6 **Abstract.** Gross primary productivity (GPP), the CO₂ uptake by means of photosynthesis, cannot be measured directly on
7 ecosystem scale, but has to be inferred from proxies or models. One newly emerged proxy is the trace gas carbonyl sulfide
8 (COS). COS diffuses into plant leaves in a fashion very similar to CO₂, but is generally not emitted by plants. Laboratory
9 studies on leaf level gas exchange have shown promising correlations between the leaf relative uptake (LRU) of COS to CO₂
10 under controlled conditions. However, *in situ* measurements including daily to seasonal environmental changes are required,
11 to test the applicability of COS as a tracer for GPP at larger temporal scales. To this end, we conducted concurrent
12 ecosystem scale CO₂ and COS flux measurements above an agriculturally managed temperate mountain grassland. We also
13 determined the magnitude and variability of the soil COS exchange, which can affect the LRU on ecosystem level. The
14 cutting and removal of the grass at the site had a major influence on the soil flux as well as the total exchange of COS. The
15 grassland acted as a major sink for CO₂ and COS during periods of high leaf area. The sink strength decreased after the cuts
16 and the grassland turned into a net source for CO₂ and COS on ecosystem level. The soil acted as a small sink for COS when
17 the canopy was undisturbed, but also turned into a source after the cuts, which we linked to higher incident radiation hitting
18 the soil surface. However, the soil contribution was not large enough to explain the COS emission on ecosystem level,
19 hinting to an unknown COS source possibly related to dead plant matter degradation. Over the course of the season, we
20 observed a concurrent decrease of CO₂ and COS uptake on ecosystem level. With the exception of the short periods after the
21 cuts, the LRU under high light conditions was rather stable and indicates a high correlation between the COS flux and GPP
22 across the growing season.

23

24 1 Introduction

25 Carbonyl sulfide (COS) is the most abundant sulfur-containing gas in the atmosphere with tropospheric mixing ratios of
26 ~500 ppt. Within the atmosphere, COS acts as a greenhouse gas with a 724 times higher direct radiative forcing efficiency as
27 CO₂ (Brühl et al., 2012). After reaching the stratosphere, it reacts to sulfur aerosols via oxidation and photolysis, hence
28 contributing to the backscattering of solar radiation and having a cooling effect on Earth's atmosphere (Krysztofiak et al.,
29 2015;Whelan et al., 2018). The intra-seasonal atmospheric COS mixing ratio follows the pattern of CO₂ as terrestrial
30 vegetation acts as the largest known sink for both species (Montzka et al., 2007;Whelan et al., 2018;Le Quere et al., 2018).
31 However, the relative decrease in ambient mixing ratio during summer of the northern hemisphere is 6 times stronger for
32 COS than for CO₂ (Montzka et al., 2007) as COS is generally not emitted by plants like CO₂, which is released in respiration
33 processes.

34 The uptake of COS by plants is mostly mediated by the enzyme carbonic anhydrase (CA), but also photolytic enzymes like
35 Ribulose-1,5-bisphosphate-carboxylase/-oxygenase (Rubisco) (Lorimer and Pierce, 1989). This in turn means that COS and
36 CO₂ share a similar pathway into leaves through the boundary layer, the stomata and the cytosol, up to their reaction sites.
37 Compared to CO₂, COS is processed in a one-way reaction to H₂S and CO₂ (Protoschill-Krebs and Kesselmeier, 1992;Notni
38 et al., 2007) and therefore not released by plants, with the exception of severely stressed plants (Bloem et al., 2012;Gimeno

39 et al., 2017). That makes COS an interesting tracer for estimating the stomatal conductance and the gross uptake of CO₂,
40 referred to as gross primary production (GPP), on ecosystem level (Asaf et al., 2013;Kooijmans et al., 2017;Kooijmans et al.,
41 2019). However, to estimate GPP using COS, the relative uptake of COS to GPP deposition velocities (LRU) must be known
42 beforehand (see Eq.1), so that GPP can be estimated on the basis of the COS flux.

$$43 \quad LRU = \frac{\frac{F_{COS}}{\chi_{COS}}}{\frac{F_{CO_2}}{\chi_{CO_2}}} \quad (\text{Eq.1})$$

44 F_{COS} is the COS leaf flux (pmol m⁻² s⁻¹), F_{CO₂} is the gross CO₂ uptake on leaf level (μmol m⁻² s⁻¹) and χ_{COS} and χ_{CO₂} are the
45 ambient COS and CO₂ mixing ratios in ppt and ppm, respectively. Leaf level studies for C₃ plants have estimated the LRU to
46 be around 1.7 with the 95% confidence interval between 0.7 and 6.2 (Whelan et al., 2018;Seibt et al., 2010;Sandoval-Soto et
47 al., 2005). The large spread of the LRU most likely originates from differences between plant species, for example, leaf
48 structure and plant metabolism (Wohlfahrt et al., 2012;Seibt et al., 2010), which questions the applicability of the concept of
49 LRU in real-world ecosystems under naturally varying environmental conditions. It is also known that the LRU is just stable
50 under high light conditions, since the uptake of CO₂ by means of photosynthesis is a light driven process, while CA is able to
51 process COS independently of light conditions (Maseyk et al., 2014;Yang et al., 2018;Stimler et al., 2011). Any model of
52 LRU should therefore reflect diurnal changes in light conditions. Kooijmans et al. (2019) recently discovered that the vapor
53 pressure deficit (VPD) appears to have a stronger control on F_{COS} than on F_{CO₂}, in an evergreen needle forest. If generally
54 true, this would add further variability to the LRU and complicating the application of COS to estimate GPP. Besides inter-
55 specific differences in LRU, the question remains unanswered if the LRU is also susceptible to seasonal changes of
56 ecosystems for example, changes in species composition or phenology, which would further complicate the application of
57 COS in carbon cycle research. Maseyk et al. (2014) observed COS emissions on ecosystem scale over a winter wheat field
58 going into senescence, indicating that potentially strong sources of COS could distort LRU.

