophic bacteria (Dixon et al., 2011).

The most recent global atmospheric budget of acetone calculates that the ocean is both the largest
source (51.8 Tg yr^{-1}) and the largest sink of acetone (-59.2 Tg yr^{-1}) (Brewer et al., 2017). This results in
a net oceanic sink of -7.5 Tg yr^{-1} , which represents approximately 11 % of the total acetone sink from
the atmosphere (Brewer et al., 2017). Based on direct flux measurements over the Pacific Ocean,
100 Marandino et al. (2005) estimate a global net oceanic sink of -42 Tg yr^{-1} . During a transatlantic transect,
Yang et al. (2014b) observed that the acetone flux can be either in or out of the ocean, depending on
location. This leads to highly uncertain global extrapolations as these authors predict the ocean to be a
net sink of -1 Tg yr^{-1} with a propagated uncertainty of $\pm 19 \text{ Tg yr}^{-1}$. In the global acetone budget by
Fischer et al. (2012) and Brewer et al. (2017), the surface seawater concentration is set to a constant 15
105 nmol dm^{-3} . In comparison, previous observations have shown that seawater acetone concentrations in
the oceans range from about 2 nmol dm^{-3} (Beale et al., 2013) to up to 41 nmol dm^{-3} (Tanimoto et al.,
2014). The assumption of a constant seawater concentration will lead to errors in modelled air mixing
ratios and air-sea fluxes. For example, Brewer et al. (2017) highlight the importance of surface ocean
acetone concentrations for accurately predicting atmospheric mixing ratios over the Southern
110 Hemisphere. Acetone is thought to be produced in the oceans primarily by photochemical degradation
of organic carbon (Dixon et al., 2013) and is consumed by microbes (Dixon et al., 2013, 2014). More
recently, a biological source for oceanic acetone has also been suggested from field measurements

(Schlundt et al., 2017) and laboratory phytoplankton cultures (Halsey et al., 2017). The typical open ocean lifetimes of acetone ranges between 5 and 55 days (Dixon et al., 2013).

115 The ocean flux of acetaldehyde is highly uncertain. In a global atmospheric budget, the ocean was modelled to be the second largest source at a net flux of 57 Tg yr⁻¹ (Millet et al., 2010), which represents approximately 27 % of the total source of acetaldehyde. More recently, using an updated air-sea exchange scheme, Wang et al. (2019) estimate the net oceanic source of acetaldehyde to be 34 Tg yr⁻¹. Direct flux measurements from a transatlantic transect suggest that the oceans are both a source and
120 a sink of acetaldehyde (Yang et al., 2014b). These authors estimate the net oceanic emission of acetaldehyde to be much lower, around 3 (propagated uncertainty ± 14) Tg yr⁻¹ (Yang et al., 2014b). Similar to the case for acetone, the large propagated uncertainty is because the air and water concentrations were highly variable, resulting in large variability in flux magnitude and also direction. In the ocean, acetaldehyde is produced by photochemical degradation of organic carbon (Dixon et al.,
125 2013; Zhu and Kieber 2018; Kieber et al., 1990; De Bruyn et al., 2011a). A substantial light dependant biological source for acetaldehyde has been suggested from laboratory phytoplankton cultures (Halsey et al., 2017). Bacterial consumption of acetaldehyde is rapid, resulting in very short open ocean lifetimes of less than 1 day (Dixon et al., 2013; de Bruyn et al., 2017, 2013).

To the best of our knowledge, methanol, acetone and acetaldehyde seawater concentrations in the
130 Southern Ocean have not been measured previously. Thus their air-sea fluxes and saturations in the Southern Ocean are largely unknown. The Southern Ocean is expected to play an important role in determining the air mixing ratios of these compounds in the southern hemisphere due to the low land mass and so the paucity of dominant sources such as terrestrial vegetation (e.g. for acetone, Brewer et al. (2017)).

135 The few sets of high resolution measurements of DMS and other VOCs in seawater (Asher et al., 2011; Kameyama et al., 2010; Royer et al., 2016; Tortell, 2005; Tran et al., 2013) indicate that these short lived gases display spatial variability on the order of tens of kilometres (Asher et al., 2011; Royer et al., 2015) and some diel temporal variability. High resolution measurements are important for estimating regional emissions (for example of DMS, Webb et al. (2019)). Ambient air and seawater concentrations
140 of VOCs have rarely been measured together at a high frequency to explore the spatial/temporal

variability in their air-sea exchange (Williams et al., 2004; Yang et al., 2014a, 2014b). Concurrent measurement of a broad range of gases also enables correlation analyses of their concentrations and identification of common sources and sinks.

Here, we present hourly averaged ambient air and seawater measurements of a suite of simultaneously measured gases (dimethyl sulfide, isoprene, acetone, acetaldehyde and methanol) from the Atlantic sector of the Southern Ocean during the transition from late austral summer into autumn. Our measurements are used to compute hourly saturations and air-sea fluxes. These observations represent a valuable dataset of a broad range of gases in a climatically important but under-sampled region.

2. Experimental

2.1 Description of the cruise

The measurements were made during the ANDREXII cruise from 25/02/19 to 14/04/19 on board of the RRS *James Clark Ross* (JCR), which is part of the ORCHESTRA project (<https://orchestra.ac.uk/>). The vessel transited from the Falkland Islands across Drake Passage to Elephant Island near the Antarctic Peninsula. The vessel then followed a transect along a latitude of approximately 60° S eastwards past the South Orkney Islands and the South Sandwich Islands. After that, the vessel transited further east until 30° E, and then followed a return track to repeat some stations and finished in the Falkland Islands. The sampling track of the ANDREXII cruise on board JCR is shown in Figure 1 and coloured by chlorophyll a concentration (determined from underway WET Labs WSCHL fluorometer). The underway chlorophyll a measurements determined via fluorescence are relatively uncertain due to sensor drift but have been corrected using the fluorescence measured at 5–7 m by a sensor (WET Labs ECO-AFL/FL) on the CTD rosette (Figure 2). A range of other physical and biogeochemical parameters were also measured, such as underway fCO₂ (Kitidis et al., 2012, 2017), sea surface temperature (SST) measured using SBE38 Sea-Bird, and sea surface salinity (sal) monitored using a SBE45 Sea-Bird Thermosalinograph. Time series of underway salinity, sea surface temperature as well as chlorophyll a and fCO₂ data are shown in Figure 2. The highest fCO₂ values of up to 450 µatm were observed from 01/03/19 through to 03/03/19, which corresponded to upwelling waters near

the Antarctic Peninsula (Amos, 2001; Takahashi et al., 2009). Some of the highest concentrations of chlorophyll a (up to $1.2 \mu\text{g dm}^{-3}$) were observed directly to the east of the South Sandwich Islands, where the ship undertook a detailed mapping of a phytoplankton bloom (around 13/03/19). The partial pressure of CO_2 was drawn down within this bloom (around $310 \mu\text{atm}$).

2.2 VOC measurements

During ANDREXII, VOCs in seawater and ambient air were measured with a Proton Transfer Reaction-Mass Spectrometer (PTR-MS, High Sensitivity Model by Ionicon). To measure seawater concentrations, a segmented flow coil equilibrator (SFCE) was used to equilibrate underway seawater with “zero air” (Wohl et al., 2019). The underway seawater inlet of the JCR is situated at approximately 5–7 m depth and set flush with the hull. The SFCE nominally sampled from the bottom of a small (ca. 200 cm^3) glass vessel that was overflowing rapidly with underway seawater. In addition to the underway measurements, approximately once a day seawater sampled from the 5m Niskin bottle from the CTD was measured to verify that the ship’s underway seawater inlet did not affect the measured concentrations. There was no significant difference in VOC concentration sampled from the underway seawater inlet and the 5m Niskin bottle (t -test, $n=35$, $p<0.05$).

A thermometer was installed at the seawater exhaust of the SFCE to continuously measure the seawater temperature. This revealed that when using the SFCE continuously with very cold seawater (cruise mean 1°C) and zero air cylinders mounted outside on deck, the seawater temperature in the coil only reached 18°C (despite the water bath holding the SFCE set to 25°C). This is in contrast to earlier lab measurements and an Arctic deployment, during which the water exiting the SFCE was always 20°C with the zero air cylinder housed inside of the lab. The continuously recorded temperature was used to calculate the Henry’s solubility and hence the seawater concentrations for this cruise. SFCE calibrations using MilliQ water (20°C) and cold seawater revealed that these gases fully equilibrated regardless of the initial temperature (see appendix A).

An air inlet was installed on a 40 cm pole extending forward from the railing of the walkway in front of the ship’s bridge at approximately 16 m above the ocean surface. Ambient air was pumped towards the PTR-MS via a $\sim 90 \text{ m}$ PTFE (Polytetrafluoroethylene) air sampling tube (o.d. 9.5 mm, wall thickness

1.5 mm) using a Vacuubrand Diaphragm pump MD 4 NT at a flow rate of circa $30 \text{ dm}^3 \text{ min}^{-1}$. The
195 sampling tube followed a complex path around the ship, had a number of tight turns, and was mostly
sheltered from direct sunlight. The PTR-MS subsampled from this sample tube upstream of the pump at
a flow of approximately $100 \text{ cm}^3 \text{ min}^{-1}$. We do not expect large aerosols to make it to the PTR-MS
because of the tight turns in the main sampling tube as well as the low subsample flow. The residence
time of ambient air in the sampling tube was approximately 6 s. The blank measurements for ambient
200 air mixing ratios were made by diverting ambient air through a custom-made Platinum-catalyst at
 450°C . The high efficiency of this Pt-catalyst at oxidizing all VOCs in air to CO_2 has been
demonstrated elsewhere (Yang and Fleming, 2019).

PTFE solenoid valves (1/8", Takasago Fluid Systems) controlled by the PTR-MS were used to create
an hourly measurement cycle of 40 min SFCE headspace (proportional to seawater concentration), 5
205 min ambient air scrubbed by the Pt-catalyst at 450°C (catalyst blank) and 15 min of ambient air
measurements.

