21 acidification; Ocean warming

22 **Abstract**

23 In Low Nutrient Low Chlorophyll areas, such as the Mediterranean Sea, atmospheric
24 fluxes represent a considerable external source of nutrients likely supporting primary production
25 especially during periods of stratification. These areas are expected to expand in the future due to
26 lower nutrient supply from sub-surface waters caused by climate-driven enhanced stratification,
27 likely further increasing the role of atmospheric deposition as a source of new nutrients to
28 surface waters. Whether plankton communities will react differently to dust deposition in a
29 warmer and acidified environment remains, however, an open question. The potential impact of
30 dust deposition both in present and future climate conditions was investigated in three
31 perturbation experiments in the open Mediterranean Sea. Climate reactors (300 L) were filled
32 with surface water collected in the Tyrrhenian Sea, Ionian Sea and in the Algerian basin during a
33 cruise conducted in the frame of the PEACETIME project in May/June 2017. The experiments
34 comprised two unmodified control tanks, two tanks enriched with a Saharan dust analog and two
35 tanks enriched with the dust analog and maintained under warmer (+3 °C) and acidified (-0.3 pH
36 unit) conditions. Samples for the analysis of an extensive number of biogeochemical parameters
37 and processes were taken over the duration (3-4 d) of the experiments. Dust addition led to a
38 rapid release of nitrate and phosphate, however, nitrate inputs were much higher than phosphate.
39 Our results showed that the impacts of Saharan dust deposition in three different basins of the
40 open Northwestern Mediterranean Sea are at least as strong as those observed previously, all
41 performed in coastal waters. The effects of dust deposition on biological stocks were different
42 for the three investigated stations and could not be attributed to differences in their degree of
43 oligotrophy but rather to the initial metabolic state of the community. Ocean acidification and
44 warming did not drastically modify the composition of the autotrophic assemblage with all
45 groups positively impacted by warming and acidification. Although autotrophic biomass was
46 more positively impacted than heterotrophic biomass under future environmental conditions, a

47 stronger impact of warming and acidification on mineralization processes suggests a decreased
48 capacity of Mediterranean surface plankton communities to sequester atmospheric CO₂
49 following the deposition of atmospheric particles.

50 1. Introduction

51 Atmospheric deposition is well recognized as a significant source of micro- and macro-
52 nutrients for surface waters of the global ocean (Duce et al., 1991; Jickells et al., 2005; Moore et
53 al., 2013). The potential modulation of the biological carbon pump efficiency and the associated
54 export of carbon by atmospheric deposition events are still poorly understood and quantified
55 (Law et al., 2013). This is especially true for Low Nutrient Low Chlorophyll (LNLC) areas
56 where atmospheric fluxes can play a considerable role in nutrient cycling and that represent 60%
57 of the global ocean surface area (Longhurst et al., 1995) as well as 50% of global carbon export
58 (Emerson et al., 1997). These regions are characterized by low availability of macronutrients (N,
59 P) and/or micronutrients (trace metals, in particular Fe) that can severely limit or co-limit
60 phytoplankton growth during large periods of year.

61 The Mediterranean Sea is a typical example of these LNLC regions with overall surface
62 chlorophyll *a* concentrations below 0.2 $\mu\text{g L}^{-1}$ all year round, except in the Ligurian Sea where
63 relatively large blooms can be observed in late winter-early spring (Mayot et al., 2016). Recent
64 estimates indicate that the atmospheric input of nutrients in the Mediterranean Sea is within the
65 same order of magnitude as riverine inputs (Powley et al., 2017), and, therefore, a considerable
66 external source of nutrients (Richon et al., 2018). Atmospheric deposition originates both from
67 natural (mainly Saharan dust) and anthropogenic sources (e.g. Bergametti et al., 1989; Desboeufs
68 et al., 2018). Dust deposition, mostly in the form of pulsed inputs, is mainly associated with wet
69 deposition (Loÿe-Pilot and Martin, 1996). Ternon et al. (2010) reported an average annual dust
70 flux over four years of 11.4 $\text{g m}^{-2} \text{yr}^{-1}$ (average during the period 2003–2007) at the DYFAMED
71 station in the Northwestern Mediterranean Sea. In this region, the most important events reported
72 in the 2010 decade amounted to $\sim 22 \text{ g m}^{-2}$ (Bonnet and Guieu, 2006; Guieu et al., 2010b).

73 Atmospheric deposition provides new nutrients to surface waters (Guieu et al., 2010b;
74 Kouvarakis et al., 2001; Markaki et al., 2003; Ridame and Guieu, 2002), Fe (Bonnet and Guieu,
75 2006) and other trace metals(Desboeufs et al., 2018; Guieu et al., 2010b; Theodosi et al., 2010),
76 representing significant inputs likely supporting primary production in particular during the
77 period of stratification in spring/summer (Bonnet et al., 2005; Ridame and Guieu, 2002),
78 although no direct correlation between dust and ocean color could be found from long series of
79 satellite observation in that part of the Mediterranean basin (Guieu and Ridame, 2020).

80 Previous micro- and mesocosm experiments have shown that wet dust deposition events
81 in the Northwestern Mediterranean Sea (the dominant deposition mode in that basin) are a
82 stronger source of bioavailable nutrients compared to dry deposition. Wet deposition provides
83 both new N and P while dry deposition supplies primarily P and, in contrast to wet deposition,
84 does not stimulate the growth of the autotrophic community with the exception of diazotrophs
85 (Ridame et al., 2013), resulting in no significant increase in chlorophyll *a* concentrations and
86 primary production (Guieu et al., 2014a). In addition, wet dust deposition also modifies the
87 bacterial assemblage leading to even stronger enhancements of heterotrophic production and
88 respiration rates (Pulido-Villena et al., 2014). The carbon budget established from four artificial
89 seeding experiments during the DUNE project (Guieu et al., 2014a) showed that by stimulating
90 predominantly heterotrophic bacteria, atmospheric wet dust deposition can enhance the
91 heterotrophic behavior of these oligotrophic waters. This has the potential to reduce organic
92 carbon export to deep waters during the winter mixing period (Pulido-Villena et al., 2008) and
93 ultimately limit net atmospheric CO₂ drawdown.

94 Conversely, the deposition of lithogenic particle from Saharan dust can promote
95 aggregation and ballast organic matter leading to enhanced vertical export of organic carbon
96 (Bressac et al., 2014; Desboeufs et al., 2014; Louis et al., 2017a; Ternon et al., 2010). These
97 lithogenic processes can represent a major part of the carbon export following a dust deposition

98 event (up to 50% during the DUNE experiment; Bressac et al., 2014). Recently, Louis et al.
99 (2017a) showed that Saharan dust deposition can also trigger the abiotic formation of transparent
100 exopolymeric particles (TEP), leading to the formation of organic-mineral aggregates, a
101 formation process that is highly dependent on the quality and quantity of TEP-precursors initially
102 present in seawater.

103 In response to ocean warming and increased stratification, nutrient cycling in the open
104 ocean is being and will continue to be perturbed in the next decades with regionally variable
105 impacts (IPCC, 2019). Overall, LNLC areas are expected to expand in the future (Irwin and
106 Oliver, 2009; Polovina et al., 2008) due to thermal stratification related reduction of nutrients
107 supply from sub-surface waters (Behrenfeld et al., 2006). As such, the role of atmospheric
108 deposition as a source of new nutrients to surface waters might increase. Ongoing warming and
109 acidification (IPCC, 2019) are also evidenced in the Mediterranean Sea (e.g. Kapsenberg et al.,
110 2017; The Mermex group, 2011). Whether or not plankton communities will respond differently
111 to dust deposition in future conditions is still largely unknown. Although dependent on resource
112 availability, it is well known that remineralisation by bacteria is subject to positive temperature
113 control (López-Urrutia and Morán, 2007). Given that warming has no effect on primary
114 productivity when plankton communities are nutrient limited (Marañón et al., 2018), temperature
115 increase will most likely further push the balance towards net heterotrophy in oligotrophic areas.

116 In contrast, an *in situ* mesocosm experiment conducted during the summer stratification
117 period in the Northwestern Mediterranean Sea showed that the plankton community was not
118 sensitive to ocean acidification under strong nutrient limitation (Maugendre et al., 2017, and
119 references therein). A batch experiment (Maugendre et al., 2015) showed that, under nutrient-
120 depleted conditions in late winter, ocean acidification has a very limited impact on the plankton
121 community and that small species (e.g. Cyanobacteria) might benefit from warming with a
122 potential decrease of the export and energy transfer to higher trophic levels. In contrast, in more

123 eutrophic (coastal) conditions, Sala et al. (2016) showed that ocean acidification had a positive
124 effect on phytoplankton, especially on the pico and nano size classes. Similarly, Neale et al.
125 (2014) showed that ocean acidification could lead to enhanced chlorophyll levels under low light
126 conditions with an opposite effect under high irradiance, in coastal communities of the Alboran
127 Sea.