59 Since CA and other enzymes known to emit or take up COS are also present in microorganisms (Ogawa et al., 2013;Seefeldt
60 et al., 1995;Ensign, 1995;Smeulders et al., 2013;Whelan et al., 2018), recent studies have also quantified the contribution of
61 soils to the COS ecosystem flux (Kooijmans et al., 2017;Spielmann et al., 2019;Maseyk et al., 2014). COS soil fluxes could
62 modify the LRU on ecosystem level and hence inferred GPP, if they are substantial compared to COS canopy fluxes. Similar
63 to the ecosystem fluxes, the soil fluxes could not only be prone to diurnal, but also seasonal changes, depending on the
64 substrate availability, environmental conditions (e.g. soil temperature and moisture), substrate quality and quantity, and
65 changes in composition of the microbial communities (Kitz et al., 2019;Meredith et al., 2019). Recent studies have also
66 linked COS soil emissions to abiotic processes dependent on light and/or temperature (Whelan and Rhew, 2015;Kitz et al.,
67 2019;Meredith et al., 2018).

68 The goal of our study was to provide new insights into the seasonal variability of COS fluxes on ecosystem, soil and canopy
69 level. To this end, we conducted a 6-month campaign on a managed temperate mountain grassland, measuring ecosystem as
70 well as soil COS fluxes. Since the grassland was cut four times during the campaign, we were able to observe multiple
71 growing cycles and investigate the diel and seasonal changes of the COS fluxes and the LRU in this highly dynamic
72 ecosystem. We hypothesize that (H1) the grassland, given its large CO₂ uptake capacity (Wohlfahrt et al. 2008), is a major
73 sink for COS and that the sink strength decreases over the course of the season, (H2) the drying of the cut grass leads to a
74 release of COS, (H3) the LRU will change after the cuts, due to stressed plants and drying plant parts in the field, but is
75 otherwise stable, (H4) the cuts turn the soil into a COS source, due to the larger amount of light reaching the soil surface
76 (Kitz et al., 2017), but once a reasonably high leaf area index (LAI) has developed, COS is taken up by soil.

77 2 Methods

78 2.1 Study site and period

79 The study was conducted at an intensively managed mountain grassland in the municipal territory of Neustift (Austria) in
80 Stubai valley (FLUXNET ID: AT-Neu; doi: [10.18140/FLX/1440121](https://doi.org/10.18140/FLX/1440121)). The grassland is situated at an elevation of 970 m a.s.l.
81 in the middle of the flat valley bottom. The soil was classified as Fluvisol with an estimated depth of 1 m with the majority
82 of roots located within the first 10 cm. Measurements were conducted between 01.05.2015 and 31.10.2015 (183 days). The
83 vegetation was described as Pastincao-Arrhenatheretum and consisted mainly of *Dactylis glomerata*, *Festuca pratensis*,
84 *Alopecurus pratensis*, *Trisetum flavescens*, *Ranunculus acris*, *Taraxacum officinale*, *Trifolium repens*, *Trifolium pratense*,
85 and *Carum carvi* (Kitz et al., 2017). During the campaign, the grassland was cut four times (02.06./07.07./21.08./01.10.2015)
86 and the biomass left to dry on the field for up to one day, before being removed as silage. Each year, the field site was
87 fertilized with solid manure and cattle slurry (Hörtnagl et al., 2018) at the end of the season (07.10 in 2015).

88 2.2 Leaf area index

89 The LAI was estimated from assessments of the average canopy height, which were related to destructive LAI
90 measurements, using the following sigmoid function:

$$91 \text{LAI} = \frac{1}{(1 + \exp(-(a_1 \text{DOY} + a_2)))} (b_1 - b_2) \quad (\text{Eq.2})$$

92 where DOY is the day of the year and a_1 , a_2 , b_1 and b_2 are factors that were optimized for each growing period, for
93 example, before the first cut, between cuts and after fourth cut (Wohlfahrt et al., 2008). Additionally, biomass samples were
94 taken at 15 occasions, to assist with the LAI calculation.

95 2.3 Mixing ratio measurements

96 The CO_2 (χ_{CO_2}) and COS (χ_{COS}) mixing ratios were measured using a Quantum Cascade Laser (QCL) Mini Monitor
97 (Aerodyne Research, Billerica, MA, USA) at a wavenumber of ca. 2056 cm^{-1} and at a frequency of 10 Hz. To minimize the
98 effect of air temperature (T_{air}) changes on the instrument, we placed it in an insulated box which in turn was located in a
99 climate controlled instrument hut (30°C). The cooling of the laser was achieved by a chiller (ThermoCube 400, Solid State
100 Cooling Systems, Wappinger Falls, NY, USA).