2.2.1 Calibrations

Weekly dynamic gas phase calibrations were conducted during the cruise using a certified gas
calibration standard and two mass flow controllers (Apel-Riemer Environmental Inc., Miami, Florida,
210 USA; nominal volume mixing ratio of 500 ppbv for acetaldehyde, methanol, acetone, isoprene DMS,
benzene, toluene). Calibration slopes were typically within 10 % of each other.

A lower PTR-MS drift tube voltage of 640 V was applied during this cruise compared to Wohl et al.
(2019), while other PTR-MS settings were kept the same. Thus the humidity dependence of the signal
and the background was slightly different from Wohl et al. (2019). The background measurement of
215 methanol and possibly acetaldehyde showed a humidity dependence at 640 V. The calibration slope for
isoprene was corrected for its humidity dependence using a fragmentation ratio specifically determined
at 640 V in the PTR-MS (Wohl et al., 2019). The other VOCs did not show a humidity dependence in
either the slope or background. Several different types of blanks were measured in order to compute the
seawater concentrations (supplementary information S1). Due to the aforementioned humidity
220 dependence in the background of methanol and acetaldehyde, we used blanks that were measured at the

same humidity as the equilibrator headspace for those two VOCs (Table 1). For compounds that do not display a humidity dependence in the background, hourly measurement of ambient air scrubbed by the Pt-catalyst was used as a seawater blank because of its high frequency.

225 Two methods were used to determine the SFCE calibration slopes for seawater methanol, acetone, and acetaldehyde concentrations during this cruise: invasion and evasion. In evasion calibrations, pure solvents were dissolved by serial dilution in MilliQ water and seawater as described previously (Wohl et al., 2019). These diluted standards were measured with the SFCE-PTR-MS system using the same procedure as for seawater samples. During invasion experiments, a known amount of certified gas standard was added to the carrier gas, which was equilibrated with essentially VOC-free MilliQ water
230 or very deep seawater.

For the fully equilibrating gases, the calibration slopes are proportional to the Henry gas solubility (H). Invasion and evasion experiments represent independent estimates of solubility of these gases at environmentally relevant concentrations. For acetone and methanol, our invasion and evasion calibrations agreed only if we divide their recommended solubilities (Burkholder et al., 2015) by 1.4
235 and 1.6 respectively (see appendix A). We use these experimentally determined H to compute the concentrations, saturations, and fluxes of acetone and methanol here. The reference of Burkholder et al. (2015) is used here since it represents a critical tabulation of the latest experimental data. The solubilities inferred by our study are within the range of previously published solubilities.

As with previous calibrations, these measurements on board showed that the SFCE achieved essentially
240 full (i.e. 100%) equilibration for all the VOCs measured here except for isoprene (Wohl et al., 2019). The equilibration efficiency of isoprene was determined to be 87 ± 9 % ($\pm 1\sigma$) from onboard invasion experiments. This is higher than the equilibration efficiency observed during our earlier laboratory tests, probably due to the higher seawater flow (120 instead of $100 \text{ cm}^3 \text{ min}^{-1}$) used on this cruise. We use this measured equilibration efficiency to determine seawater isoprene concentrations.

245 **2.2.2 Limit of detection estimates**

Measurement uncertainty and limit of detection (LOD) of this system have already been described in Wohl et al. (2019). Here we reassess the limit of detection (LOD) of our seawater and ambient air

concentration measurements. This is to address the possibilities that (i) our previous estimates (Wohl et al., 2019) might have represented an overidealized case and (ii) the LOD is dependent on the PTR-MS quadrupole settings, dwell times (Yang et al., 2013c), as well as calibration slopes (Wohl et al., 2019), which may differ between deployments. The most appropriate seawater background for the ANDREXII cruise is listed in Table 1. The mean of the 5 min Pt-catalyst blank measurements was interpolated over the time series of measurements. The standard deviation of the detrended blanks (after subtracting the interpolation) was multiplied by the gas phase calibration and represents the measurement noise (1σ) in ppbv of the ambient air measurement. To calculate the measurement noise of the seawater concentration, this mixing ratio was converted to a seawater concentration in the same way as the seawater measurement (Wohl et al., 2019). The LOD was defined as 3σ . The underway ambient air and seawater data were also first averaged to 5 min means, with each hourly average containing 6 continuous 5 min means of equilibrator headspace and 2 continuous 5 min means of ambient air measurements (i.e. the first minutes after automated valve switch were discarded to account for residual air in the tubing). The measurement noise derived from this analysis was divided by the square root of the number of 5 min measurements in each hourly cycle to calculate the hourly measurement noise and limit of detection listed in Table 1.

2.2.3 Light-driven contamination in the seawater measurement

The SFCE was installed near the starboard windows in the main lab. During the early part of the cruise, intense sunlight sometimes shined directly at the SFCE. This led to observations of extremely high headspace mixing ratios that were presumably due to photochemical production within the SFCE. This effect disappeared instantly after covering the air-water separating tee from direct sunlight. The air-water separating tee of the SFCE was thereafter covered from direct sunlight and the blinds were kept closed from 04/03/19 onwards. The effect of this light reduction measure is illustrated in Figure 3. Hence, daytime seawater concentrations of acetaldehyde, acetone and isoprene prior to 04/03/19 were not used in further analysis. Daytime data after 04/03/19 did not show any dependence on the ship's heading, indicating that this artefact had been satisfactorily dealt with. The exact cause of this light-driven contamination in the SFCE system is unclear. Photochemical production of isoprene and

275 carbonyl compounds at the sea surface microlayer has been observed before (Brüggemann et al., 2018;
Ciuraru et al., 2015). It could be that similar reactions were taking place on the water surfaces inside of
the SFCE.

2.2.4 Filtering of Atmospheric VOC measurements

Ambient air measurements were filtered to remove the influence of ship stack contamination.
280 Firstly, all measurements made during a sampling cycle were discarded if the concentration of benzene
or toluene was above a threshold of 0.2 ppbv. This was to eliminate small scale contamination from the
ventilation pipes on the foremast. Secondly, data were discarded if the relative wind speed was less than
4 m s⁻¹. Thirdly, only ambient air measurements with the wind coming from 10–70° either side of the
bow were used for further analysis. Filtering was carried out using 1 min averaged wind measurements
285 from a Metek sonic anemometer installed on the foremast and resulted in the removal of 55 % of the
ambient air measurements.

2.3 Flux calculations

The saturation (%Sat) of the surface ocean relative to the atmosphere is calculated using Eq. (1).

$$\%Sat = \left(\frac{C_w}{C_a * H} \right) * 100 \quad (1)$$

290 Where a saturation above 100 % corresponds to oceanic outgassing. H is the dimensionless liquid over
gas form of the Henry solubility.

The net air-sea flux (F, positive from sea to air) is determined using the two layer model flux equation
(Liss and Slater, 1974) illustrated in Eq. (2).

$$F = k * (C_w - H * C_a) \quad (2)$$

295 Where the gas transfer velocity (k) is defined by Eq. (3).

$$k = \frac{1}{\frac{1}{k_w} + \frac{H}{k_a}} \quad (3)$$

To calculate the airside (k_a) transfer velocity, we use the following parametrization derived from direct measurements of air-sea methanol transfer (Yang et al., 2013a) (Eq. (4)). This was chosen to be the k_a for all VOCs of concern since we do not expect them to differ by more than ~10 %:

$$k_a = 8814 u_* + 6810 u_*^2 \quad (4)$$

300

Here the friction velocity u_* is simplistically calculated using the parameterization from Johnson (2010) (Eq.(5)).

$$u_* = u_{10} * \sqrt{1.3 * 10^{-3}} \quad (5)$$

305 Wind speed from a Metek sonic anemometer was adjusted to 10 m height (u_{10}). For isoprene, the waterside transfer velocity (k_w) is calculated using the parameterisation by Nightingale et al. (2000) (Eq. (6)).

$$k_w = (0.222 * u_{10}^2 + 0.333 * u_{10}) * \left(\frac{Sc_w}{Sc_{600}} \right)^{-0.5} \quad (6)$$

310 Sc_w is the waterside Schmidt number and Sc_{600} is the Schmidt number of 600. This parametrisation most likely represents an overestimation of k_w for gases that have similar or greater solubility than DMS because of the solubility dependence in bubble-mediated gas exchange (Yang et al., 2011). Thus for DMS, acetaldehyde, acetone and methanol, mean k_w determined from DMS measurements from five different cruises was used here (Yang et al., 2011) and scaled to the ambient temperature assuming $Sc_w^{-0.5}$.

315 The water phase Schmidt numbers (Sc_w) of methanol, acetone, acetaldehyde and DMS are determined following Johnson (2010). The Schmidt number of isoprene is calculated using the equation presented in Palmer and Shaw (2005). Henry solubility values are converted from freshwater to seawater using the method presented by Johnson (2010). Methanol and acetone concentrations, fluxes and saturations are calculated using the experimentally determined solubility presented in the appendix A.

3. Underway ambient air mixing ratios, seawater concentrations and air-sea fluxes

320 In the following sub-sections, the ambient air and seawater concentrations of DMS, isoprene, methanol,
acetone and acetaldehyde as well as their saturations and fluxes are discussed. Saturations below 100 %
indicate undersaturation in seawater (i.e. air-to-sea, or negative flux). Two versions of fluxes are
presented: fluxes when both ambient air and seawater data were available, and continuous flux
estimates despite missing ambient air data (e.g. wind direction out of sector), which were estimated by
325 smooth interpolation of the ambient air mixing ratios.

As a quick overview and for reference, cruise mean air and seawater concentrations are
presented in Table 2. Cruise mean saturations and calculated fluxes are shown in Table 3. Also included
are the median and quantiles as well as the standard deviation. We also show two tables (Table 4 and
Table 5) summarising some previous ambient marine air and seawater measurements of these
330 compounds. These tables do not represent comprehensive reviews of previously published
measurements, but instead aid comparison of our measurements to previous measurements from the
Southern Ocean and other regions.

3.1 Dimethyl sulfide

The time series of DMS ambient air and seawater concentrations as well as the corresponding
335 fluxes and saturations are presented in Figure 4.