128 To date and to the best of our knowledge, there have been no attempts to evaluate the
129 behavior of plankton communities influenced by atmospheric deposition in the context of future
130 temperature and pH changes. Such experiments were, therefore, conducted in the framework of
131 the PEACETIME project (ProcEss studies at the Air-sEa Interface after dust deposition in the
132 MEditerranean sea; <http://peacetime-project.org/>) on board the R/V “Pourquoi Pas?” during
133 May/June 2017. The project aimed at studying and parameterizing the chain of processes
134 occurring in the Mediterranean Sea driven by atmospheric deposition events including under on-
135 going environmental changes (Guieu et al., 2020). During the cruise, three perturbation
136 experiments were conducted in climate reactors (300 L tanks) filled with surface water collected
137 in the Tyrrhenian Sea (TYR), Ionian Sea (ION) and Algerian basin (FAST; Fig. 1). Six tanks
138 were used to follow simultaneously and with a high temporal resolution, the evolution of
139 biological activity and stocks, nutrients, dissolved organic matter as well as particles dynamics
140 and export, following a dust deposition event simulated, both under present environmental
141 conditions and under a realistic climate change scenario for 2100 (ca. +3 °C and -0.3 pH units;
142 IPCC, 2013). In this manuscript, we will present the general setup of the experiments and the
143 evolution of nutrient and plankton communities (heterotrophic and autotrophic prokaryotes,
144 photosynthetic eukaryotes as well as micro- and meso-zooplankton). Other manuscripts, related
145 to these experiments in this special issue, focus on plankton metabolism (primary production,
146 heterotrophic prokaryote production) and carbon export (Gazeau et al., 2021), microbial food

147 web (Dinasquet et al., 2021), nitrogen fixation (Céline Ridame, unpublished results) and on the
148 release of insoluble elements (Fe, Al, REE, Th, Pa) from dust (Roy-Barman et al., 2021).

149 **2. Material and Methods**

150 **2.1. General setup**

151 Six experimental tanks (300 L; Fig. 2), in which the irradiance spectrum and intensity can
152 be finely controlled and future ocean acidification and warming conditions can be fully
153 reproduced, were installed in a temperature-controlled container. The tanks are made of trace-
154 metal free high-density polyethylene (HDPE) with a height of 1.09 m, a diameter of 0.68 m, a
155 surface area of 0.36 m² and a volume of 0.28 m³. Each tank was equipped with a lid containing
156 six rows of LEDs (Alpheus©). Each of these rows were composed of blue, green, cyan and white
157 units in order to mimic the natural sun spectrum. At the conical base of each tank, a polyethylene
158 (PE) bottle was screwed onto a polyvinyl chloride (PVC) valve that remained open during the
159 duration of the whole experiment to collect the sinking material. Photosynthetically active
160 radiation (PAR; 400-700 nm) and temperature were continuously monitored in each tank using
161 respectively QSL-2100 Scalar PAR Irradiance Sensors (Biospherical Instruments©) and pt1000
162 temperature sensors (Metrohm©) connected to a D230 datalogger (Consort©).

163 Prior to the start of the experiments, tanks were cleaned following the protocol described
164 by Bressac and Guieu (2013). Three sets of experiments were carried out at the long duration
165 stations ION, TYR and FAST, respectively, and comprised two unmodified control tanks (C1
166 and C2), two tanks enriched with Saharan dust (D1 and D2) and two tanks enriched with Saharan
167 dust and maintained under warmer (+3 °C) and acidified (-0.3 pH unit) conditions (G1 and G2).
168 The atmosphere above tanks C1, C2, D1 and D2 was flushed with ambient air (ca. 400 ppm, 6 L
169 min⁻¹) and tanks G1 and G2 were flushed with air enriched with CO₂ (ca. 1000 ppm, 6 L min⁻¹)
170 in order to prevent CO₂ degassing from the acidified tanks. CO₂ partial pressure (*p*CO₂) in both
171 ambient air and CO₂-enriched air was monitored using two gas analysers (LI-820, LICOR©).

172 The CO₂ concentration in the CO₂-enriched air was manually controlled through small injections
173 of pure CO₂ (Air Liquide©) using a mass flow controller. Mixing in the tanks was ensured by a
174 rotative PVC blade (9 rpm) mimicking natural turbulence

175 The tanks were filled by means of a peristaltic pump (Verder© VF40 with EPDM hose,
176 flow of 1200 L h⁻¹) collecting seawater below the base of the boat at around 5 m, used to supply
177 continuously surface seawater to a series of instruments during the entire campaign. In order to
178 homogeneously fill the tanks, the flow was divided into six HDPE pipes distributing the water
179 simultaneously into the different tanks. The procedure was started at the end of the day at all
180 three stations and took approximately 2 h (including rinsing and initial sampling. While filling
181 the tanks, samples were taken for the measurements of selected parameters (sampling time = t-
182 12h before dust seeding; Table 1). After filling the tanks, seawater in tanks G1 and G2 was
183 slowly warmed overnight using 500 W heaters, controlled by temperature-regulation units
184 (COREMA©), to reach an offset of +3 °C. ¹³C-bicarbonate was added to all tanks at 4:00 am
185 (local time; Gazeau et al., 2021) and at 4:30 am G1 and G2 were acidified by addition of CO₂-
186 saturated filtered (0.2 µm) seawater (~1.5 L in 300 L; collected when filling the tanks at each
187 station) to reach a pH offset of -0.3. Further samples for a range of parameters were taken
188 (sampling time = t₀, Table 1), followed by dust seeding carried out between 7:00 and 9:00 (local
189 time) in tanks D1, D2, G1 and G2. The same dust analog flux was applied as in the DUNE 2009
190 experiments described in Desboeufs et al. (2014). The dust was derived from the <20 µm
191 fraction of soil collected in Southern Tunisia (a major source for material transported and
192 deposited in the Northwestern Mediterranean) consisting of quartz (40%), calcite (30%) and clay
193 (25%) with most particles (99%) smaller than 0.1 µm (Desboeufs et al., 2014). The collected
194 material underwent an artificial chemical aging process by addition of nitric and sulfuric acid
195 (HNO₃ and H₂SO₄, respectively) to mimic cloud processes during atmospheric transport of
196 aerosol with anthropogenic acid gases (Guieu et al., 2010a, and references therein). To mimic a

197 realistic wet flux event for the Mediterranean of 10 g m^{-2} , 3.6 g of this analog dust were quickly
198 diluted in 2 L ultrahigh-purity water (UHP water; $18.2 \text{ M}\Omega \text{ cm}^{-1}$ resistivity), and sprayed at the
199 surface of the tanks using an all-plastic garden sprayer (duration = 30 min). The total N and P
200 mass in the dust were $1.36 \pm 0.09\%$ and $0.055 \pm 0.003\%$, respectively (see Desboeufs et al.,
201 2014, for a full description of dust chemical composition). Biogeochemical parameters and
202 processes measured during the experiments are listed in Table 1. The experiment lasted 3 days
203 (72 h) at stations TYR and ION and 4 days (96 h) at station FAST, as constrained by the time
204 available between stations. Seawater sampling was conducted 1 h (t1h), 6 h (t6h), 12 h (t12h), 24
205 h (t24h), 48 h (t48h) and 72 h (t72h) after dust additions in all three experiments with an
206 additional sample after 96 h (t96h) at FAST). Acid-washed silicone tubes were used for
207 transferring the water collected by gravity from the tanks to the different vials or containers.

208 **2.2. Analytical methods**

209 **2.2.1. Carbonate chemistry**

210 Seawater samples for pH measurements were stored in 300 mL glass bottles with a glass
211 stopper, pending analysis on board (within 2 h). Samples were transferred to 30 mL quartz cells
212 and absorbances at 434, 578 and 730 nm were measured at $25 \text{ }^\circ\text{C}$ on an Cary60 UV-
213 Spectrophotometer (Agilent©) before and after addition of 50 μL of purified meta-cresol purple
214 provided by Robert H. Byrne (University of South Florida, USA) following the method
215 described by Dickson et al. (2007). pH on the total scale (pH_T) was computed using the formula
216 and constants of Liu et al. (2011). The accuracy of pH measurements (0.007 pH units) was
217 estimated using a TRIS buffer solution (salinity 35, provided by Andrew Dickson, Scripps
218 university, USA).

219 Seawater samples (500 mL) for total alkalinity (A_T) measurements were filtered on GF/F
220 membranes and analyzed onboard within one day. A_T was determined potentiometrically using a
221 Metrohm© titrator (Titrand 888) and a glass electrode (Metrohm©, ecotrode plus) calibrated
222 using first NBS buffers (pH 4.0 and pH 7.0, to check that the slope was Nernstian) and then
223 using a TRIS buffer solution (salinity 35, provided by Andrew Dickson, Scripps university,
224 USA). Triplicate titrations were performed on 50 mL sub-samples at 25 °C and A_T was calculated
225 as described by Dickson et al. (2007). Titrations of standard seawater provided by Andrew
226 Dickson (Scripps university, USA; batch 151) yielded A_T values within 5 $\mu\text{mol kg}^{-1}$ of the
227 nominal value and a standard deviation of 1.5 $\mu\text{mol kg}^{-1}$ ($n = 40$).