101 We used ¼ inch Teflon™ tubing, stainless steel fittings (SWAGELOK, Solon, OH, USA and FITOK, Offenbach, HE,
102 Germany), Teflon Filters (Savilex, EdenPrarie, MN, USA) as well as COS-inert valves (Parker-Hannafin, Cleveland, OH,
103 USA) to ensure that only materials known not to interact with COS were used for the measurement and calibration airflow.
104 Since the data of the QCL and the sonic anemometer were saved on two separate PCs, a network time protocol software
105 (NTP, Meinberg, NI, Germany) was used to keep the time on both devices synchronized. We corrected known χ_{COS} drift
106 issues of the QCL (Kooijmans et al., 2016) by doing half hourly calibrations for 1 min with a gas of known χ_{COS} . The gas
107 cylinders (working standards) used for the calibrations were either pressurized air (UN 1002) or nitrogen (UN 1066), which
108 were cross-compared (when working standard cylinders were full and close to empty) to an Aculife-treated aluminum
109 pressurized air cylinder obtained from the National Oceanic & Atmospheric Administration (NOAA). The latter was
110 analyzed by the central calibration laboratory of NOAA for its χ_{COS} using gas chromatography with mass spectrometric
111 detection (GC-MS) on 06.04.2015. We then linearly interpolated between the offsets of the half hourly calibrations and used
112 the retrieved values to correct the high frequency COS data. Due to issues with the scale gas cylinder, no absolute
113 concentrations were available before the 16.06. The COS mixing ratios were extrapolated to the 1st cut to increase the
114 amount of available data for the first post cut period. This was done on the basis of the measured CO_2 mixing ratios and the
115 mean half hourly ratio of the ambient CO_2 to COS mixing ratios between the 16. and the 18.6..

116 **2.3.1 Mixing ratio measurements within the canopy**

117 In order to investigate the χ_{COS} within the canopy, we used a multiplexer and 8 ¼ inch Teflon™ tubes to measure the χ_{COS} at
118 8 heights within and above the canopy i.e. at 2, 5, 10, 20, 30, 40, 50 & 250 cm height above ground with a tube length of
119 15 m for each height. The upper two intakes were located at the eddy covariance measurement and canopy height,
120 respectively. Each height was measured for 1 min at 1 Hz and 2 l min⁻¹, while the other lines were each flushed at 2 l min⁻¹.
121 The χ_{COS} drift was also corrected by doing half hourly calibrations (see section 2.3).
122

123 **2.4 COS soil fluxes**

124 **2.4.1 Soil chamber setup**

125 To quantify soil COS fluxes, we installed four stainless steel (SAE grade: 316L) rings 5 cm into the soil. They remained on
126 site for 112 days (10.06.2015 – 30.09.2015). Two additional rings were installed on the 31.08.2015 and the 02.10.2015 to
127 examine any long-term effects of the ring placement and to replace the original rings for the measurements in September and
128 October. The aboveground biomass within each ring was removed at the day of installation and again at least one day prior
129 to each measurement day. The roots within as well as the vegetation surrounding the rings were not removed and natural
130 litter was left in place. At days without measurements the soil within the rings was covered by fleece to prevent it from
131 drying out.

132 To measure the soil fluxes, a transparent fused silica-glass chamber (Kitz et al., 2017) was placed into the water filled
133 channel of the steel rings, while air was sucked through the chamber to the QCL at a flow rate of 1.5 l min⁻¹. The chamber
134 χ_{COS} was then compared with the ambient χ_{COS} above the chamber, using a second inlet to which we switched before the
135 chamber measurement and after reaching stable readings inside the chamber. The intake height of the ambient as well as the
136 inlet of the chamber air were located at 0.12 m above the ground and thus within the canopy height with the exception of
137 measurements right after the cuts (see cutting dates in Section 2.1). Overall, 243 chamber measurements were conducted
138 over the course of the campaign including day and nighttime measurements. Additional manual measurements included a
139 hand-held sensor (WET-2, Delta-T Devices, Cambridge, England) to measure soil water content (SWC) and soil temperature
140 (T_{soil}) at a soil depth of 5 cm simultaneously with the soil chamber measurements next to the rings.

141 **2.4.1 COS soil flux calculation**

142 The COS soil flux was calculated using the following equation:

$$143 \quad F = q(\chi_{\text{COS}2} - \chi_{\text{COS}1})/A \quad (\text{Eq.3})$$

144 where F is the COS soil flux (pmol m⁻² s⁻¹), q denotes the flowrate in (mol s⁻¹), $\chi_{\text{COS}2}$ and $\chi_{\text{COS}1}$ are the chamber and ambient
145 χ_{COS} in ppt, respectively and A the soil surface area (0.032 m²) covered by the chamber. A more detailed description can be
146 found in Kitz et al. (2017).