The campaign mean seawater concentration of DMS was $2.60 \text{ nmol dm}^{-3}$ and the median was $1.39 \text{ nmol dm}^{-3}$. This illustrates the positive skewness of the DMS seawater concentrations due to episodic high concentrations of DMS. The highest DMS seawater concentrations were observed near the Antarctic Peninsula upwelling region (around 28/02/19, up to $7.55 \text{ nmol dm}^{-3}$) and east of the South Sandwich
340 Islands (around 13/03/19, up to $24.44 \text{ nmol dm}^{-3}$). Chlorophyll a was also elevated in those regions. These and other fine-scale hot spots of DMS were well resolved due to our use of continuous and fast-responding measurements. To remove the effect of ship sampling bias on the overall cruise mean (e.g. spending multiple days surveying a plankton bloom), the DMS concentrations were first averaged in 1° longitudinal bins. The mean of spatially averaged seawater DMS concentration for this campaign was
345 $1.87 \text{ nmol dm}^{-3}$ (confidence interval of the mean: $1.46\text{-}2.28 \text{ nmol dm}^{-3}$). This is similar to the Lana et al.

(2011) climatology in this region and during these months (average of 1.5 nmol dm^{-3} and range: $0\text{--}3 \text{ nmol dm}^{-3}$).

Cruise mean and median ambient air mixing ratios of DMS were 0.17 ppbv and 0.16 ppbv respectively. These values are comparable to previous measurements over the Southern Ocean at this time of year
350 (Bell et al., 2015; Colomb et al., 2009; Curran et al., 1998; Guérette et al., 2019; Koga et al., 2014; Yang et al., 2011). Ambient air mixing ratios were up to about 0.5 ppbv on occasions, and did not correlate with seawater concentrations. This is probably because air parcels travel much faster than seawater, leading to a decoupling between air and sea DMS concentrations.

The campaign mean DMS flux was $4.3 \text{ } \mu\text{mole m}^{-2} \text{ d}^{-1}$. Fluxes were typically $< 7 \text{ } \mu\text{mole m}^{-2} \text{ d}^{-1}$ but
355 exceeded $30 \text{ } \mu\text{mole m}^{-2} \text{ d}^{-1}$ within the phytoplankton bloom encountered on around 13/03/2019. Our mean DMS flux compares well to direct measurements of DMS flux over the Southern Ocean (Bell et al., 2015; Yang et al., 2011). Averaging the DMS flux in 1° longitudinal bins (as with the seawater concentration above) results in a spatial mean flux of $3.2 \text{ } \mu\text{mole m}^{-2} \text{ d}^{-1}$. From now on we discuss only temporal statistics.

360 **3.2 Isoprene**

The time series of isoprene ambient air and seawater concentrations as well as the corresponding fluxes and saturations are presented in Figure 5.

The campaign mean isoprene seawater concentration was $0.0133 \text{ nmol dm}^{-3}$. This is comparable to previous measurements in the open ocean (Hackenberg et al., 2017; Ooki et al., 2015) and also in the
365 Southern Ocean (Kameyama et al., 2014). Isoprene concentrations as high as $0.040 \text{ nmol dm}^{-3}$ were observed near the Antarctic Peninsula and in the phytoplankton bloom near the South Sandwich Islands. As shown in Fig. 2 and Fig. 5, these areas were also associated with high chlorophyll a concentration and low $f\text{CO}_2$.

The linear regression between underway isoprene (nmol dm^{-3}) and chlorophyll a ($\mu\text{g dm}^{-3}$) yielded a
370 slope of $0.0136 \text{ nmol dm}^{-3} \text{ isoprene } (\mu\text{g chl a dm}^{-3})^{-1}$ with an R^2 value of 0.35 and an intercept of $0.0087 \text{ nmol dm}^{-3} \text{ isoprene}$ ($P= 0.000$, $N=799$). There also appears to be a first order relationship between chlorophyll a and seawater isoprene concentrations in other oceanic basins, with variable R^2 values of

37% (Kameyama et al., 2014), 12 % (Baker et al., 2000) and 52 % (Broadgate et al., 1997). The regression slope from our campaign, where SST was generally between 0 and 2°C, compares best to
375 previous measurements in colder waters. For example, Ooki et al. (2015) have found a slope of 0.0143
nmol dm⁻³ isoprene (μg chla dm⁻³)⁻¹ and intercept of 0.00223 nmol dm⁻³ isoprene in waters with
temperatures between 3.3–17°C. Hackenberg et al. (2017) have found slopes of 0.0379 nmol dm⁻³
isoprene (μg chla dm⁻³)⁻¹ and 0.0341 nmol dm⁻³ isoprene (μg chla dm⁻³)⁻¹ for SST below 20°C in the
Atlantic and Arctic Oceans respectively. The slope between chlorophyll a vs. isoprene concentration
380 appears to increase in steepness with temperature (Hackenberg et al., 2017; Ooki et al., 2015).

Our dataset showed a significant negative correlation between seawater isoprene and fCO₂ (slope: -
0.00015 nmol dm⁻³ isoprene (μatm fCO₂)⁻¹, intercept: 0.0699 nmol dm⁻³ isoprene, R² 0.44, P=0.000,
N=690). This might be because isoprene is produced by phytoplankton (Dani and Loreto, 2017; Shaw et
al., 2010), and high biological productivity tends to reduce seawater fCO₂ in phytoplankton blooms
385 (Blain et al., 2007; Wingenter et al., 2004). A negative correlation between the partial pressure of CO₂
(pCO₂, whether temperature-normalized or not) and seawater isoprene concentrations has been reported
previously (Kameyama et al., 2014) but this correlation only held for waters south of 53° S. In the study
of Kameyama et al. (2014), the SST normalised pCO₂ was viewed as a proxy for net community
production.

390 The mean ambient air mixing ratio of isoprene on this cruise was 0.053 ppbv and the median was 0.045
ppbv, illustrating a positive skewness in the isoprene ambient air mixing ratio. This positive skewedness
is probably caused by biology- and wind speed-dependent emissions as well as the short lifetime of
isoprene in the atmosphere that prevents it from being more fully mixed. Positively skewed atmospheric
isoprene mixing ratios have also been observed previously over the ocean (Kim et al., 2017). The mean
395 of our measurements compares best to previous measurements over the Southern Ocean (Colomb et al.,
2009; Nadzir et al., 2019; Yokouchi et al., 1999) as well as other biologically productive areas (Shaw et
al., 2010).

Isoprene was supersaturated by 760 % in the mean. The large supersaturation and low solubility of
isoprene suggest that ambient air mixing ratios influence isoprene saturation levels very little. . A mean
400 isoprene flux of 0.028 μmole m⁻² d⁻¹ is computed for this deployment, which exceeded 0.07 μmole m⁻²

d⁻¹ on occasions. Our fluxes compare well to some published estimates from other oceans (Baker et al., 2000; Tran et al., 2013), but they are about 10-fold lower than an estimate from the Southern Ocean by Kameyama et al. (2014). This is probably due to the lower seawater concentrations measured during our campaign compared to the seawater concentrations reported by Kameyama et al. (2014). Our fluxes are also comparable to direct flux measurements in the Labrador Sea where mean isoprene fluxes were found to be dominated by episodic emissions (Kim et al., 2017).

3.3 Methanol

The time series of methanol ambient air and seawater concentrations as well as the corresponding fluxes and saturations are presented in Figure 6.

Median and mean seawater methanol concentrations were the same at 67 nmol dm⁻³. These are higher than previous high latitude measurements in the South Atlantic in the austral spring (Beale et al., 2013; Yang et al., 2014b) and in the Labrador sea in late boreal autumn (Yang et al., 2014a), and are similar in magnitude to measurements in parts of the North Atlantic during the boreal autumn (Beale et al., 2013). The highest seawater methanol concentrations of up to 226 nmol dm⁻³ were observed in the phytoplankton bloom encountered around 13/03/19. Interestingly, the range of observations on this cruise (below detection to 226 nmol dm⁻³) encompasses a broad range of previously published values of 15 to 361 nmol dm⁻³ in tropical and temperate waters (Beale et al., 2013, 2015; Kameyama et al., 2009; Williams et al., 2004; Yang et al., 2013a, 2014a). The large range in seawater methanol concentrations highlights the advantage of our high frequency measurement system.

Regression analysis of seawater concentrations of methanol against isoprene gave a significant positive relationship (slope: 3524 nmol dm⁻³ methanol (nmol dm⁻³ isoprene)⁻¹, intercept: 22 nmol dm⁻³ methanol, R²=0.38 P=0.000, N=771). Furthermore, methanol significantly correlated with fCO₂ (slope: -1.0 nmol dm⁻³ methanol (μatm fCO₂)⁻¹, intercept: 450 nmol dm⁻³ methanol, R² 0.58, P=0.000, N=651), which suggests production of methanol by phytoplankton. However, seawater methanol concentrations did not correlate significantly with chlorophyll a, which is consistent with previous seawater measurements in the Atlantic (Yang et al. 2013).

The correlation between methanol and isoprene on our cruise suggests that both compounds may be produced by similar phytoplankton species. Measurements of laboratory phytoplankton cultures show that cyanobacteria (*Synechococcus* and *Trichodesmium*) are strong producers of isoprene (Bonsang et al., 2010), but weak producers of methanol (Mincer and Aicher, 2016). In contrast, *Phaeodactylum*, a temperate diatom, was found to produce large amounts of methanol (Mincer and Aicher, 2016) but moderate amounts of isoprene (Bonsang et al., 2010). *Emiliania Huxley*, a coccolithophore, was observed to produce moderate amounts of both isoprene and methanol (Bonsang et al., 2010; Mincer and Aicher, 2016). Unfortunately no plankton composition measurements were made during our cruise so we are unable to comment further.

Ambient air mixing ratios of methanol were very low (mean= 0.17 ppbv, median= 0.17 ppbv), in agreement with previous measurements in the Southern Hemisphere of about 0.2 ppbv in the South Atlantic (Yang et al., 2013) and up to 0.54 ppbv above the Southern Indian Ocean (Colomb et al., 2009). Lower ambient air mixing ratios of methanol in the Southern Hemisphere compared to the Northern Hemisphere are probably due to the relatively sparse landmass and vegetation coverage (Yang et al., 2013).