228 All parameters of the carbonate chemistry were determined from pH_T , A_T , temperature,
229 salinity, as well as phosphate and silicate concentrations using the R package seacarb.
230 Propagation of errors on computed parameters was performed using the new function “error” of
231 this package, encompassing errors associated with the estimation of A_T , pH_T as well as errors on
232 the dissociation constants (Orr et al., 2018).

233 **2.2.2. Nutrients**

234 Seawater samples for dissolved nutrients were collected in polyethylene bottles after
235 passage through sterile membrane filter capsules (Sartobran” 300; 0.2 μm) connected to the
236 sampling tubes of each tank (Sartobran© 300; 0.2 μm), and analyzed directly on board. Nitrate +
237 nitrite (NO_x) and silicate ($\text{Si}(\text{OH})_4$) measurements were conducted using a segmented flow
238 analyzer (AAIII HR Seal Analytical©) according to Aminot and K  rouel (2007) with a detection
239 limit of 0.05 $\mu\text{mol L}^{-1}$ for NO_x and 0.08 $\mu\text{mol L}^{-1}$ for $\text{Si}(\text{OH})_4$. In addition, at t-12h, NO_x was
240 also analysed by spectrometry at 540 nm, with a 1 m Liquid Waveguide Capillary Cell (LWCC),
241 with a detection limit of $\sim 10 \text{ nmol L}^{-1}$ and the reproducibility was $\sim 6\%$. Ammonium
242 concentrations in samples from t-12h were also measured on board using a Fluorimeter TD-700

243 (Turner Designs©) according to Holmes et al. (1999). This later method is based on the reaction
244 of ammonia with orthophthaldialdehyde and sulfite and has a detection limit of 0.01 $\mu\text{mol L}^{-1}$.
245 Dissolved inorganic phosphorus (DIP) concentrations were quantified using the Liquid
246 Waveguide Capillary Cell (LWCC) method according to Pulido-Villena et al. (2010). The
247 LWCC was 2.5 m long and the detection limit was 1 nmol L^{-1} .

248 **2.2.3. Pigments**

249 For pigment analysis, 2.5 L seawater from the tanks were filtered onto GF/F filters,
250 immediately frozen in liquid nitrogen and stored at -80 °C pending analysis at the SAPIGH
251 analytical platform at the Institut de la Mer de Villefranche (IMEV, France). Filters were
252 sonicated at -20 °C in 3 mL methanol (100%) containing an internal standard (vitamin E acetate,
253 Sigma©) and clarified one hour later by vacuum filtration through GF/F filters. The extracts
254 were rapidly analyzed (within 24 h) on a complete Agilent© Technologies 1200 series HPLC
255 system. The pigments were separated and quantified as described in Ras et al. (2008).

256 **2.2.4. Flow cytometry**

257 For flow cytometry, samples (4.5 mL) were fixed with glutaraldehyde grade I (1% final
258 concentration), and incubated for 30 min at 4 °C, quick-frozen in liquid nitrogen and stored at -
259 80 °C until analysis. Samples were thawed at room temperature. Counts were performed on a
260 FACSCanto II flow cytometer (Becton Dickinson©) equipped with 3 air-cooled lasers: blue
261 (argon 488 nm), red (633 nm) and violet (407 nm). Following Marie et al. (2010),
262 *Synechococcus* spp. was discriminated by its strong orange fluorescence (585 ± 21 nm), and
263 autotrophic pico- and nano-eukaryotes were discriminated by their scatter signals of red
264 fluorescence (> 670 nm). For the enumeration of heterotrophic prokaryotes, cells were stained
265 with SYBR Green I (Invitrogen – Molecular Probes) at 0.025% (vol / vol) final concentration for

266 15 min at room temperature in the dark. Stained prokaryotic cells were discriminated and
267 enumerated according to their right-angle light scatter (SSC) and green fluorescence at 530/30
268 nm. Heterotrophic prokaryotes were distinguished from autotrophic prokaryotes based on the
269 green vs. red fluorescent signal. The same procedure was used for the enumeration of HNF, after
270 staining with 0.05% (v/v) final SYBR Green I concentration for 15-30 min at room temperature
271 in the dark (Christaki et al., 2011). Fluorescent beads (1.002 μm ; Polysciences Europe©) were
272 systematically added to all samples as internal standard. Cell concentrations were determined
273 based on counts and flow rate, estimated with TruCount beads (BD biosciences©). Biomass of
274 each group were estimated based on conversion equations and/or factors found in the literature
275 (see section 2.3.2).

276 **2.2.5. Micro-phytoplankton and -heterotrophs**

277 At t-12h, 500 mL samples were collected in glass vials and immediately preserved with
278 5% final concentration acidic Lugol's solution. Back at the Laboratoire d'Océanographie de
279 Villefranche (LOV, France), 100 mL aliquots were transferred to sedimentation chambers
280 (Utermohl) and counted under an inverted microscope at x 200 to x 400 magnification.

281 **2.2.6. Mesozooplankton**

282 At the end of each experiment, the sedimentation bottles were removed, fixed with
283 formaldehyde 4% (see Gazeau et al., 2021) and stored for analysis back in the home laboratory.
284 Subsequently, the valve at the base of each tank, that allowed retrieval of the sedimentation
285 bottles without disturbance, was opened, the remaining water inside the tanks (165-180 L at
286 TYR; 172.5 L at ION and 150 L at FAST) as filtered through a 100 μm mesh size PVC sieve.
287 The organisms retained were gently removed using a washing bottle filled with filtered seawater
288 (0.2 μm), and transferred directly in a 250 mL bottle and fixed with 4% final concentration

289 formaldehyde. These samples were processed using a ZooSCAN (Hydroptic©; Gorsky et al.,
290 2010) at the PIQv-platform of EMBRC-France. Organisms were identified and counted using
291 automatic classification with a reference dataset in EcoTaxa (<https://ecotaxa.obs-vlfr.fr/>, last
292 access: 17/04/2020), followed by manual validation.

293 **2.3. Data analyses**

294 **2.3.1. Nutrient inputs from dust**

295 The maximum percentage of dust-born dissolved N and P was estimated based on initial
296 N and P composition of the dust analog (see section 2.1; Desboeufs et al., 2014) and maximal
297 concentrations observed in tanks D and G at t1h and t6h after seeding, as follows:

$$298 \quad \%_{dissolution} = \frac{CONC_{max} - CONC_{init}}{CONC_{dust}} \cdot 100 \quad (1)$$

299 where $CONC_{init}$ is the concentration of the corresponding nutrient in each tank before seeding
300 (t_0), $CONC_{max}$ corresponds to the concentration of the corresponding nutrient in each tank when
301 nutrient concentration was at a maximum within the first 6 h after seeding, and $CONC_{dust}$ is the
302 maximum potential concentration, assuming a 100% dissolution from dust analog (based on dust
303 content; Desboeufs et al. 2014; section 2.1).

304 **2.3.2. Autotrophic and heterotrophic biomass**

305 Given that samples for micro-phytoplankton counts were taken only at t-12h, as a first
306 approximation, autotrophic biomass was estimated as the sum of *Synechococcus*, autotrophic
307 pico-eukaryotes and nano-eukaryotes biomass (based on flow cytometry). Conversion of
308 abundances to carbon units was carried out assuming 250 fg C cell⁻¹ for *Synechococcus* (Kana
309 and Glibert, 1987). The biovolume to carbon content relationship of Verity et al. (1992) was used

310 for autotrophic pico- and nano-eukaryotes assuming a spherical shape and a diameter of 2 and 6
311 μm , respectively. Heterotrophic biomass was computed as the sum of heterotrophic prokaryotes
312 (HP) biomass and heterotrophic nanoflagellates (HNF) biomass. Conversion to carbon biomass
313 were done assuming $20 \text{ fg C cell}^{-1}$ (Lee and Fuhrman, 1987) for heterotrophic prokaryotes and
314 $220 \text{ fg C } \mu\text{m}^{-3}$ (Børsheim and Bratbak, 1987) with a spherical shape and $3 \mu\text{m}$ diameter for
315 heterotrophic nanoflagellates. The ratio of autotrophic and heterotrophic biomass during the
316 experiments was used to evaluate the trophic status of the investigated communities and its
317 evolution. Finally, a proxy for micro-phytoplankton biomass (B_{micro}) was estimated following
318 Vidussi et al. (2001), as the sum of Fucoxanthin and Peridinin.

319 **3. Results**

320 **3.1. Initial conditions**

321 Initial conditions at the three sampling stations while filling the tanks (t-12h before
322 seeding) are shown in Table 2. pH_T, total alkalinity concentrations increased from west to east
323 (Table 2). NO_x and DIP concentrations followed different patterns with highest NO_x values at
324 station FAST and highest DIP concentrations at station TYR. Consequently, the lowest NO_x:DIP
325 ratio was measured at TYR (0.8), compared to ION and FAST (2.8 and 4.6, respectively).
326 Ammonium concentrations ranged between 0.045 μmol L⁻¹ to below detection limit at FAST.
327 Silicate concentrations were similar at stations TYR and ION (~ 1 μmol L⁻¹) and higher than at
328 station FAST (0.64 μmol L⁻¹).