147 **2.4.2 COS soil exchange modelling**

148 Due to the removal of the aboveground biomass and the consequent higher shortwave radiation reaching the soil surface in
149 the chambers, compared to the soil below the canopy, we simulated the soil COS exchange for natural conditions. The soil
150 flux was modelled using our measured soil fluxes and additionally retrieved soil and meteorological data - T_{soil} , soil water
151 content (SWC) at 5 cm depth next to the chambers and incident shortwave radiation reaching the soil surface ($R_{\text{SW-soil}}$) - as
152 input for a random forest regression model (Liaw and Wiener, 2002). The soil fluxes were modelled on half hourly basis for
153 the whole duration of the measurement campaign to calculate the COS canopy fluxes from the difference of the COS
154 ecosystem and soil fluxes. To this end we used the scikit-learn (sklearn Ver. 0.19.1) package, the pandas library and the

155 Python Software Distribution Anaconda (Ver. 5.2.0) in the command shell Ipython (Ver. 6.4.0) based on the Programming
 156 language Python (Ver. 3.3.5). We used the Beer-Lambert law to model R_{SW_soil} under undisturbed conditions as the
 157 aboveground vegetation was removed to measure the COS exchange of bare soil:

$$158 \quad R_{SW-soil} = R_{SW} \exp(-K LAI) \quad (\text{Eq.4})$$

159 where $R_{SW-soil}$ (Wm^{-2}) is the shortwave radiation (SW) reaching the soil surface, R_{SW} is the incoming SW radiation reaching
 160 the top of the canopy, LAI is the plant area index (Eq. 2) and K is the canopy extinction coefficient assuming a spherical leaf
 161 inclination distribution (Wohlfahrt et al., 2001), which was calculated using the following equation:

$$162 \quad K = \frac{1}{2 \cos(\psi)} \quad (\text{Eq.5})$$

163 where ψ is the zenith angle of the sun in radians.

164

165 A random forest with 1000 trees was grown which resulted in an out of bag (OOB) score of (0.82). The OOB score can be
 166 interpreted as a pseudo-R2 and is widely used in random forest analyses (regression and classification), especially in the
 167 absence of a proper test dataset. It uses the data not seen by the trees (random forest uses bootstrapping) as a test dataset. The
 168 optimal input parameters, including maximum tree depth, were determined with the function GridSearchCV from the sklearn
 169 package.

170 **2.5 Ecosystem fluxes**

171 **2.5.1 Setup for ecosystem fluxes**

172 The COS, CO_2 and H_2O ecosystem fluxes were obtained using the eddy covariance method (Aubinet et al., 1999; Baldocchi,
 173 2014). We used a 3-axis sonic anemometer (Gill R3IA, Gill Instruments Limited, Lymington, UK) to obtain high-resolution
 174 data of the 3 wind components. The intake of the tube for the eddy covariance measurements was installed in close
 175 proximity to the sonic anemometer and insulated as well as heated above T_{air} to prevent condensation within the tube. The air
 176 was sucked to the QCL at a flowrate of 7 l min^{-1} using a Vacuum Pump (Agilent Technologies, CA, USA).

177 **2.5.2 Ecosystem flux calculation**

178 In a first step we used a self-developed software to determine the time lag, introduced by the separation of tube intake and
 179 the sonic anemometer and the tube length, between the QCL and sonic dataset (Hortnagl et al., 2010). The data were then
 180 processed using the software EdiRe (University of Edinburgh, UK) and Matlab2019a (MathWorks, MA, USA). We used the
 181 laser drift corrected χ_{COS} data and linear detrending to process the data before following the procedure to correct for sensor
 182 response, tube attenuation, path averaging and sensor separation following Gerdel et al. (2017). The random flux uncertainty
 183 was calculated following Langford et al. (2015).

184 We estimated the COS canopy flux from the difference between the measured COS ecosystem and the modelled COS soil
 185 flux.

186 **2.5.3 Flux partitioning and leaf relative uptake**

187 The GPP on ecosystem level was determined using the FP+ model put forward by Spielmann et al. (2019). The model
 188 estimates the GPP on the basis of nighttime net ecosystem exchange (NEE) measurements of CO_2 that are assumed to
 189 provide the temperature response of the ecosystem respiration (RECO) as well as a light dependency curve to estimate GPP
 190 based on the daytime NEE (Lasslop et al., 2010):

$$191 \quad NEE = \frac{\alpha \beta R_{PAR}}{\alpha R_{PAR} + \beta} + r_b e^{E_0 \left(\frac{1}{T_{ref} - T_0} - \frac{1}{T_{air} - T_0} \right)} \quad (\text{Eq.6})$$

192 where α denotes the canopy light utilization efficiency ($\mu\text{mol CO}_2 \mu\text{mol}^{-1}$ photons), β the maximum CO_2 uptake rate of the
 193 canopy at light saturation ($\mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$), R_{PAR} the incoming photosynthetic active radiation ($\mu\text{mol m}^{-2} \text{s}^{-1}$), r_b the
 194 ecosystem base respiration ($\mu\text{mol m}^{-2} \text{s}^{-1}$) at the reference temperature T_{Ref} ($^{\circ}\text{C}$), which is set to 15°C , T_{air} ($^{\circ}\text{C}$) refers to the
 195 air temperature and E_0 ($^{\circ}\text{C}$) to the temperature sensitivity of RECO. T_0 was kept constant at -46.02°C . We did not use the
 196 VPD modifier of beta put forward by Lasslop et al. (2010) as its value could not be estimated with confidence. We
 197 determined the parameter E_0 by using nighttime data minimizing the root squared mean error. For the determination of the
 198 remaining five unknown model parameters of the two flux partitioning models we used DREAM, a multi-chain Markov
 199 Chain Monte Carlo algorithm (for more detail see Spielmann et al. (2019)). We calculated the parameters for ~15 day
 200 windows but adjusted them to not overlap with a cut of the grassland.

201 The ecosystem relative uptake (ERU) was calculated using Eq. 1 substituting the GPP with the NEE and using the COS
 202 ecosystem flux for F_{COS} .