The Southern Ocean was a net sink of methanol on average with a mean saturation of 83 % and flux of $-2.4 \mu\text{mol m}^{-2} \text{d}^{-1}$. The presence of occasional waters with high methanol concentrations, combined with relatively low ambient air mixing ratios, led to episodes of outgassing of methanol over phytoplankton blooms (up to $\sim 10 \mu\text{mol m}^{-2} \text{d}^{-1}$). Net sea-to-air transfer of methanol is somewhat unexpected given the extremely high solubility of methanol. Previous direct flux measurements of methanol along a meridional transect through the Atlantic (Yang et al., 2013a) and in the Labrador sea (Yang et al., 2014a) have shown that the flux of methanol was consistently into the ocean, with the largest air-to-sea flux in regions downwind of continents. Outgassing of methanol from the ocean has been suggested previously for some waters of the North Atlantic (Beale et al., 2013). In our calculation, we note that the methanol flux is insensitive to the choice of solubility. If we instead calculated the methanol flux and seawater methanol concentrations using the recommended solubility by Burkholder et al. (2015), the mean seawater concentration of methanol, saturation and flux would have been 125 nmol dm^{-3} (60 % higher) 83 % (unchanged), $-2.4 \mu\text{mol m}^{-2} \text{d}^{-1}$ (unchanged) respectively. Saturation and flux remain

455 unchanged since seawater concentration and solubility change by the same factor and the two changes cancel out.

3.4 Acetone

The time series of acetone ambient air and seawater concentrations as well as the corresponding fluxes and saturations are presented in Figure 7.

460 The mean ($\pm 1\sigma$) seawater acetone concentration of 5.5 ± 2.5 nmol dm⁻³, while the median was 5.1 nmol dm⁻³. These values compare well to previous measurements of less than 10 nmol dm⁻³ in the South Atlantic (Beale et al., 2013; Yang et al., 2014b) and in the Labrador sea (Yang et al., 2014a). Seawater acetone concentrations from this cruise are also similar to other open ocean measurements (Hudson et al., 2007; Kameyama et al., 2010; Marandino et al., 2005; Schlundt et al., 2017). Unlike methanol, 465 seawater acetone concentration was usually quite consistent and ranged from 4.3 (lower quantile) to 5.9 (upper quantile).

A significant negative correlation of acetone with fCO₂ is observed (slope: -0.053 nmol dm⁻³ acetone (μatm CO₂)⁻¹, intercept: 26.51 nmol dm⁻³ acetone, R² 0.58, P=0.000, N=671), excluding high seawater acetone measurements from 08/04/19 and 10/04/19. These elevated data are considered strong outliers 470 (higher than the upper quantile plus three times the interquantile range) for reasons currently unknown. This correlation of acetone with fCO₂ suggests a possible role for biology in the production of acetone. Previous investigators have found correlations between seawater acetone concentration and the abundance of haptophytes and pelagophytes (Schlundt et al., 2017), suggesting direct production by phytoplankton and/or bacterial communities associated with these phytoplankton. Taddei et al. (2009) 475 have also observed higher emission of acetone in high chlorophyll a areas in the remote South Atlantic. Our acetone data showed a weak, although significant positive correlation with chlorophyll a concentration (slope: 4.84 nmol dm⁻³ acetone (μg chla)⁻¹, intercept: 4.11 nmol dm⁻³ acetone, R² 0.07, P=0.000, N=750). Despite this, the main source of acetone in seawater is probably photochemical production, which has been found to account for up to 100 % of gross production rates of acetone in 480 seawater (Dixon et al., 2013). The underway acetone air and water concentrations presented here show

a small but statistically significant difference between daytime and nighttime, which will be discussed further in section 4.

The mean ($\pm 1\sigma$) ambient air mixing ratio of acetone measured during this cruise was very low (mean of 0.081 ± 0.031 ppbv and median 0.076 ppbv). This compares well with clean marine air measurements of 0.188 ppbv at Cape Grim, Tasmania (Galbally et al., 2007), air coming off Antarctica with an average of 0.128 ppbv (Legrand et al., 2012) and marine air measurements with an average of 0.127 ppbv over the South Atlantic at 55° S (Williams et al., 2010). The mean ambient air mixing ratio reported here is considerably lower than the modelled annual mean acetone air mixing ratio over the Southern Ocean of about 0.2 ppbv (Fischer et al., 2012). An updated global budget of acetone predicts slightly lower annual mean air mixing ratios over the Southern Ocean of 0.1-0.2 ppbv (Brewer et al., 2017). This decrease is largely due to an increased photolysis rate of acetone in the updated model (Brewer et al., 2017). Both of these works assume a fixed acetone seawater concentration of 15 nmol dm^{-3} (nearly three times our measurements), and so have the potential to overestimate air mixing ratios above the Southern Ocean. Further observations are needed to capture the seasonality of seawater acetone concentrations.

The mean seawater saturation of acetone was 88 %. Saturations of between 50 and 200 % are typical for acetone (Schlundt et al., 2017; Yang et al., 2014a, 2014b). A mean net flux into the ocean of $-0.55 \mu\text{mol m}^{-2} \text{ d}^{-1}$ suggests that the net flux of acetone is on average into the Southern Ocean this time of the year. Though occasional outgassing was also observed. Using a *t*-test, the mean acetone flux was found to be significantly different from zero and the confidence interval of the campaign mean flux was -0.44 to $-0.67 \mu\text{mol m}^{-2} \text{ d}^{-1}$. The mean flux reported here is within the uncertainties of direct flux measurements of acetone over the Atlantic, who report an mean flux of -0.2 (propagated uncertainty 2.5) $\mu\text{mol m}^{-2} \text{ d}^{-1}$ (Yang et al., 2014b). The global budget of acetone suggests that the that the Southern Ocean is a weak sink for acetone (Fischer et al., 2012), in agreement with our measurements.

If the recommended solubility of Burkholder et al. (2015) is used in our calculations, the mean acetone seawater concentration, saturation and flux become 8.0 nmol dm^{-3} (37 % increase), 88 % (unchanged) and $-0.59 \mu\text{mol m}^{-2} \text{ d}^{-1}$ (unchanged). The saturation and flux remain effectively unchanged, again because the mean concentration and solubility change by the same factor.

3.5 Acetaldehyde

510 The time series of acetaldehyde ambient air and seawater concentrations as well as the corresponding fluxes and saturations are presented in Figure 8.

The cruise mean seawater concentration of acetaldehyde was 2.6 nmol dm^{-3} , while the median concentration was 2.5 nmol dm^{-3} , suggesting a normal distribution in concentrations. The seawater concentrations measured here were generally lower than 6 nmol dm^{-3} , which compares well to other
515 open ocean measurements (Beale et al., 2013; Kameyama et al., 2010; Schlundt et al., 2017; Williams et al., 2004; Yang et al., 2014b; Zhu and Kieber, 2018), but is lower than measurements near the coast in the English Channel (Beale et al., 2015) and off the West Coast of Florida (Mopper and Stahovec, 1986). No seawater concentrations of acetaldehyde were reported for the first four days of the
520 SFCE compared to the other VOCs. No significant correlations between seawater acetaldehyde concentrations with $f\text{CO}_2$ or with chlorophyll a were observed, possibly due to rapid oxidation of acetaldehyde in seawater (Dixon et al., 2013) that prevents the build up of significant concentrations.

Mean ambient air mixing ratios of acetaldehyde were low at 0.049 ppbv and showed limited variability. Our measurement compares well with the previous atmospheric measurements of Legrand et al. (2012),
525 who observed an average of 0.08 ppbv acetaldehyde in ambient air off of the Antarctic continent. Our measurement is also consistent with the interhemispheric gradient in acetaldehyde concentrations, where lower ambient air mixing ratios of acetaldehyde are generally observed in the Southern Hemisphere (Galbally et al., 2007; Guérette et al., 2019; Yang et al., 2014b). We did not observe any correlation in the ambient air mixing ratios 1) among all the VOCs, and 2) between atmospheric VOCs
530 and atmospheric CO_2 . This is in contrast to observations by Yang et al. (2014b), who have found that methanol, acetone and acetaldehyde ambient air concentrations correlated between each other and with CO_2 . These earlier air measurements were taken along a transatlantic cruise and were likely more impacted by continental emissions (Yang et al., 2014b). Acetaldehyde showed clear diurnal variability in both seawater and ambient air, which will be discussed in more detail in Section 4.

535 The mean ($\pm 1\sigma$) saturation of acetaldehyde was 88 (± 50) %, which is within the range of previously reported acetaldehyde saturations (Schlundt et al., 2017; Yang et al., 2014b). The mean flux of

acetaldehyde was $-0.28 \mu\text{mol m}^{-2} \text{d}^{-1}$ and thus weakly into the Southern Ocean this time of the year. Using a *t*-test, we calculated that the mean acetaldehyde net flux was significantly different from zero with a confidence interval of the mean of -0.51 to $-0.25 \mu\text{mol m}^{-2} \text{d}^{-1}$. Our measurement is within the
540 uncertainties of direct flux measurements across the Atlantic of 0.6 (propagated uncertainty 2.5) $\mu\text{mol m}^{-2} \text{d}^{-1}$ (Yang et al., 2014b), but is less than the estimated flux over South China and Sulu Sea at $-10.11 \mu\text{mol m}^{-2} \text{d}^{-1}$ (Schlundt et al., 2017), probably due to the higher ambient air mixing ratios at those locations. The fluxes from this cruise are similar in magnitude to the modelled acetaldehyde fluxes in the Southern Ocean by Wang et al. (2019), who predict that the Southern Ocean is near equilibrium
545 with respect to acetaldehyde.

4. Diurnal variability in VOCs

Here we analyse our data for possible diurnal variability and look for light-driven sources and sinks for these compounds. Dixon et al. (2013) estimated that photochemical production accounts for up to 100 % and 68 % of the gross production rates of acetone and acetaldehyde respectively in seawater.
550 Halsey et al. (2017) suggested a strong light-dependent biological source for acetaldehyde and a weaker source of acetone. It might therefore be expected that these VOCs would display diurnal changes in their seawater concentrations. Zhou and Mopper (1997) and Mopper and Stahovec (1986) reported diurnal variability in seawater acetaldehyde off the West Coast of Florida, with the highest concentrations after solar zenith. Similarly, Takeda et al. (2014) observed diurnal variability in
555 acetaldehyde concentrations in an enclosed coastal area. However, Beale et al. (2013) and Yang et al. (2014b) found no significant difference in seawater acetone and acetaldehyde concentrations between samples collected at predawn and solar noon during crossings of the open ocean of the Atlantic. In the case of isoprene, diurnal variability in seawater concentrations has not been observed previously (Booge et al., 2018; Hackenberg et al., 2017; Moore and Wang, 2006; Tran et al., 2013) despite modelling
560 studies suggesting its existence (Gantt et al., 2009).