329 Very low chlorophyll *a* concentrations were measured at the three stations (0.063 - 0.072
330 μg L⁻¹). The proportion of the different major pigments (Fig. 3) indicates that phytoplankton
331 communities were similar with a dominance of Prymnesiophytes (i.e. 19'-
332 hexanoyloxyfucoxanthin; Ras et al., 2008) followed by Cyanobacteria (i.e. Zeaxanthin; Ras et
333 al., 2008) at stations TYR and ION. In contrast, at station FAST, the plankton community was
334 clearly dominated by photosynthetic prokaryotes (i.e. Zeaxanthin and Divinyl-chlorophyll *a* as
335 proxies for Cyanobacteria and Prochlorophytes, respectively; Ras et al., 2008). At all three
336 stations, the proportion of pigments representative of larger species (i.e. Fucoxanthin and
337 Peridinin; diatoms and dinoflagellates respectively; Ras et al., 2008) were very small (< 5%).

338 At all stations, autotrophic nanoplankton contributed most to total biomass. Autotrophic
339 and heterotrophic biomass and abundances were highest at station FAST, followed by ION for
340 the autotrophs and TYR for heterotrophs (Table 2). Differences in standing stocks between
341 stations were more pronounced for the heterotrophs. As a consequence, the ratio between

342 autotrophic biomass and heterotrophic biomass ranged from ~0.6 at TYR and FAST to 1.3 at
343 ION.

344 **3.2. Conditions of irradiance, temperature and pH during** 345 **the experiments**

346 Irradiance levels during the experiments are shown in Fig. 4. Decrease in water
347 transparency after dust addition was observed at all three stations with the lowest impact at
348 station FAST where irradiance levels decreased by only $60 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$ after dust
349 addition, reaching similar levels as observed for tanks D and G. At station TYR, a more
350 pronounced decrease was observed in acidified and warmed tanks (G1 and G2) with a decrease
351 of daily average maximum irradiance of ~ 60 and $\sim 160 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$ compared to dust-
352 amended tanks D and controls, respectively. Temperature control (Fig. 4) was not optimal
353 showing deviations between replicates of treatment G of up to $1.0 \text{ }^\circ\text{C}$ (station FAST).
354 Temperature in controls and D tanks displayed a daily cycle, increasing during the day and
355 decreasing at night (Fig. 4). The differences between the warmed treatment (G) and the other
356 tanks were $+3$, $+3.2$ and $+3.6 \text{ }^\circ\text{C}$ at TYR, ION and FAST, respectively.

357 Addition of CO_2 -saturated filtered seawater led to a decrease in pH_T from 8.05 ± 0.004
358 (average \pm SD of C1, C2, D1 and D2 at t_0) to 7.74 (average between G1 and G2) at station TYR,
359 from 8.07 ± 0.002 to 7.78 at station ION and from 8.05 ± 0.001 to 7.72 at station FAST (Fig. 5).
360 pH_T levels remained more or less constant in the control and D tanks during all three
361 experiments with no clear impact of dust addition. In G tanks, pH levels gradually increased
362 during the experiments with larger variability between duplicates. These increases remained
363 moderate thanks to the flushing of CO_2 -enriched air above the tanks ($p\text{CO}_2$ of 1017 ± 11 , $983 \pm$
364 96 , 1023 ± 25 ppm at TYR, ION and FAST, respectively; data not shown). Partial pressure of
365 CO_2 in ambient air was 410 ppm, similar for the three stations. In all experiments, the addition of

366 ^{13}C -bicarbonate led to an increase of total alkalinity between 6 and 11 $\mu\text{mol kg}^{-1}$ at t_0 . Dust
367 addition, right after t_0 in tanks D and G, led to a A_T decrease between 8 and 16 $\mu\text{mol kg}^{-1}$ at 24h
368 with no apparent effects of warming and acidification. Overall, no large changes in A_T were
369 observed during the experiments (Fig. 5).

370 **3.3. Changes in nutrient concentrations**

371 Dust addition led to a rapid increase in NO_x ($\sim 11 \mu\text{mol L}^{-1}$ as observed during the first 6
372 h; Fig. 6; Table 3) at all three stations with no differences between treatments D and G. The
373 corresponding percent dissolution of N from dust ranged between 94 and 99%. In contrast,
374 maximum DIP release was much smaller, ranging between 20 and 37 nmol L^{-1} , with slightly
375 higher values at FAST (31-37 nmol L^{-1}) as compared to the other stations. Percent dissolution for
376 DIP corresponded to 9.2 to 17.3% of total phosphorus contained in dust. As a consequence,
377 NO_x :DIP ratios increased from initial values below 5 to above 300, within 6 h after dust seeding,
378 in tanks D and G (Fig. 6).

379 After the rapid increase of N and P, both nutrients decreased with time. While nutrient
380 variability was small in control tanks (NO_x and DIP variations below 20 and 3 nmol L^{-1} ,
381 respectively), large decrease in both elements occurred in dust amended tanks (D and G; Table 4).
382 Similar linear decrease in NO_x were observed throughout the experiments at stations TYR and
383 ION with no visible differences between tanks D and G. In contrast, at station FAST, a more
384 pronounced decrease in NO_x was observed in dust-amended (D and G) tanks, as well as in
385 warmed and acidified tanks relative to the D treatment. Nevertheless, at all stations, NO_x
386 concentrations in D and G treatments remained far above ambient levels throughout the
387 experiments ($> 9 \mu\text{mol L}^{-1}$). Abrupt decreases in DIP were observed during the three experiments
388 after the initial increase. At station TYR, after 24 h, all DIP released from dust decreased to
389 initial levels in tanks G while it took two more days to reach initial levels in tanks D. In contrast,

390 at station ION, no clear difference in DIP dynamics was observed between treatments D and G,
391 with concentrations that decreased rapidly during the first 24 h but remained above initial levels
392 until the end of the experiment. At station FAST, similarly to station TYR, DIP decreased
393 rapidly from t12h in treatment G, reaching levels close to initial conditions at the end of the
394 experiment. DIP decrease was much lower in treatment D (Table 4) with concentrations
395 maintained far above ambient levels throughout the experiment. As a consequence of the
396 differences between NO_x and DIP dynamics as well as differences among stations, NO_x:DIP
397 ratio increased, with clear differences between stations (Fig. 6), and remained much higher than
398 in the controls.

399 At all stations, silicate concentrations were higher in dust amended tanks relative to the
400 controls. At TYR, while concentrations remained stable in control tanks, they increased linearly
401 with time in the other tanks (D and G) with no apparent effect of the imposed increase in
402 temperature and decrease in pH (i.e. tanks G). Difference in Si(OH)₄ concentrations between
403 dust amended treatments (D and G) and controls was ~0.1 μmol L⁻¹ at the end of the experiment.
404 At station ION, after an initial decrease in concentrations between t-12h and t0, concentrations
405 increased in all tanks until the end of the experiment with higher values in dust amended tanks
406 (D and G) than in controls and no difference between D and G treatments. In contrast, at FAST,
407 concentrations increased from t-12h to t48h (with higher values in dust amended tanks) and
408 decreased onward until the end of the experiment. At the end of the experiment (t96h), Si(OH)₄
409 concentrations were higher in the G treatment than in the D treatment which were similar to the
410 controls.

411 **3.4. Changes in biological stocks**

412 Temporal dynamics in biological parameters showed very different patterns at each
413 station. At TYR, total chlorophyll *a* concentrations did not change in the dust amended D tanks

414 (Fig. 7) and even led to slightly decreased values 24 h after dust addition (e.g. -35 to -38% in D1
415 and D2, respectively as compared to controls; Table 5). No clear effects of dust addition (tanks D
416 vs. C) were detectable for all groups based on pigment analyses (Fig. 7). Results obtained based
417 on flow cytometry counts (Fig. 8) were coherent with these observations and showed stronger
418 decreases in cell abundances for < 20 μm autotrophic groups in tanks D1 and D2 (-77 to -80%).
419 In contrast, the abundance of heterotrophic prokaryotes (HP) increased rapidly after dust addition
420 both under ambient (+53-68%) and future (+68%) environmental conditions, with no clear
421 difference among treatments. In warmed and acidified tanks (G), strong discrepancies between
422 the duplicates were observed for pigments and autotrophic cell abundances: tank G1 showed
423 moderate increases for all variables with the exception of autotrophic pico-eukaryotes, while in
424 G2 all variables responded strongly to dust addition with maximum relative changes of > 300%,
425 with the exception of autotrophic nano-eukaryotes. While HNF abundances responded positively
426 to the treatments in D1, D2 and G2, abundances increased sharply in tank G1 towards the end of
427 the experiment.