203 The FP+ model by Spielmann et al. (2019) extends the daytime FP (Eq.6) to also estimate the COS ecosystem fluxes by
 204 linking the GPP resulting from the first part on the right-hand side of Eq.6 with the COS exchange through:

$$205 \quad F_{\text{COSmodel}} = \frac{\text{GPP LRU} \chi_{\text{COS}}}{\chi_{\text{CO}_2}} \quad (\text{Eq.7})$$

206 developed by Sandoval-Soto et al. (2005), where F_{COSmodel} is the modelled COS flux ($\text{pmol m}^{-2} \text{s}^{-1}$), χ_{COS} (ppt) and χ_{CO_2} (ppm)
 207 are the measured ambient mixing ratios of COS and CO_2 respectively and LRU (-) is the leaf relative uptake rate:

$$208 \quad \text{LRU} = \iota e^{\left(\frac{\kappa}{R_{\text{PAR}}}\right)} \quad (\text{Eq.8})$$

209 where ι (-) corresponds to the LRU at high light intensity and the parameter κ ($\mu\text{mol m}^{-2} \text{s}^{-1}$) governs the increase of LRU at
 210 low light conditions. While mathematically ι is only obtained at infinitely high PAR, in practice above about $700 \mu\text{mol m}^{-2} \text{s}^{-1}$
 211 PAR (Kooijmans et al., 2019) only insignificant change is reported in other studies (Stimler et al., 2011). The light
 212 dependency of LRU originates from the fact that the COS uptake by the enzyme CA is light-independent, while the CO_2
 213 uptake by Rubisco depends on solar radiation absorbed by leaf chlorophyll (Whelan et al., 2018;Kooijmans et al.,
 214 2019;Wohlfahrt et al., 2012).

215 The method stated above infers LRU solely on the basis of ecosystem scale fluxes, whereas other studies typically use
 216 branch/leaf chamber measurements (Yang et al., 2018) to determine the relationship between the COS and CO_2 uptake rates.

217 2.5.4 Linear perturbation analysis

218 The relative contribution of the parameters GPP, F_{COSmodel} , χ_{CO_2} and χ_{COS} that drive ι (Eq. 7) were estimated through a linear
 219 perturbation analysis (Stoy et al., 2006).

220 The changes in ι ($\delta\iota$) between the target and the reference window (before the 2nd cut, i.e. 18.06.2015-07.07.2015) are
 221 considered the total derivative of Eq. 7 and can be represented by a multivariate Taylor's expansion where the higher-order
 222 terms are neglected in this first-order analysis:

$$223 \quad \delta\iota = \frac{\partial\iota}{\partial F_{\text{COSmod}}} dF_{\text{COSmod}} + \frac{\partial\iota}{\partial\chi_{\text{COS}}} d\chi_{\text{COS}} + \frac{\partial\iota}{\partial\text{GPP}} d\text{GPP} + \frac{\partial\iota}{\partial\chi_{\text{CO}_2}} d\chi_{\text{CO}_2} \quad (\text{Eq.9})$$

224 The relative contributions of the parameters were determined by computing the partial derivatives of Eq. 7.

$$225 \quad \frac{\partial\iota}{\partial F_{\text{COSmod}}} = \frac{\chi_{\text{CO}_2}}{\chi_{\text{COS}} \text{GPP}} \quad (\text{Eq.10})$$

$$226 \quad \frac{\partial\iota}{\partial\chi_{\text{COS}}} = \frac{-\chi_{\text{CO}_2} F_{\text{COSmod}}}{\chi_{\text{COS}}^2 \text{GPP}} \quad (\text{Eq.11})$$

$$227 \quad \frac{\partial\iota}{\partial\text{GPP}} = \frac{\chi_{\text{CO}_2} F_{\text{COSmod}}}{\chi_{\text{COS}} \text{GPP}^2} \quad (\text{Eq.12})$$

$$228 \quad \frac{\partial\iota}{\partial\chi_{\text{CO}_2}} = \frac{F_{\text{COSmod}}}{\chi_{\text{COS}} \text{GPP}} \quad (\text{Eq.13})$$