This dataset in the Atlantic sector of the Southern Ocean shows diurnal variability in acetaldehyde, and to a lesser degree in acetone and isoprene. To illustrate this, we have taken two different approaches. First, measurements of acetaldehyde, acetone and isoprene were put into 24

hourly bins corresponding to the local solar time (indicated as “h”) and then averaged. Second, the
565 measurements were initially normalised by the respective daily mean concentrations and then bin-
averaged. This second approach reduces the impact of spikes and short-term variability on the overall
bin average, as reflected by the generally lower relative standard deviations. These results are shown in
Figure 9.

Each hourly mean shown in Figure 9 is based on between a minimum of 8 (h13–15) and a maximum of
570 25 (h4) hourly measurements. A table with the normalised bin-averages of these VOCs (i.e. the second
approach above) can be found in the supplementary material (Table S2). Daytime was defined as h6–18
for this analysis, which corresponds on average to the twelve hours of sunlight. Hourly mean daytime
acetaldehyde seawater concentration was 2.9 nmol dm^{-3} , which is 26% higher than the mean nighttime
concentration of 2.3 nmol dm^{-3} ($t=-3.7$, $P=0.002$). Acetaldehyde air mixing ratios were also found to be
575 significantly different between daytime (avg: 0.061 ppbv) and nighttime (avg: 0.040 ppbv, $t=-3.7$,
 $P=0.001$), a change of 53%.

Significantly different seawater acetone concentrations were also observed during daytime (avg:
6.3 nmol dm^{-3}) compared to nighttime (avg: 5.8 nmol dm^{-3} , $t=-3.8$, $P=0.001$), which amounts to 9%
difference. Acetone air mixing ratios varied between on average 0.076 ppbv at night and 0.086 ppbv
580 during the day, again a small (13%) but significant difference ($t=-3.5$, $P=0.003$). Daytime seawater
isoprene concentrations (avg: $0.0143 \text{ nmol dm}^{-3}$) were significantly higher than nighttime
concentrations ($0.0133 \text{ nmol dm}^{-3}$, $t=-3.3$, $P=0.004$) by 8%. Daytime isoprene air mixing ratios (avg:
0.056 ppbv) were significantly higher than nighttime isoprene air mixing ratios (avg: 0.050 ppbv, $t=-$
2.6, $P=0.020$) by 12%. The diurnal cycle becomes more obvious in the overall bin-average in our data
585 thanks to the large number of hourly underway samples, which reduces random noise and averages out
other sources of variability. Interestingly, the amplitude of the daily cycle of these gases was not found
to be significantly correlated to the light intensity. This may suggest that light intensity alone is not
driving the diurnal variability of these compounds. For example, De Bruyn et al (2011) have found that
the origin of dissolved organic matter strongly influences photochemical production yields. The
590 phytoplankton community producing these VOCs directly was also likely variable.

Over the southern Indian Ocean, previous investigators have found diel changes in ambient air acetaldehyde, acetone and isoprene mixing ratios of up to a factor of 4, 10–15 % and up to a factor of 2 respectively with maxima when solar intensity was highest (Colomb et al., 2009). The remoteness of the Southern Ocean and the paucity of other atmospheric sources probably made it easier to detect diurnal
595 variability in the ambient air mixing ratios here.

5. Conclusion

This paper presents underway seawater and ambient air measurements of simultaneously measured DMS, isoprene, methanol, acetone and acetaldehyde. The measurements were taken in the Atlantic sector of the Southern Ocean along a 60° S transect during the transition from late austral summer to
600 early autumn. Our mean DMS concentration was within the range of the most recent global climatology of DMS (Lana et al., 2011). Isoprene concentrations were generally between 0.01 and 0.02 nmol dm⁻³. To the best of our knowledge, this represents the first set of published seawater concentrations and fluxes for methanol, acetone and acetaldehyde in the Southern Ocean. Our High resolution measurements showed a large range in seawater methanol concentration, while acetone and
605 acetaldehyde seawater concentrations showed limited variability and compare well to previous open ocean measurements in temperate waters. The atmospheric concentrations of methanol, acetone and acetaldehyde were very low and consistent with previous measurements at similar latitudes, likely due to the remoteness of the sampling location and little influence from terrestrial emissions.

The high frequency measurements and frequent alternation between measuring ambient air and
610 seawater allowed us to compute the fluxes and saturations for all of these compounds at a high temporal/spatial resolution. This improves the accuracy in the estimated flux by better capturing the fine scale variability in the flux direction/magnitude. DMS flux to the atmosphere varied by more than an order of magnitude, with the largest emission associated with a phytoplankton bloom. The Southern Ocean is strongly and consistently supersaturated in isoprene, implying a continuous source of isoprene
615 to the marine atmosphere from the surface ocean, probably year round. Methanol was transferred mostly from the atmosphere to the ocean during this cruise, giving a campaign mean flux of -2.3 μmol m⁻² d⁻¹. However, episodes of high methanol seawater concentrations were observed within a

phytoplankton bloom, which led to somewhat unexpected occasions of methanol outgassing from the ocean. Due to the high solubility of methanol and the fact that outgassing was observed only in very productive areas, we hypothesise that the Southern Ocean is on average a net sink of methanol year
620 round. Acetone and acetaldehyde were both absorbed and emitted by the ocean depending on location. This sector of the Southern Ocean was calculated to be a very weak sink of acetone and acetaldehyde during this period, with a mean flux of $-0.55 \mu\text{mol m}^{-2} \text{d}^{-1}$ and $-0.24 \mu\text{mol m}^{-2} \text{d}^{-1}$ respectively. Given that these measurements were made in the summer/autumn, when there was still reasonable light and
625 biological activity, it seems unlikely for the Southern Ocean to be a net source of acetone and acetaldehyde to the atmosphere when annually averaged.

Simultaneous measurement of multiple compounds allowed possible common sources and sinks to be identified. For example, seawater methanol and isoprene concentrations were found to positively correlate, possibly due to similar biological sources for these two gases. Isoprene seawater
630 concentrations were found to negatively correlate with $f\text{CO}_2$ and with chlorophyll a, supporting a biological origin for isoprene. Seawater acetone and methanol concentrations were found to correlate negatively with $f\text{CO}_2$, possibly pointing towards biological sources in seawater. These correlations are perhaps more obvious in the Southern Ocean due to the remoteness and solely marine influence. We suggest that $f\text{CO}_2$ may be one of the key factors in predicting seawater isoprene, methanol and acetone
635 in the Southern Ocean. Acetaldehyde concentrations did not clearly correlate with the other gases, possibly due to its strong photochemical production and very rapid oxidation by bacteria (Dixon et al., 2013) which prevented significant accumulations.

This dataset contains observational evidence for statistically significant diurnal variability in seawater and ambient air concentrations of acetaldehyde, and to a lesser degree also of acetone and isoprene.
640 Such diurnal changes in these VOC seawater concentrations in the open ocean have not been observed before. The large number of hourly measurements and remoteness of the sampling location from terrestrial and anthropogenic influences made it possible to resolve such subtle diurnal cycles in the marine environment.

The observations presented here represent a unique dataset that can be used in models to elucidate more
645 accurately not only the role of the ocean in the cycling of these VOCs, but also the impact of these

VOCs on the atmosphere. In particular, elevated concentrations of seawater DMS, isoprene, methanol, and acetone were observed in Southern Ocean phytoplankton blooms. We expect the atmosphere downwind of these hot spots of emission to be the most impacted in terms of atmospheric oxidative capacity, aerosols and clouds.

650

Appendix A: Suggested solubility for acetone and methanol in seawater

As mentioned in the main text, the invasion and evasion experiments provide two independent solubility (H) estimates at environmentally relevant concentrations. In theory the H values determined from invasion and from evasion experiments should agree with each other. For invasion, a certified reference gas standard (Apel-Riemer Environmental Inc., Miami, Florida, USA; nominal volume mixing ratio of 500 ppbv for acetaldehyde, methanol, acetone, isoprene, DMS, benzene, toluene) diluted with zero air (controlled by mass flow controllers) was used. For evasion, liquid standards produced by serial dilution of the pure compounds were used. Most conventional methods for determining solubility of these gases rely on serial dilution of pure solvent in water (Benkelberg et al., 1995; Clayton McAuliffe, 1971; Snider and Dawson, 1985; Zhou and Mopper, 1990), which is challenging to do reliably at environmental concentrations because of the volatility and ease of contamination of these VOCs (Wohl et al., 2019). The three evasion calibrations for methanol, acetone and acetaldehyde carried out during this cruise displayed a smaller variability than observed previously (Wohl et al., 2019), possibly due to the lower number of calibrations. The invasion calibrations during this cruise were carried out using higher input mixing ratios than previously (up to 250 ppbv), resulting in improved signal to noise ratio (Wohl et al., 2019). Invasion and evasion calibrations for acetone were found to agree with each other only by assuming that the solubility of acetone is 30 % lower than that recommended by Burkholder et al. (2015) (Figure A1 and Figure A2). The response in Fig. A2 is not linear due to the addition of a large volume of standard gas to the carrier gas, which changed the total gas flow and thus the purging factor (Wohl et al., 2019). This was accounted for in the computation of the expected equilibrator headspace mixing ratio. The solubility recommended from our works is however within the range of other

660

665

670

previously published solubility values and previous laboratory calibrations of the SFCE. It is also within the uncertainty estimate by Burkholder et al. (2015).

675 For methanol, we used the solubility from the evasion calibration. No invasion calibration for methanol was obtained due to the extremely high solubility of methanol. However, the agreement between acetone evasion and invasion calibrations provided us with confidence in the serial dilution procedure, as methanol and acetone are dissolved together during the first step of the serial dilution. Therefore, we also suggest a 40 % lower solubility for methanol than what is recommended by Burkholder et al. (2015) (Fig. A3). This is as well within the uncertainty of the solubility value estimated by Burkholder
680 et al. (2015).