428 At ION, clear differences between treatments were observed for almost all pigments and
429 cell abundances (Fig. 7, Fig. 8). With the exception of autotrophic nano-eukaryotes and HNF, all
430 variables (pigments and cell abundances) increased as a response to both dust addition and
431 warmed/acidified conditions (Table 5). The maximum relative changes as compared to controls
432 observed for total chlorophyll *a* were 109-183% and 399-426% in tanks D and G, respectively.
433 The highest stimulation by dust addition was observed for *Synechococcus* with +317-390% and
434 +805-1425% increase in abundances in D and G tanks respectively (Table 5). Autotrophic nano-
435 eukaryotes and HNF abundances did not respond to dust addition under ambient conditions but
436 an increase in abundances occurred in treatment G. In contrast to observations at TYR,
437 temperature and pH affected heterotrophic prokaryotes in all dust-amended tanks at station ION
438 with a higher impact of dust addition under future environmental conditions.

439 At station FAST, all biological stocks increased strongly after dust addition (Fig. 7, Fig. 8
440 and Table 5). Total chlorophyll *a* increased following exponentially until the end of the
441 experiment with slightly lower values observed under ambient environmental conditions (+237-
442 318% in D tanks and ~ +400% in G tanks). Prymnesiophytes (i.e. 19'-hexanoyloxyfucoxanthin)
443 and diatoms (i.e. Fucoxanthin) appeared as the groups benefiting the most from dust addition
444 with no large impacts of warming/acidification while Pelagophytes (i.e. 19'-
445 butanoyloxyfucoxanthin) and green algae (i.e. Total Chlorophyll *b*) showed a stronger response
446 in treatment G. Finally, although Cyanobacteria (i.e. Zeaxanthin) responded faster to dust
447 addition under future environmental conditions (tanks G), this effect attenuated towards the end
448 of the experiment. In contrast to estimates based on pigments, increases in cell abundances did
449 not generally last until the end of the experiments. While abundances of autotrophic pico-
450 eukaryotes increased until t96h in treatment D, abundances sharply declined between t72h and
451 t96h for this group in treatment G. The same trend was observed for *Synechococcus*, although
452 discrepancies between duplicates in treatment D at t96h did not allow drawing conclusions on
453 the behavior of this group by the end of the experiment. Abundances of autotrophic nano-
454 eukaryotes declined sharply between t72h and t96h under present and future conditions. The
455 decline in HP abundances occurred earlier during the experiment with moderate maximum
456 relative differences as compared to controls at t48h. HP abundances declined very sharply
457 between t48h and t96h in treatment G, reaching control levels, while this decline was less sharp
458 under present environmental conditions. Finally, HNF dynamics during this experiment was hard
459 to interpret given the large increase in abundances in only one duplicate of treatment G (t24h)
460 followed by a gradual decline.

461 Abundances of meso-zooplankton at the end of the experiments showed relatively similar
462 values at stations TYR and ION while much higher levels were observed at station FAST (Fig.
463 9). As a consequence of large variability between duplicates at stations TYR and ION, no clear

464 effects of treatments were detected. At station FAST, although the sample size was too low to
465 statistically test for differences, higher total abundances of meso-zooplankton species were
466 observed in the dust-amended tanks with no differences between ambient and future conditions
467 of temperature and pH. However, differences in abundance were visible between these two
468 treatments for specific groups, with respectively higher abundance of Harosa and lower
469 abundance of Crustacea (other than copepods) and Mollusca in warmed and acidified tanks.

470 **4. Discussion**

471 **4.1. Initial conditions**

472 During this study, the mixed layer depth (MLD) was somewhat shallower at TYR (20 m)
473 than at ION and FAST (~ 10 and ~15 m, respectively) at the time of the sampling (Van
474 Wambeke et al., 2020a). Such shallow MLDs are characteristic of the stratified and oligotrophic
475 conditions encountered in the western Mediterranean basin in late spring/early summer
476 (D'Ortenzio et al., 2005). Although direct measurements of NO_x and DIP concentrations using
477 nanomolar techniques (as performed in our study) are scarce in the Mediterranean Sea, the low
478 levels measured during the cruise are in agreement with DIP values reported for the three basins
479 (Djaoudi et al., 2018) and with NO_x and DIP concentrations measured in coastal waters of
480 Corsica in late spring/early summer (Louis et al., 2017b; Pulido-Villena et al., 2014; Ridame et
481 al., 2014). NO_x:DIP molar ratios in surface waters were well below the Redfield ratio (16:1) and
482 are also consistent previous studies. The low NO_x:DIP ratios and nutrient concentrations suggest
483 that communities found at the three stations experienced N and P co-limitation at the start of the
484 experiments, as previously shown by Tanaka et al. (2011). Nutrient enrichment experiments
485 confirmed that, at the three sites, heterotrophic bacteria were mainly N-P co-limited (Van
486 Wambeke et al., 2020b). In contrast to N and P, dissolved Fe in surface seawater, ranged from
487 1.5 nmol L⁻¹ at TYR to 2.5 nmol L⁻¹ at ION (Roy-Barman et al., 2021) and were unlikely
488 limiting for biological activity as previously shown in the Mediterranean Sea under stratified
489 conditions (Bonnet et al., 2005; Ridame et al., 2014).

490 The low total chlorophyll *a* concentrations in surface waters were typical for the Western
491 and Central Mediterranean Sea in late spring/early summer, as estimated from remote sensing
492 (Bosc et al., 2004), and from *in situ* measurements (Manca et al., 2004). While large species (i.e.
493 diatoms, dinoflagellates) represented only ~10% of the total chlorophyll *a* biomass, the

494 composition of the smaller size phytoplankton communities differed substantially, with
495 autotrophic nano-eukaryotes dominating at stations TYR and ION and a larger contribution from
496 autotrophic pico-eukaryotes and Cyanobacteria at station FAST. Due to their low
497 competitiveness under nutrient limitation, the small contribution of large phytoplankton cells at
498 the start of the experiment is a fingerprint of LNLC areas in general, and of surface
499 Mediterranean waters in late spring and summer (Siokou-Frangou et al., 2010).

500 Biomass of both heterotrophic nanoflagellates and prokaryotes followed a west to east
501 gradient (FAST > TYR > ION), with high relative contribution by heterotrophs at stations TYR
502 and FAST (60% of biomass) while at ION autotrophs contributed 60% to plankton biomass.
503 Accordingly, net community production (NCP) rates (Gazeau et al., 2021) showed an initial
504 community close to metabolic balance (mean \pm SE: $-0.06 \pm 0.09 \mu\text{mol O}_2 \text{ L}^{-1} \text{ d}^{-1}$) at ION and
505 highest community respiration rates and consequently lowest NCP rates at station TYR (-1.9
506 $\mu\text{mol O}_2 \text{ L}^{-1} \text{ d}^{-1}$) suggesting that the autotrophic plankton community was not very active and
507 relied on regenerated nutrients, as shown by the high level of NH_4^+ at the start of the experiment
508 at TYR. In contrast, although slightly heterotrophic (Gazeau et al., 2021) and limited by the low
509 amount of nutrients, the community at FAST showed by the highest levels of ^{14}C production and
510 heterotrophic prokaryote production (Gazeau et al., 2021) as well as N_2 fixation (Céline Ridame,
511 unpublished results). Altogether, the heterotrophic signature of the three investigated stations,
512 although closer to metabolic balance at ION, reflected typical biogeochemical conditions in the
513 Mediterranean Sea during late spring to early summer (Regaudie-de-Gioux et al., 2009).

514 **4.2. Critical assessment of the experimental system and** 515 **methodology**

516 The experimental tanks used in this study have been successfully validated in previous
517 studies designed to investigate the inputs of macro- and micro-nutrients (e.g. NO_x , DIP, DFe)

518 and the export of organic matter, under close-to-abiotic conditions (natural seawater filtered onto
519 0.2 μm) following simulated wet dust events using the same analog as used in our study (Bressac
520 and Guieu, 2013; Louis et al., 2017a, 2018). Louis et al. (2017a, 2018) further investigated these
521 impacts under lowered pH conditions resulting in a rapid increase of pH levels in the acidified
522 filtered seawater due to CO_2 outgassing (from ~ 7.4 to ~ 7.7 in six days). In the present study, our
523 experimental system further allowed to control atmospheric $p\text{CO}_2$ in addition to light and
524 temperature (i.e. climate reactors). Thereby, this allowed to significantly reduce CO_2 outgassing
525 and maintain pH levels close to their targets. The regulation of atmospheric CO_2 was, however,
526 consistently more efficient in tank G2 compared to G1 (Fig. 5), resulting in a small discrepancy
527 in terms of pH (highest difference of 0.04 pH units between the two G tanks at FAST), possibly
528 due to a potential leak or a longer flushing time above tank G1. Nevertheless, as no systematic
529 differences in nutrient dynamics and biological response were observed between the two tanks,
530 these small differences in pH had no detectable effect on the obtained results.