229

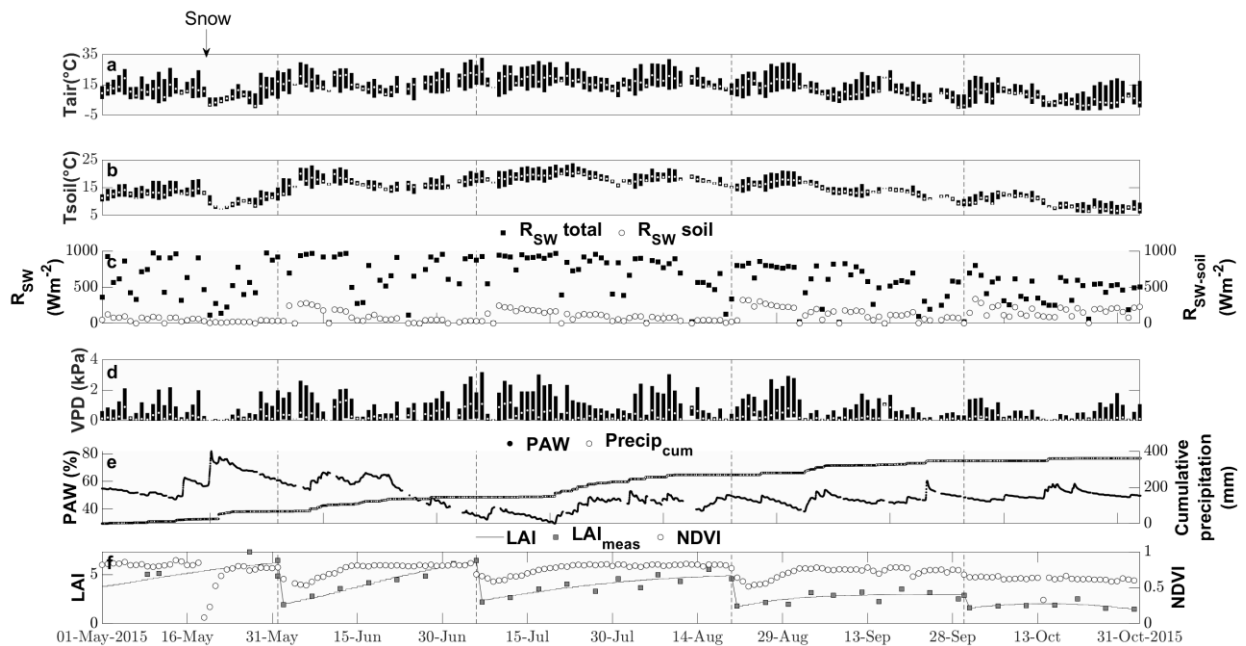

230 2.6 Ancillary data

231 Supporting meteorological measurements included T_{air} (RFT-2, UMS, Munich, GER), T_{soil} (TCAV, Campbell Scientific,
232 Logan, UT, USA), SWC (ML2x, Delta-T Devices, Cambridge, UK), incident solar radiation (CNR-1, Klipp and Zonen,
233 Delft, NLD), incident photosynthetic active radiation (PAR) (BF2H, Delta-T Devices Ltd, Cambridge, UK) and the
234 Normalized Difference Vegetation Index (NDVI) sensor (SRS-NDVI, Meter, Pullman, WA, USA). The data were recorded
235 throughout the whole season as 1 min values and stored as half-hourly means and standard deviations.

236 3 Results

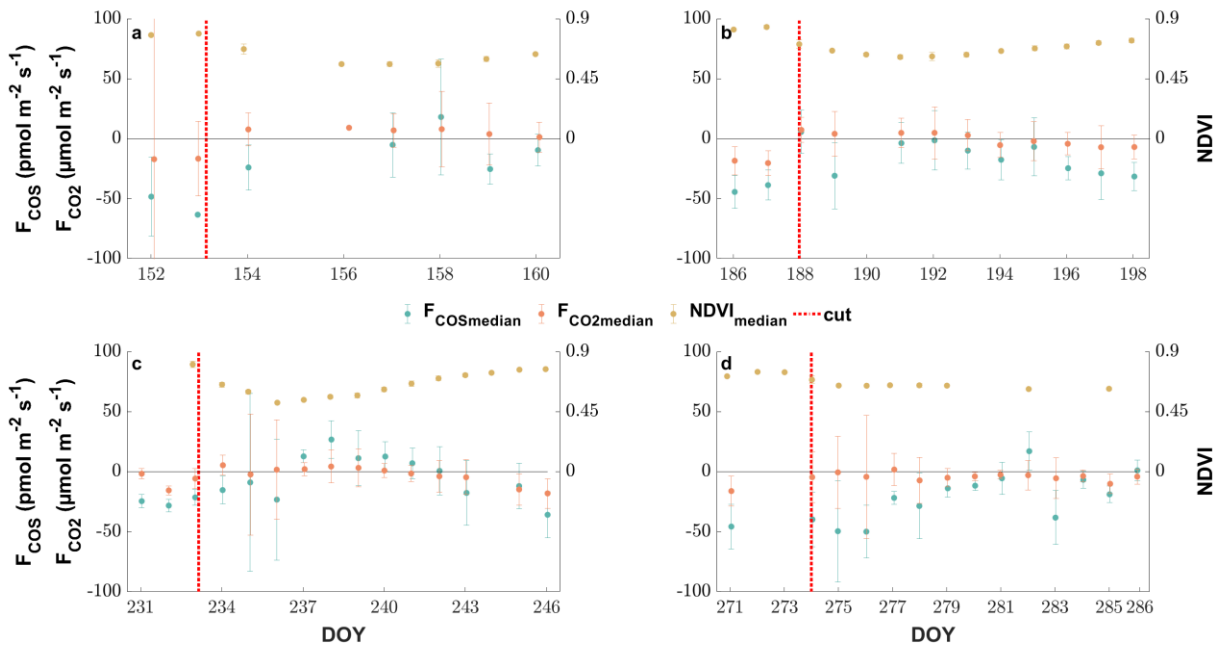

237 3.1 Environmental conditions

238 Air temperature ranged between $-2\text{ }^{\circ}\text{C}$ and $33\text{ }^{\circ}\text{C}$ with a mean of $13\text{ }^{\circ}\text{C}$ during the study period from 15th of May to first of
239 November (Fig. 1). While the majority of precipitation (total 360.5 mm) fell as rain, we observed an exceptionally late snow
240 event on the 20th of May, which did not melt for almost two days (Fig. 1). Although the VPD reached values of above 2 kPa
241 during 25 days, and plant available water dropped below 50 % on 111 days during the campaign (Fig. 1), we did not observe
242 any relationship with COS (see Fig S1-S2). Due to the removal of the aboveground biomass, the cuts reduced LAI. They
243 also reduced the normalized difference vegetation index (NDVI) (Fig. 1), which is a measure of canopy greenness (Tucker,
244 1979). The NDVI further decreased in the subsequent days as a consequence of dying plant parts remaining at the field site
245 (Fig 2 panels a-c). This can also be observed in the webcam photos (Photo S1-S3).