In Wohl et al. (Wohl et al., 2019), the recommended solubility of these compounds from the literature (Burkholder et al., 2015) was used to calculate seawater concentrations in order to be consistent with previous observations. Our novel method of matching up the calibrations of these gases using evasion and invasion should lead to a more accurate determination of their solubility in seawater at
685 environmentally relevant concentrations. Note that the choice of solubility affects the dissolved gas concentrations, but not the saturations or fluxes in our data. This is because C_w and $C_a \cdot H$ change by the same proportion as a function of solubility.

The invasion and evasion calibrations for acetaldehyde do not agree with each other (Fig. A4 and Fig. A5). The evasion results were found to agree with the recommended solubility (Burkholder et al., 2015)
690 but the invasion results do not. This could be due to acetaldehyde hydration reactions, which affect the air-water exchange of acetaldehyde (Bell et al., 1956; Kurz and Coburn, 1967; Yang et al., 2014b). In fact, around 60 % of the acetaldehyde in solution is thought to be present as a hydrate (Bell et al., 1956), but only the unhydrated form is thought to be available for air-sea exchange (Yang et al., 2014b). Bell et al. (1956) suggest a half-life of the hydration reaction of acetaldehyde between 6 and 60 seconds.
695 Given that the residence time in the segmented flow tube is 40 seconds (Wohl et al., 2019) it is possible that there is not enough time for complete hydration of acetaldehyde within the SFCE. The solubility of acetaldehyde recommended by Burkholder et al. (2015) is an apparent solubility that represents the sum of acetaldehyde and acetaldehyde hydrate. In our study, the evasion calibration is considered a more realistic analogue of the actual seawater measurement since liquid standards represent the sum of

700 acetaldehyde hydrate and pure acetaldehyde. Therefore the solubility recommended by Burkholder et al. (2015), which agrees with our evasion calibrations, was used to compute seawater acetaldehyde concentrations, fluxes and saturations.

Data availability

Data presented here will be available at BODC (<https://www.bodc.ac.uk/>).

705 **Author contribution**

CW carried out the measurements and calibrations on board under the supervision of MY. PN, AJ, DC and WS provided input to the setup on board. PN and CW wrote the Collaborative Antarctic Support Scheme proposal to secure a berth on ANDREXII. IB measured underway seawater CO₂ using the setup installed with VK. CW prepared the manuscript with contributions from all co-authors.

710 **Competing Interest**

The authors declare that they have no conflict of interest.

Acknowledgements

Thanks a lot, to the users of the PTR-MS at Plymouth Marine Laboratory who shared their time on the instrument and made it possible to take the PTR-MS on this deployment. Thanks a lot to all those
715 involved in the transport of the PTR-MS who played a key role in making these measurements possible. Many thanks to the crew and the chief scientist, Andrew Meijers (British Antarctic Survey), for accommodating this work. Thanks also to Richard Sims (University of Calgary) and Thomas Bell (Plymouth Marine Laboratory) for providing the seawater temperature sensors.

Financial support

720 This work was supported by the Natural Environment Research Council through the EnvEast Doctoral Training Partnership [grant number NE/L002582/1]. A berth on the ANDREXII cruise was secured through the British Antarctic Survey Collaborative Antarctic Science Scheme. The ANDREXII cruise was financed through the ORCHESTRA project (NE/N018095/1).

1080

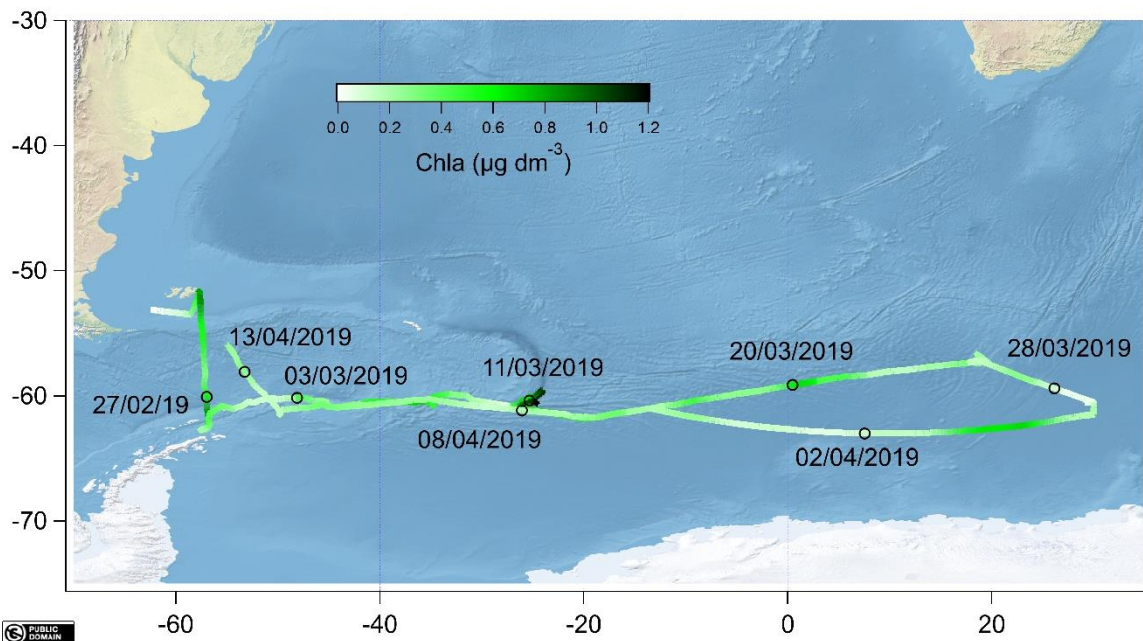

Figure 1: Map showing the cruise track coloured by underway chlorophyll a (chla) with sampling dates indicated as black circles. All the data was created from public domain GIS data found on the Natural Earth web site (<http://www.naturalearthdata.com>). It was read into Igor using the IgorGIS XOP beta.

Figure 2: (a) Sea surface temperature and surface salinity, (b) chlorophyll a concentrations measured underway and from the sensor installed on the CTD at 5 m depth as well as underway fCO_2 and (c) photosynthetic active radiation along with the longitude measured along the cruise track.

1085

Figure 3: Underway seawater concentrations binned in 24 hourly bins for the week before and 2 weeks after protecting the SFCE equilibrator from sunlight on 04/03/19.

1090

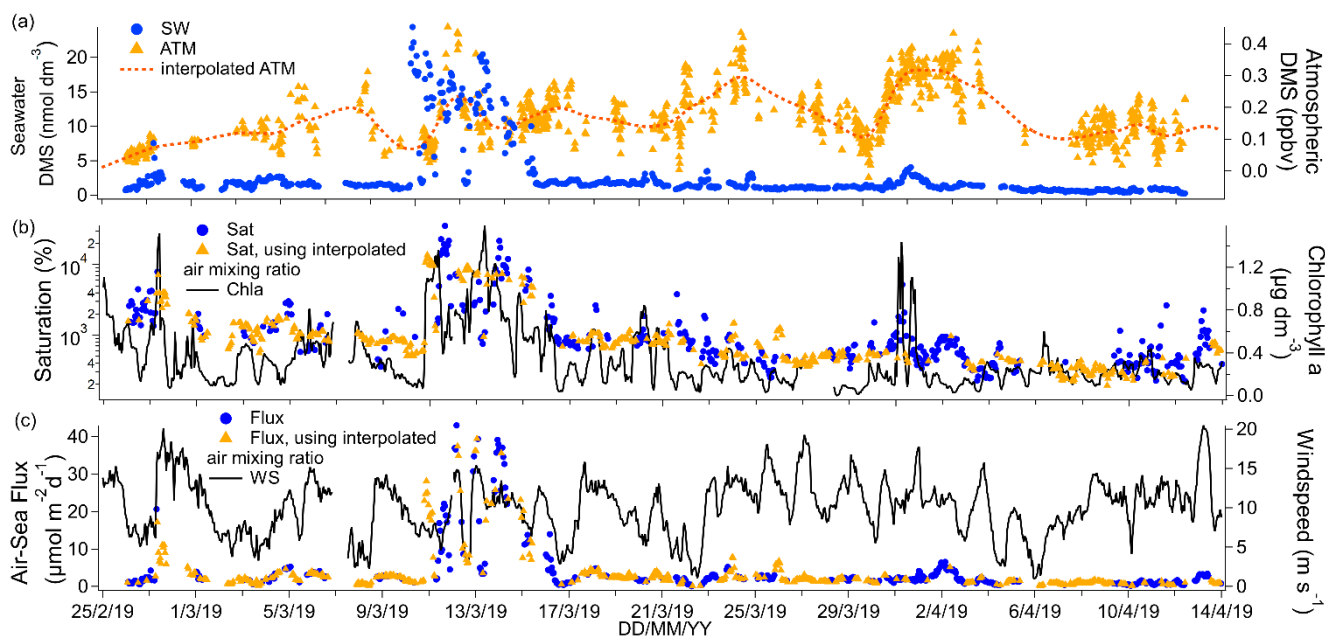

Figure 4: (a) Time series of DMS seawater (SW) concentrations as well as measured and interpolated marine boundary layer air mixing ratios (ATM and interpolated ATM). (b) Time series of DMS saturations determined using the measured air mixing ratio and interpolated air mixing ratio and time series of chlorophyll a. (c) Time series of air–sea DMS fluxes calculated using the measured air mixing ratio and interpolated air mixing ratio and time series of wind speed.