531 The lids above tanks, equipped with LEDs in order to reproduce sunlight intensity and
532 spectrum, were used for the first time during these experiments. While simulated intensities were
533 close to estimates for the Northwestern Mediterranean Sea at 5 m depth in June ($\sim 1100 \mu\text{mol}$
534 $\text{photons m}^{-2} \text{s}^{-1}$; Bernard Gentili, personal communication, 2017) and fairly consistent between
535 duplicates under control and dust-amended conditions, largest differences were also observed
536 between tanks G1 and G2. These discrepancies could result from small differences in PAR
537 sensors calibration and/or of different turbidity related to the amount of particles remaining in the
538 tanks. As for pH, replication in terms of macronutrient dynamics and biological response
539 appeared satisfactory (except at station TYR; see below).

540 Continuous measurements in the tanks showed that temperature was not spatially
541 homogeneous, leading to significant differences among replicates. This was more pronounced
542 for warmed tanks (treatment G) with a maximum average difference over the experimental

543 period of 0.7 °C during the FAST experiment. As for pH and light, these discrepancies did not
544 systematically lead to observable differences in the investigated stocks and processes between
545 duplicates (except at TYR, see below).

546 The necessity to carry out the incubations in a clean container limited our possibility to
547 set up additional replicates for the three treatments. As described above, differences between
548 duplicates were, for the vast majority of studied variables and processes, lower than differences
549 between treatments and appear robust considering the difficulty to incubate plankton
550 communities for which slight differences in initial composition can translate into important
551 differences in dynamics (Eggers et al., 2014). Nevertheless, important discrepancies were
552 detected for autotrophic stocks (in particular *Synechococcus*) as well as HNF and processes
553 (Gazeau et al., 2021) for the warmed and acidified treatment (tanks G1 and G2) at station TYR.
554 The reasons behind these differences are most likely due to the grazing impact of heterotrophic
555 nano-flagellates on prokaryotic picoplankton (Sherr and Sherr, 1994) in tank G1 where HNF
556 abundance sharply increased during the experiment. Overall, while the methodology used in this
557 study allowed to successfully evaluate the impacts of dust addition under both present and future
558 environmental conditions at two out of three tested waters, the discrepancies at station TYR
559 prevent us from drawing any strong conclusion on the effect of dust addition on the dynamics of
560 the community under future environmental conditions at that station.

561 **4.3. Impact of dust addition under present environmental** 562 **conditions**

563 During all experiments, the observed increases in NO_x and DIP few hours after dust
564 addition under present environmental conditions were similar to the enrichment obtained during
565 the DUNE experiments at the surface of the mesocosms (~ 50 m³) after the simulation of a wet
566 dust deposition using the same dust analog and the same simulated flux (Pulido-Villena et al.,

567 2014; Ridame et al., 2014). The intensity of the simulated wet deposition event (i.e. 10 g m^{-2})
568 represents a high but realistic scenario, as several studies reported even higher short wet
569 deposition events in this area of the Mediterranean Sea (Bonnet and Guieu, 2006; Loÿe-Pilot and
570 Martin, 1996; TERNON et al., 2010). Furthermore, based on previous studies reporting the mixing
571 between dust and polluted air masses during the atmospheric transport of dust particles (e.g.
572 Falkovich et al., 2001; Putaud et al., 2004), we used an evapo-condensed dust analog that mimics
573 the processes taking place in the atmosphere prior to deposition, essentially the adsorption of
574 inorganic and organic soluble species (e.g. sulfate and nitrate; see Guieu et al., 2010a, for further
575 details). The imposed evapo-condensation processes are responsible for the large nitrate
576 releasing capacity of the dust particles used in our study. As a consequence, the addition of new
577 nutrients from dust in our study and during the P and R DUNE experiments were much higher,
578 especially for NO_x , than those observed by Pitta et al. (2017, and references therein) and Ridame
579 et al. (2014) following the simulation of a dry Saharan dust deposition event. This confirms that
580 wet dust deposition is a more efficient source of bioavailable nutrients than dry dust deposition.

581 Although NO_x and DIP increases after dust addition were similar in all experiments, the
582 subsequent dynamics of these elements and the impacts on plankton community composition and
583 functioning were drastically different. While NO_x levels decreased moderately over the course of
584 our experiments due to biological uptake, more abrupt decreases were observed for DIP released
585 by dust, reaching values close to the ones observed in the controls, except at station FAST where
586 concentrations were still above ambient levels at the end of the experiment.

587 Previous experiments on the effect of dust addition in the Mediterranean Sea showed
588 significant increases in chlorophyll *a* concentrations (mean $\sim 90\%$ increase; Guieu and Ridame,
589 2020). Interestingly, no stimulation of autotrophic biomass and primary production rates (Gazeau
590 et al., 2021) was observed in dust-amended tanks under present conditions at station TYR. To the
591 best of our knowledge, this is the first experimental evidence of a complete absence of response

592 from an autotrophic community following dust wet deposition. The absence of response from
593 autotrophic stocks could be due to a tight top-down control by grazers hiding potential responses
594 from the autotrophic community (Lekunberri et al., 2010; Marañón et al., 2010) and/or a
595 competition for nutrients with heterotrophic prokaryotes (Marañón et al., 2010). Feliú et al.
596 (2020) have shown that the mesozooplankton assemblage at TYR was clearly impacted by a dust
597 event that took place nine days before sampling at that station as evidenced from particulate
598 inventory of lithogenic proxies (Al, Fe) in the water column (Bressac et al., 2021), likely
599 stimulating phytoplankton growth and consequently increased the abundance of herbivorous
600 grazers (copepods) and attracted carnivorous species well before the start of the experiment.
601 Heterotrophic bacteria are also limited by inorganic nutrients, mainly DIP, in oligotrophic
602 systems (Obernosterer et al., 2003; Van Wambeke et al., 2001). Recent studies have shown
603 significant increases in heterotrophic bacterial abundance, respiration and/or production
604 following dust deposition (and nutrient enrichment) in these areas (Lekunberri et al., 2010; Pitta
605 et al., 2017; Pulido-Villena et al., 2008; Romero et al., 2011). Heterotrophs appear to be more
606 stimulated by dust pulses than autotrophic plankton with increasing degree of oligotrophy,
607 modulated by the competition for nutrients between phytoplankton and bacteria (Marañón et al.,
608 2010). This response was reflected at station TYR, with heterotrophic prokaryotes reacting
609 quickly and strongly to nutrient addition both in terms of abundances and production rates
610 (Gazeau et al., 2021). These two aforementioned hypotheses are not mutually exclusive, and the
611 quick response of heterotrophic prokaryotes to dust addition is coherent with the net
612 heterotrophy at this station (see 4.1) due to increases in community respiration and decreases in
613 net community production rates in dust-amended as compared to control tanks (Gazeau et al.,
614 2021). Hence, dust addition to surface waters strongly dominated by heterotrophs leads to a
615 reduction of the capacity of these communities to export organic matter and sequester
616 atmospheric CO₂.

617 In contrast to the dynamics of the experiment at TYR, stimulation of primary producers was
618 observed at stations ION and FAST under present conditions with overall higher impact than
619 previous studies compiled by Guieu and Ridame (2020). The largest increase in chlorophyll *a*
620 concentrations at station FAST is coherent with NO_x decreases observed at this station.
621 Interestingly, at FAST, DIP concentrations were still above ambient conditions at the end of the
622 experiment. Maximum primary production rates (¹⁴C-incorporation) at the end of the experiment
623 suggest strong DIP recycling and the dominance of regenerated production towards the end of
624 the experiment (Gazeau et al., 2021). Although, in some cases, *Synechococcus* appeared
625 stimulated by dust addition (Herut et al., 2005; Lagaria et al., 2017; Paytan et al., 2009), Guieu et
626 al. (2014b) showed that, based on the analysis of several aerosols addition studies, this group had
627 generally weak responses to aerosol addition in contrast to nano- and micro-phytoplankton,
628 suggesting that aerosol deposition may lead to an increase in larger phytoplankton. Yet, at
629 stations ION and FAST, the increase in *Synechococcus* abundance in dust-amended tanks was
630 the highest relative to those of pico- and nano-eukaryotes. In particular, at station ION, no clear
631 response to nutrient enrichment was observed for nano-eukaryotes throughout the experiment.
632 However, it must be stressed that our experiments were of a relatively short period (3 to 4 days).
633 The sharp increase in Fucoxanthin paralleled by a decrease in silica, at the end of the experiment
634 at station FAST where DIP limitation was not yet apparent, suggests a delayed response of
635 diatoms as compared to smaller taxa. The sharp decline in nano-eukaryote abundances in dust-
636 amended tanks at the end of the FAST experiment, further suggests that this group reacted
637 quickly to nutrient enrichment and was progressively grazed and/or outcompeted by larger
638 phytoplankton species.

639 While, all groups of primary producers benefited from nutrient enrichment at FAST, the
640 increases in heterotrophic prokaryote abundances were moderate, leading to an increase of net
641 community production rates throughout the experiment, reaching positive levels and a

642 autotroph:heterotroph ratio of 4, while control tanks remained below metabolic balance (Gazeau
643 et al., 2021). At station ION, the situation was intermediate with a similar enhancement of both
644 autotrophic and heterotrophic stocks and no clear changes in the ratio between autotrophic and
645 heterotrophic biomass (data not shown), although the system evolved towards net autotrophy at
646 the end of the experiment in dust -amended tanks under present environmental conditions
647 (Gazeau et al., 2021).