247 **Figure 1.** Seasonal cycle of ancillary variables. Daily minimum, maximum and median (a) air and (b) soil temperatures ($^{\circ}\text{C}$) indicated by
248 the lower and upper end of the bars and the white circle, respectively. (c) Daily maximum incident shortwave radiation (W m^{-2}) reaching
249 the top of the canopy (black squares) and reaching the soil surface (white circles). (d) Daily minimum, maximum and median vapor
250 pressure deficit (kPa) indicated by the lower and upper end of the bars and the white circle, respectively. (e) Plant available water (%)
251 depicted by black squares and cumulative precipitation (mm) depicted by open circles. (f) Modelled leaf area index (black lines), measured
252 LAI (grey squares) and normalized difference vegetation index (open circles).

253

254 **Figure 2:** The response of the daily midday medians of NDVI (yellow circles), COS (blue circles) and CO₂ (red circles) ecosystem fluxes
 255 around the 4 cutting events (a-d) of the grassland. The errorbars depict the respective median absolute deviations. The cuts are marked by a
 256 red dashed line.

257 3.2 COS mixing ratios above and within the canopy

258 While the canopy depleted the ambient χ_{COS} during day as well as nighttime, we found that the χ_{COS} reached values as low as
 259 134 ppt (depletion of 102 ppt with respect to the mixing ratio at canopy height) during nighttime (see Fig. 3) at the bottom of
 260 the canopy in contrast to the midday χ_{COS} , which only went down to 389 ppt (depletion of 125 ppt with respect to the mixing
 261 ratio at canopy height). We observed a decrease in χ_{CO_2} (up to 26 ppm) within the most upper layers of the canopy compared
 262 to χ_{CO_2} at canopy height during daytime, while χ_{CO_2} increased within the lowest layers compared to χ_{CO_2} at the canopy height
 263 due to soil respiration. The above canopy χ_{COS} increased considerably starting at the onset of the day and reached 587 ppt at
 264 4 p.m. with a steep increase until 11 a.m. Over the course of the season the midday ambient χ_{COS} decreased from 500 ± 28 ppt
 265 from mid-June to mid-July to 405 ± 29 ppt in October with the trend of increasing χ_{COS} starting at the end of September (see
 266 Fig. S6).

267

268 **Figure 3.** Vertical gradient of the (a) COS and (b) CO₂ mixing ratio (ppt and ppm, respectively) depicted by the background color between
 269 the soil and the eddy covariance tower at 250 cm for one day. The left y axis shows the log of the measurement divided by the canopy
 270 height (z/h). The white circles depict the incoming shortwave radiation (R_{SW}) in ($W m^{-2}$). Plant area density (PAD) split into living (green)
 271 and dead (brown) plant material (c). Vertical gradient of the difference between the mixing ratio at canopy height and each measurement
 272 height for (d) COS and (e) CO₂.