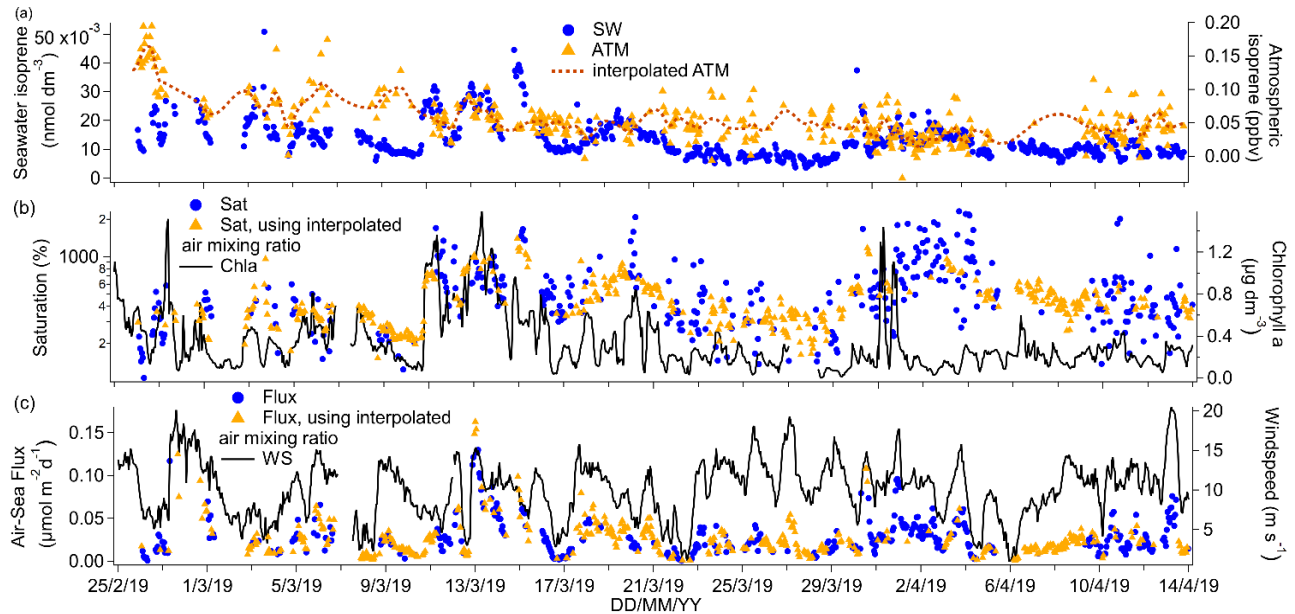

Figure 5: (a) Time series of isoprene seawater (SW) concentrations as well as measured and interpolated marine boundary layer air mixing ratios (ATM and interpolated ATM). (b) Time series of isoprene saturations determined using the measured air mixing ratio and interpolated air mixing ratio and times series of chlorophyll a. (c) Time series of air–sea isoprene fluxes calculated using the measured air mixing ratio and interpolated air mixing ratio and time series of wind speed.

Figure 6: (a) Time series of methanol seawater (SW) concentrations as well as measured and interpolated marine boundary layer air mixing ratios (ATM and interpolated ATM). (b) Time series of methanol saturations determined using the measured air mixing ratio and interpolated air mixing ratio and time series of chlorophyll a. (c) Time series of air–sea methanol fluxes calculated using the measured air mixing ratio and interpolated air mixing ratio and time series of wind speed.

1100

1105

1110

Figure 7: (a) Time series of acetone seawater (SW) concentrations as well as measured and interpolated marine boundary layer air mixing ratios (ATM and interpolated ATM). (b) Time series of acetone saturations determined using the measured air mixing ratio and interpolated air mixing ratio and time series of chlorophyll a. (c) Time series of air–sea acetone fluxes calculated using the measured air mixing ratio and interpolated air mixing ratio and time series of wind speed.

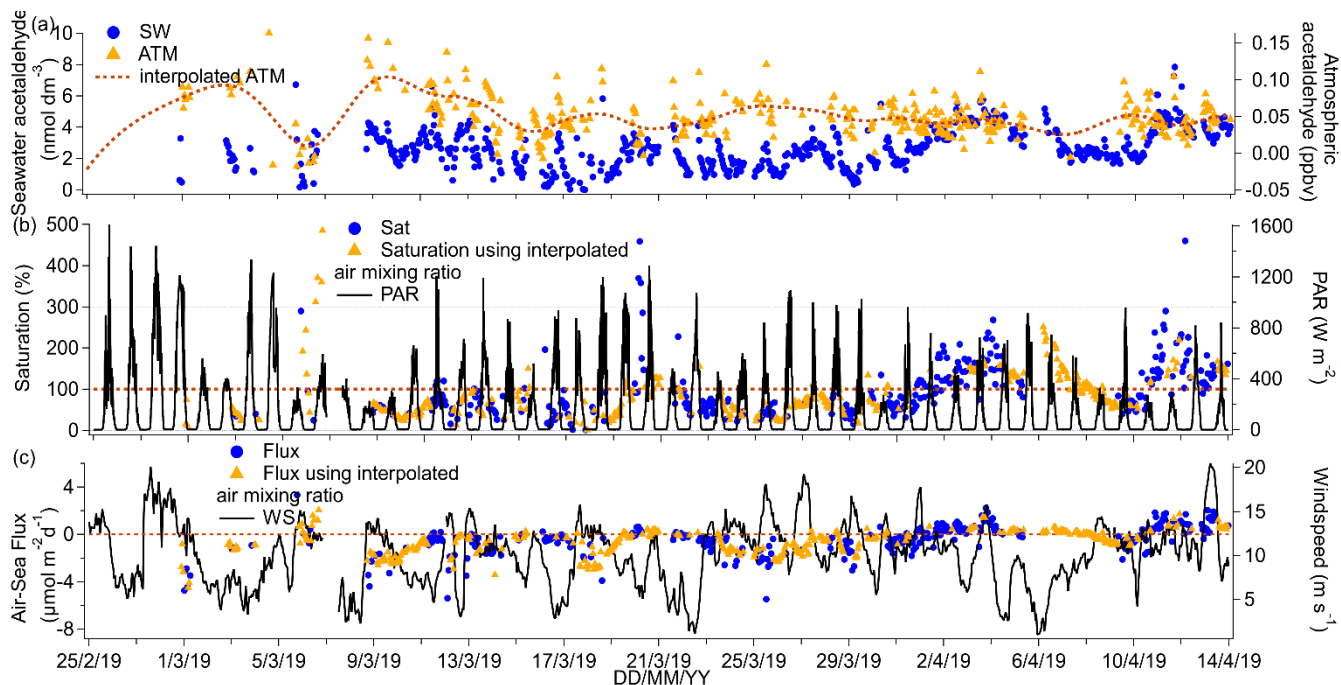

Figure 8: (a) Time series of acetaldehyde seawater (SW) concentrations as well as measured and interpolated marine boundary layer air mixing ratios (ATM and interpolated ATM). (b) Time series of acetaldehyde saturations determined using the measured air mixing ratio and interpolated air mixing ratio and time series of chlorophyll a. (c) Time series of air–sea acetaldehyde fluxes calculated using the measured air mixing ratio and interpolated air mixing ratio and time series of wind speed.

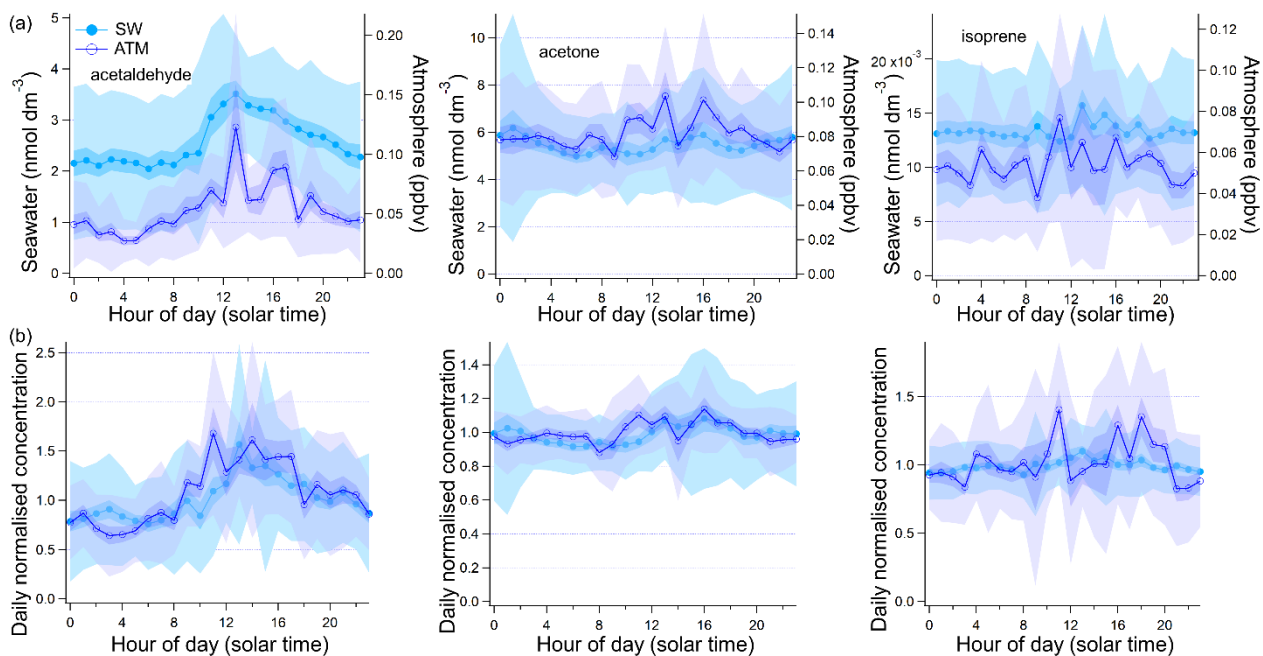

Figure 9: Diurnal changes in seawater and atmospheric concentrations expressed (a) as true 24 hourly averaged concentration and (b) daily normalised concentration where the hourly measured concentration is divided by the average of the 24 hours that this measurement is part of. Light shaded areas show the standard deviation of each hourly bin and the darker shaded areas show the standard error of each hourly bin.

Figure A1: Evasion calibrations using liquid standards of acetone produced by serial dilution in different types of water (SW= seawater, MilliQ= MilliQ water). Bottom SW refers to seawater collected from well below the mixed layer, near the bottom of the water column; Surface SW refers to seawater collected from the underway seawater inlet. The average measured slope in the 4 seawater calibrations is 0.0388 ± 0.004 (std. dev) ppbv/(nmol dm⁻³) (10 % rel.std. dev.) and the average slope in the 4 MilliQ calibrations is 0.0398 ± 0.002 (std. dev) ppbv/(nmol dm⁻³) (5 % rel. std. dev.). Expected mixing ratios are slightly different between MilliQ and SW due to the lower seawater temperature.