648 Transfer of newly produced organic matter to higher trophic levels in the different
649 treatments was assessed through the quantification of meso-zooplankton abundance at the end of
650 each experiment. Altogether it is not surprising that an increase in meso-zooplankton abundances
651 was only detected at station FAST where the strongest enhancement of primary production was
652 observed. Such an increase in meso-zooplankton abundance in the dust-amended as compared to
653 control treatment was observed during land-based mesocosm experiments in the Eastern
654 Mediterranean Sea (Pitta et al., 2017).

655 Finally, although no clear effects of dust deposition under present conditions were
656 detectable on autotrophic prokaryotes at station TYR, the strongest increase in N₂ fixation rates
657 was recorded at this station (Céline Ridame, unpublished results). However, the potential impact
658 of this process on NO_x concentration is negligible compared to the very large stock of NO_x
659 present in the dust-amended tanks, as less than 1 nmol L⁻¹ d⁻¹ of NO_x was produced through N₂
660 fixation (Céline Ridame, unpublished results).

661 **4.4. Impact of dust addition under future environmental** 662 **conditions**

663 Few studies have investigated the release and fate of nutrients from atmospheric
664 deposition under climate conditions as expected for the end of the century, and, to the best of our

665 knowledge, our study represents the first attempt to test for the combined effect of ocean
666 warming and acidification on these processes. The study by Louis et al. (2018), carried out with
667 filtered (0.2 μm mesh size) natural seawater using the same dust analog and flux as in the present
668 study showed that even an extreme ocean acidification scenario (~ -0.6 pH units) does not impact
669 the bioavailability of macro- and micro-nutrients (NO_x , DIP and DFe) in the oligotrophic
670 Northwestern Mediterranean Sea. Similar results were found by Mélançon et al. (2016) in high-
671 nutrient low-chlorophyll (HNLC) waters of the Northeastern Pacific, under a moderate ocean
672 acidification scenario (-0.2 pH units). As no differences were observed for NO_x and DIP
673 concentrations within a few hours following dust addition under present and future
674 environmental conditions, our results agree with these previous findings and further highlights
675 the absence of direct effect of ocean warming ($+3$ °C) on the release of nutrients from
676 atmospheric particles.

677 In contrast, different nutrient consumption dynamics were observed between ambient and
678 warmed/acidified tanks. No impacts of warming and acidification could be observed for NO_x at
679 stations TYR and ION due to low net uptake rates compared to the large increase following dust
680 addition. In contrast, at the most productive station FAST, as a consequence of strongly
681 enhanced biological stocks (see thereafter) and metabolic rates (Gazeau et al., 2021), larger NO_x
682 consumption rates were shown under future environmental conditions.

683 The differences in DIP dynamics between the two dust-amended treatments were more
684 complex to interpret. A clear feature of our experiments is that, in contrast to present day pH and
685 temperature conditions, all the stock of DIP released from dust was consumed at the end of the
686 three experiments under future conditions. The rate of decrease differed depending on the
687 station. While DIP dynamics were quite similar between tanks maintained under present and
688 future environmental conditions at ION, warming and acidification induced a faster decrease of
689 DIP at TYR and FAST, with a full consumption of the released DIP within 24 h. An interesting

690 outcome at station TYR was that, despite the important discrepancies observed for autotrophic
691 stocks and metabolic rates between the duplicates G1 and G2 (see section 4.2), a similar
692 dynamics was observed for DIP concentrations in these tanks. As heterotrophic prokaryote
693 biomass and production rates (Gazeau et al., 2021) did not differ between these duplicate tanks,
694 this further highlights the clear dominance of heterotrophic processes at this station, a dominance
695 which was exacerbated by dust addition under future environmental conditions, leading to an
696 even stronger heterotrophic state at the end of this experiment (Gazeau et al., 2021).

697 At station ION, large impacts of warming and acidification were found with twice the
698 chlorophyll *a* concentrations than in the dust amended D tanks. At this station, all autotrophic
699 groups increased with ocean acidification and warming. *Synechococcus* and to a lesser extent
700 pico-eukaryotes showed the strongest response. Yet these differences in abundance did not lead
701 to detectable changes in the composition of the autotrophic assemblage, with nano-eukaryote
702 largely dominating carbon biomass at the end of this experiment (62% in treatment G vs. 64% in
703 treatment D). Although the ratio between autotrophic and heterotrophic biomass appeared
704 positively impacted under future environmental conditions, reaching values of up to 2 at the end
705 of the experiment, warming and acidification led to a decrease in net community production
706 (Gazeau et al., 2021) suggesting that in the coming decades the capacity of surface seawater to
707 sequester anthropogenic CO₂ will be lowered.

708 Similarly, at FAST, all phytoplankton groups were impacted positively by warming and
709 acidification with the strongest changes detected for *Synechococcus* as compared to present
710 environmental conditions. However, in contrast to station ION, all groups reached maximal
711 abundances (and carbon biomass) after 3 days of incubations, thereafter drastically decreasing
712 most likely as a consequence of DIP limitation (see above). It must be stressed that this pattern
713 could not be observed from pigments as no samples were taken for these analyses after 3 days of
714 incubation. Also, in contrast to station ION, the abundance of heterotrophic prokaryotes in the

715 warmer and acidified treatment reached a maximum after 2 days of incubations and then
716 decreased rapidly to reach levels observed in the control treatment. This suggests that
717 heterotrophic prokaryotes were the first to suffer from DIP limitation and further highlights the
718 dominance of autotrophs in terms of nutrient consumption at this station. Although the ratio
719 between autotrophic and heterotrophic biomass increased under future environmental conditions
720 at ION, Gazeau et al. (2021) reported on a decrease in net community production rates in this
721 treatment as compared to ambient environmental conditions, suggesting that, in the future,
722 nutrient release from dust will lead to a lesser sequestration capacity of surface waters for
723 atmospheric CO₂.

724 The positive effects of warming and acidification on the abundance of mostly small (< 20
725 µm) phytoplankton taxa, as observed at ION and FAST, are in line with previously published
726 studies. Although the effect of ocean acidification on small autotrophic species shows a wide
727 range (e.g. Dutkiewicz et al., 2015), there is increasing evidence that small phytoplankton
728 species will be favored in a warmer ocean (e.g. Chen et al., 2014; Daufresne et al., 2009; Morán
729 et al., 2010). Our experimental protocol was not conceived to discriminate temperature from pH
730 effects, however results concur with those of Maugendre et al. (2015) which further suggested
731 temperature over elevated CO₂ as the main driver of increased picophytoplankton abundance in
732 the Mediterranean Sea.

733 These enhanced fertilizing effects on primary producers at ION and FAST, under future
734 as compared to present environmental conditions, did not seem to reach higher trophic levels as
735 no clear differences in meso-zooplankton abundances were observed between ambient and
736 warmed/acidified tanks at the end of the experiments. The duration of our experiments was too
737 short to carefully assess the proportion of newly formed organic matter consumed by meso-
738 zooplankton species and its effect on their biomass, yet group-specific variations were observed.

739 Finally, Gazeau et al. (2021) did not observe an additional impact of future environmental
740 conditions on the export of organic matter after dust addition.

741 **5. Conclusion**

742 These experiments conducted during the PEACETIME cruise represent the first attempt
743 to investigate the impacts of atmospheric deposition on surface plankton communities both under
744 present and future environmental conditions. Despite few experimental issues, the three
745 experiments provided new insights on these potential impacts in the open Mediterranean Sea.
746 Stark differences in the response to dust deposition were observed between the three investigated
747 stations in the Tyrrhenian Sea, Ionian Sea and in the Algerian basin. Given that the initial
748 conditions at the three stations were very similar in terms of nutrient and chlorophyll
749 concentrations, these differences seem to be rather a consequence of the initial metabolic states
750 of the community (autotrophy vs. heterotrophy). In all three cases, nutrient addition from dust
751 deposition did not strongly modify but rather exacerbated this initial state. Relative changes in
752 main parameters presented in this manuscript and processes presented in Gazeau et al. (2021) as
753 a consequence of dust addition under present and future environmental conditions are shown in
754 Fig. 10, and compared to the compilation of published data for the Mediterranean Sea from
755 Guieu and Ridame (2020). At station TYR, under conditions of a clear dominance of
756 heterotrophs on the use of resources and potentially a higher top-down control from grazers, dust
757 addition drove the community into an even more heterotrophic state with no detectable effect on
758 primary producers. At station ION, where the community was initially closer to metabolic
759 balance, both heterotrophic and autotrophic compartments benefited from dust derived nutrients.
760 At FAST, the station with the highest initial autotrophic production, addition of nutrients led to
761 an increase in both compartments but heterotrophic prokaryotes became quickly P-limited and
762 overall larger effects were observed for phytoplankton. Ocean acidification and warming did not
763 have any detectable impact on the release of nutrients from atmospheric particles. Furthermore,
764 these external drivers did not drastically modify the composition of the autotrophic assemblage

765 with all groups benefiting from warmer and acidified conditions. However, although for two out
766 of the three stations investigated, larger increases were observed for autotrophic as compared to
767 heterotrophic stocks under future environmental conditions, a stronger impact of warming and
768 acidification on mineralization processes (Gazeau et al., 2021) suggests that, in the future, the
769 plankton communities of Mediterranean surface waters will have a decreased capacity to
770 sequester atmospheric CO₂ following the deposition of atmospheric particles.

771 **Data availability**

772 All data and metadata will be made available at the French INSU/CNRS LEFE CYBER database
773 (scientific coordinator: Hervé Claustre; data manager, webmaster: Catherine Schmechtig).
774 INSU/CNRS LEFE CYBER (2020)

775 **Author contributions**

776 FG and CG designed and supervised the study. FG, CG, CR and KD sampled seawater from the
777 experimental tanks during the experiments. JMG and GDL participated in the technical
778 preparation of the experimental system and all authors participated in sample analyses. FG, CR
779 and CG wrote the paper with contributions from all authors.

780 **Financial support**

781 This study is a contribution to the PEACETIME project (<http://peacetime-project.org>), a joint
782 initiative of the MERMEX and ChArMEX components supported by CNRS-INSU, IFREMER,
783 CEA, and Météo-France as part of the programme MISTRALS coordinated by INSU.
784 PEACETIME is a contribution to SOLAS and IMBER international programme. The project was
785 endorsed as a process study by GEOTRACES. PEACETIME cruise
786 (<https://doi.org/10.17600/17000300>). The project leading to this publication has also received
787 funding from the European FEDER Fund under project 1166-39417.

788 **Acknowledgments**

789 The authors thank the captain and the crew of the RV Pourquoi Pas ? for their professionalism
790 and their work at sea. We thank Julia Uitz, Céline Dimier and the SAPIGH HPLC analytical
791 service at Institut de la Mer de Villefranche (IMEV) for sampling and analysis of phytoplankton
792 pigments, John Dolan for microscopic countings as well as Lynne Macarez and the PIQv-

793 platform of EMBRC-France, a national Research Infrastructure supported by ANR, under the
794 reference ANR-10-INSB-02, for mesozooplankton analyses.

1143 Table 2. Initial conditions (sampling time t-12h) at stations TYR, ION and FAST measured
 1144 while filling the tanks. pH_T: pH on the total scale, NO_x: nitrate + nitrite, NH₄: ammonium, DIP:
 1145 dissolved inorganic phosphorus, Si(OH)₄: silicate, TChl*a*: total chlorophyll *a*, HNF:
 1146 heterotrophic nanoflagellates. The three most important pigments in terms of concentration are
 1147 also presented (19'-hexanoyloxyfucoxanthin, Zeaxanthin and Divinyl Chlorophyll *a*). Biomasses
 1148 of the different groups analyzed through flow cytometry were estimated based on conversion
 1149 equations and/or factors found in the literature (see section 2.3). Autotrophic and heterotrophic
 1150 biomass based on flow cytometry (fraction < 20 μm). Values below detection limits are indicated
 1151 as < dl.

Table 3. Maximum input of nitrate + nitrite (NO_x) and dissolved inorganic phosphorus (DIP) released from Saharan dust in tanks D and G as observed from the discrete samples taken during the first 6 h after seeding. The estimated maximal percentage of dissolution is also presented (see section 2.3.1 for details on the calculations).

	NO _x				DIP			
	D1	D2	G1	G2	D1	D2	G1	G2
Maximum input	μmol L ⁻¹				nmol L ⁻¹			
TYR	11.0	11.1	11.1	11.0	24.6	20.4	24.6	23.9
ION	11.2	11.6	11.2	11.3	23.3	22.0	19.6	22.9
FAST	11.3	11.1	11.1	11.2	30.8	31.3	36.9	29.8
Maximum dissolution (%)								
TYR	95	96	95	94	12	10	12	11
ION	96	99	96	97	11	10	9	11
FAST	97	97	95	97	15	15	17	14

1 Table 4. Removal rate of nitrate + nitrite (NO_x) and dissolved inorganic phosphorus (DIP) in
 2 tanks D and G during the three experiments (TYR, ION and FAST). For NO_x, rates were
 3 estimated based on linear regressions between maximum concentrations (i.e. after dust
 4 enrichment, at t1h or t6h) and final concentrations (t72 h for TYR and ION and t96h for FAST).
 5 For DIP, rates were estimated based on linear regressions between maximum concentrations (i.e.
 6 after dust enrichment at t1h or t6h) and concentrations after stabilization was observed. This
 7 sampling time is shown in parentheses. All rates are expressed in nmol L⁻¹ h⁻¹.

	NO _x			DIP		
	TYR	ION	FAST	TYR	ION	FAST
D1	-6.5	-8.6	-14.3	-0.4 (t72h)	-0.5 (t48h)	-0.2 (t96h)
D2	-1.0	-8.6	-13.5	-0.3 (t72h)	-0.8 (t24h)	-0.2 (t96h)
G1	-6.7	-13.1	-21.6	-1.3 (t24h)	-0.8 (t24h)	-1.5 (t24h)
G2	-0.8	-1.6	-25.2	-1.3 (t24h)	-1.6 (t24h)	-1.1 (t24h)

9 Table 5. Percent (%) maximum relative changes in tanks D and G as compared to controls
 10 (average between C1 and C2), for the experiments TYR, ION and FAST. The sampling time at
 11 which these maximum relative changes were observed is shown in brackets. Tchl a refers to the
 12 concentration of total chlorophyll a and B $_{micro}$ to the biomass proxy of micro-phytoplankton (sum
 13 of Fucoxanthin and Peridinin, see Material and Methods) based on high performance liquid
 14 chromatography (HPLC). HP and HNF refer to heterotrophic prokaryote and heterotrophic
 15 nanoflagellate abundances, respectively, measured by flow cytometry.

Experiment	Tank	HPLC		Flow cytometry				
		TChl a	B $_{micro}$	Autotrophic Pico-eukaryotes	Autotrophic Nano-eukaryotes	<i>Synechococcus</i>	HP	HNF

Fig. 1. Location of the sampling stations in the Mediterranean Sea onboard the R/V “Pourquoi Pas ?” during the PEACETIME cruise. Background shows satellite-derived surface chlorophyll *a* concentration averaged over the entire duration of the cruise (Courtesy of Louise Rousselet).

Fig. 2. Diagram of an experimental tank (climate reactor).

Fig. 3. Proportion of the different pigments, as measured by high performance liquid chromatography (HPLC) in pumped surface seawater for the three experiments (t-12h).

Fig. 4. Continuous measurements of temperature and irradiance level (PAR) in the six tanks during the experiments at TYR, ION and FAST. The dashed vertical line indicates the time of dust seeding (after t_0).

Fig. 5. pH on the total scale (pH_T) and total alkalinity (A_T) measured in the six tanks during the experiments at TYR, ION and FAST. The dashed vertical line indicates the time of dust seeding (after t_0). Error bars correspond to the standard deviation based on analytical triplicates.

Fig. 6. Nutrients (nitrate + nitrite): NO_x , dissolved inorganic phosphorus: DIP, silicate: $\text{Si}(\text{OH})_4$ and the molar ratio between NO_x and DIP, measured in each tank during the experiments at TYR, ION and FAST. The dashed vertical line indicates the time of seeding (after t_0).

Fig. 7. Total chlorophyll *a* and major pigments, from high performance liquid chromatography (HPLC) measurements, in each tank during the experiments at TYR, ION and FAST. The dashed vertical line indicates the time of seeding (after t_0).

Fig. 8. Abundance of autotrophic pico-eukaryotes, autotrophic nano-eukaryotes, *Synechococcus*, heterotrophic prokaryotes (HP), and heterotrophic nano-flagellates (HNF), measured by flow cytometry, in each tank during the experiments at TYR, ION and FAST. The evolution of

autotrophic biomass (see Material and Methods for details on the calculation) is also shown. The dashed vertical line indicates the time of seeding (after t_0).

Fig. 9. Abundances of meso-zooplankton species as measured in each tank at the end of the experiments at TYR, ION and FAST.

Fig. 10. Maximum relative change (%) of main biological stocks (TCHl*a*: total chlorophyll *a*, HP: heterotrophic prokaryotes) and processes (BP: bacterial production; PP: ^{14}C -based primary production; see Gazeau et al., 2021; BR: bacterial respiration (no data from this study); and N_2 fixation, Céline Ridame, unpublished results) obtained during the present study at the three stations (TYR, ION and FAST) under ambient conditions of pH and temperature (open red squares) and future conditions (full green squares). Vertical extension of each squares are delimited by the range of responses observed among the duplicates for each treatment. The dotted green squares for station TYR highlight the large variability observed between duplicates for some parameters and processes that prevented drawing solid conclusions. Box-plots (Med) represent the distribution of responses observed from studies conducted in the Mediterranean Sea, as compiled by Guieu and Ridame (2020).