1130

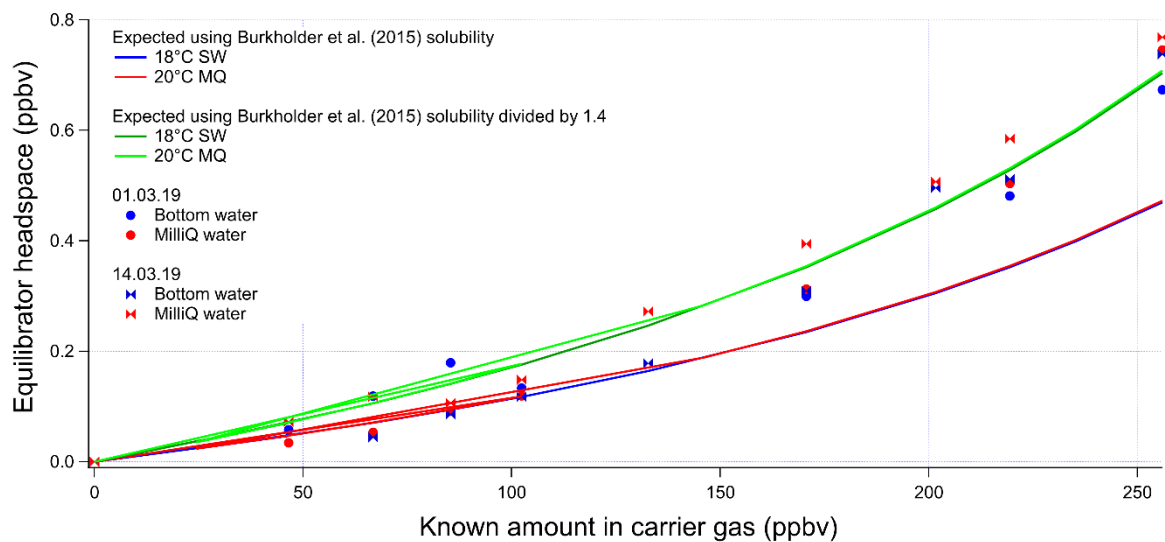

Figure A2: Invasion calibrations for acetone carried out during the deployment and using different types of water (SW= seawater, MQ= MilliQ water). Bottom SW refers to seawater collected from well below the mixed layer. The non-linear response is due to the changing gas flow as more standard gas is added to the zero air carrier gas, which alters the purging factor.

Figure A3: Evaporation calibrations using liquid standards of methanol produced by serial dilution in different types of water (SW= seawater, MQ= MilliQ water). Bottom SW refers to seawater collected from well below the mixed layer, Surface SW refers to seawater collected from the underway seawater inlet. The average measured slope in the 4 seawater calibrations is 0.00624 ± 0.00121 ppbv/(nmol dm⁻³) (rel. std. dev. 19 %) and the average slope in the 4 MilliQ calibrations is 0.00678 ± 0.000254 ppbv/(nmol dm⁻³) (rel. std. dev. 3 %). Expected mixing ratios are slightly different between MQ and SW due to the lower seawater temperature.

1135

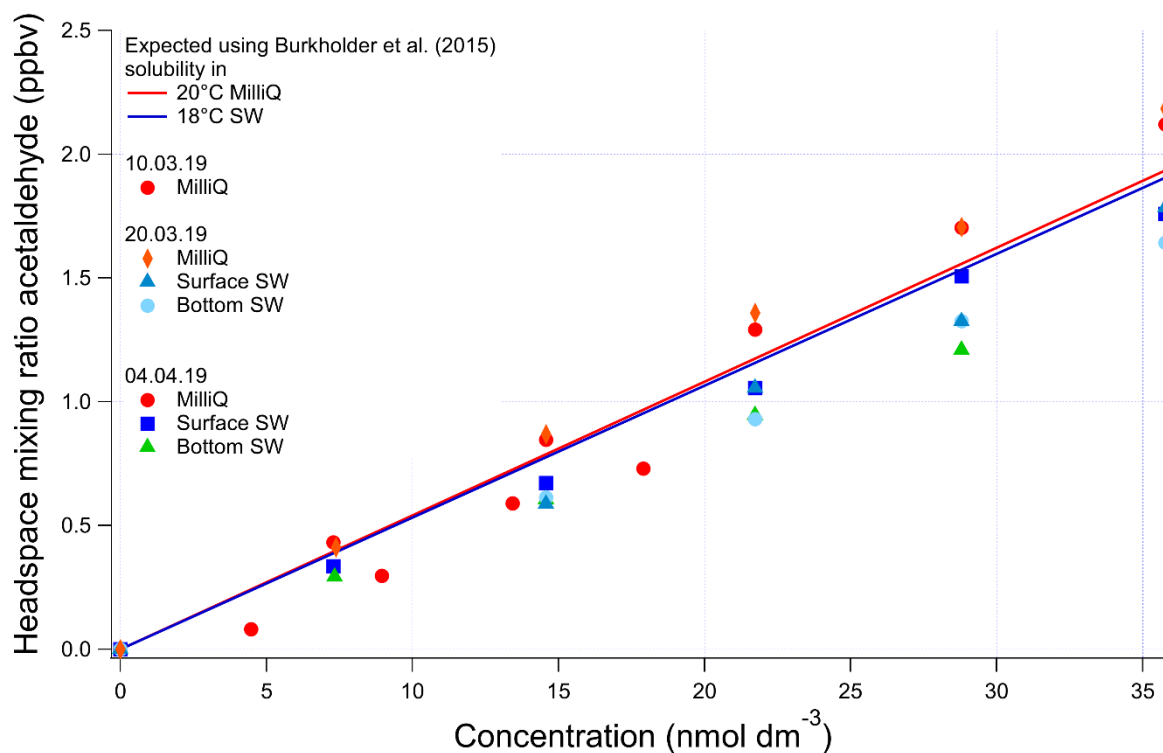

Figure A4: Evasion calibrations using liquid standards of acetaldehyde produced by serial dilution in different types of water (SW= seawater, MilliQ= MilliQ water). Bottom SW refers to seawater collected from well below the mixed layer,, Surface SW refers to seawater collected from the ship's underway seawater inlet. The average measured slope in the 4 seawater calibrations is 0.0473 ± 0.00313 ppbv/(nmol dm^{-3}) (rel. std. dev. 6 %) and the average slope in the 4 MilliQ calibrations is 0.0548 ± 0.00767 ppbv/(nmol dm^{-3}) (rel. std. dev. 14 %). Expected mixing ratios are slightly different between MilliQ and SW due to the lower seawater temperature.

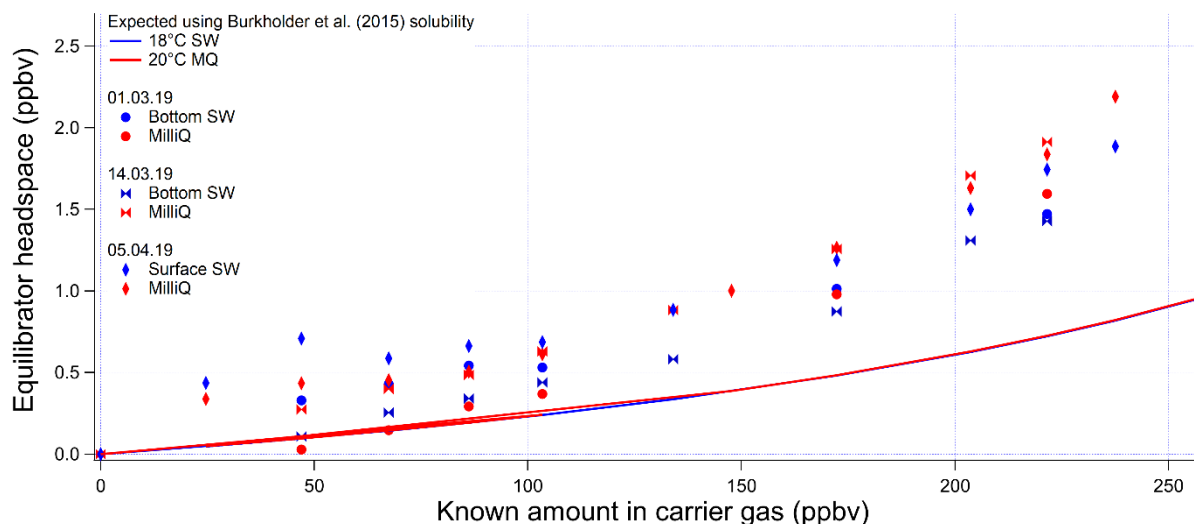

Figure A5: Invasion calibrations for acetaldehyde carried out during the deployment and using different types of water (SW= seawater, MQ= MilliQ water). Bottom SW refers to seawater collected from well below the mixed layer, Surface SW refers to seawater collected from the ship's underway seawater inlet. The non-linear response is due to the changing gas flow as more standard gas is added to the zero air carrier gas, which alters the purging factor.

1140

1145 Table 1: Seawater blank used for each compound during this deployment is listed. Hourly measurement noise (1σ) and limit of detection (3σ) of seawater and ambient air measurement are listed and were determined as described in the text.

compound	suggested seawater blank	seawater measurement noise (nmol dm^{-3})	seawater limit of detection (nmol dm^{-3})	ambient air measurement noise (ppbv)	ambient air limit of detection (ppbv)
DMS	Pt-catalyst	0.006	0.018	0.012	0.036
isoprene	Pt-catalyst	0.0003	0.0009	0.008	0.024

acetone	seawater	5.5	2.5	4.3	5.1	5.9
	ambient air	0.081	0.031	0.057	0.076	0.097
acetaldehyde	seawater	2.6	2.7	1.7	2.5	3.5
	ambient air	0.049	0.04	0.025	0.04	0.061

Table 3: Campaign mean saturation (%) and flux (μmol m⁻² d⁻¹). These calculations only include hourly fluxes and saturations for which ambient air and seawater measurements were both available. Saturations below 100 % indicate undersaturation and a negative flux indicates flux from the air into the ocean. Campaign median and quantiles are also indicated as well as the standard deviation (s dev).