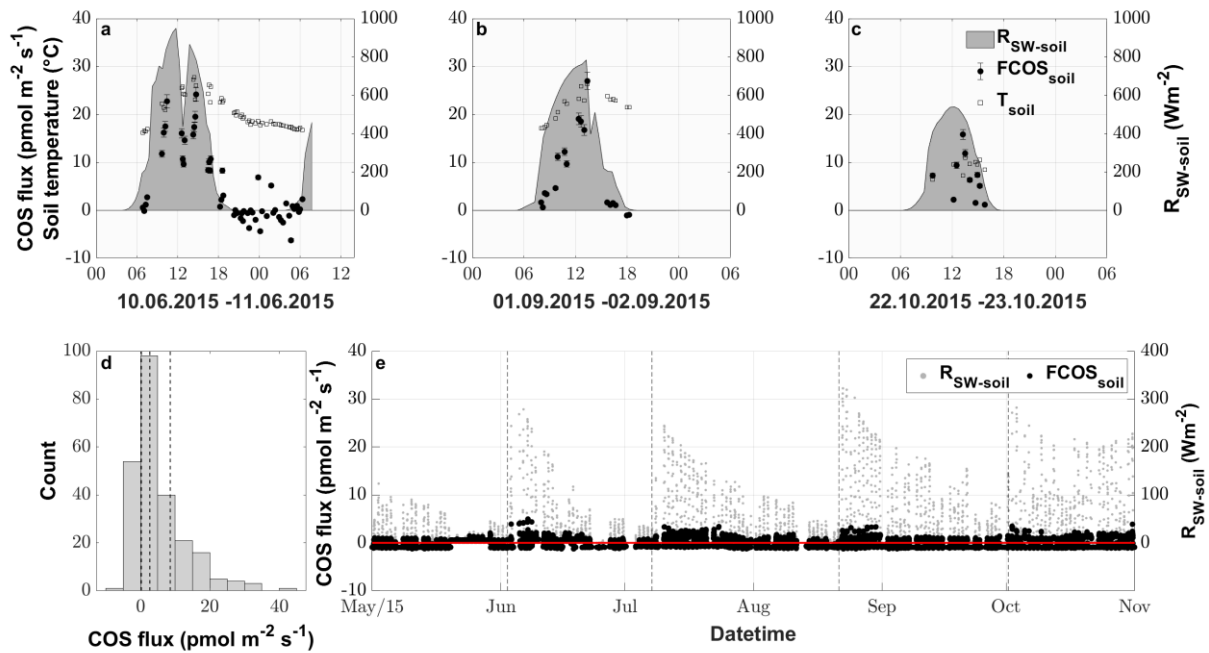

273

274 3.3 COS soil flux

275 The fluxes resulting from the soil chamber measurements ranged from -6.3 to $40.9 \text{ pmol m}^{-2}\text{s}^{-1}$, with positive fluxes denoting
 276 emission (see Fig. 4 panel d).

277 During nighttime ($R_{SW} = 0$, $n = 43$), 74.4 % of the COS fluxes were negative, implying that the soil of the grassland acted
 278 as a net sink for COS (range of -4.4 to $6.9 \text{ pmol m}^{-2}\text{s}^{-1}$), whereas soils transitioned to a source in 88.5 % of all daytime
 279 measurements ($R_{SW} > 0$, $n = 200$), reaching the highest fluxes of $40.9 \text{ pmol m}^{-2}\text{s}^{-1}$ during midday (see Fig. 4 a-c and Fig. S3).
 280 This diel pattern was maintained over the course of the season, however with decreasing maximum COS source strength of
 281 the soil towards the end of the season (Fig. 4 a-c and Fig. S3). The random forest regression revealed that the most important
 282 variable for predicting the soil fluxes was the incident shortwave radiation reaching the soil surface ($R_{SW\text{-soil}}$), accounting for
 283 more than 73.53 % of the total variance explained by the final model, while SWC and T_{soil} only accounted for 17.84 % and
 284 8.62 %, respectively. The fast response of the COS soil fluxes to changes in R_{SW} can be seen in Fig. 4 a, where we observed
 285 a decrease of $R_{SW\text{-soil}}$ as well as the COS soil flux during a cloudy period, even when the soil temperature still increased. Soil
 286 fluxes estimated with the random forest regression ranged from -1.3 to $5.0 \text{ pmol m}^{-2}\text{s}^{-1}$, reflecting the fact that under real-
 287 world conditions very little solar radiation reaches the soil surface. (Fig. 4 e). The resulting emissions peaked during daytime
 288 shortly after the cuts when a high proportion of incident radiation was reaching the soil surface, while simulated nighttime
 289 fluxes were dominated by uptake (in 93 % of all cases) for the whole season.

290

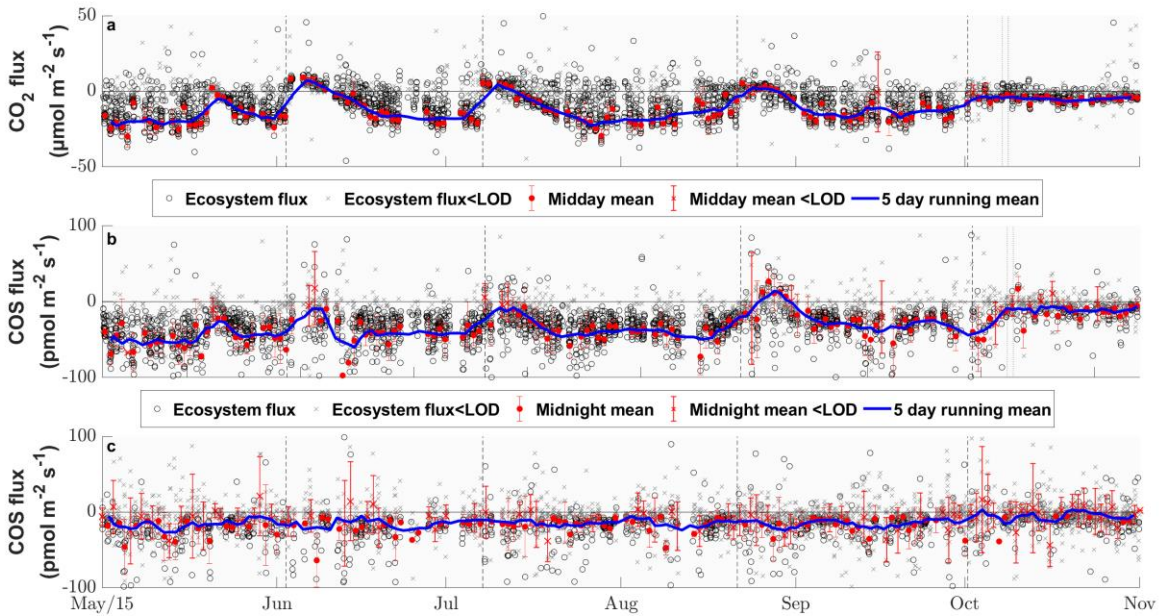

291

292 **Figure 4.** COS soil fluxes ($\text{pmol m}^{-2}\text{s}^{-1}$) originating from manual chamber measurements of three selected days (a), (b) and (c) depicted by
 293 black circles, incident shortwave radiation reaching the soil ($R_{\text{SW-soil}}$) depicted by the gray area and soil temperature (T_{soil}) depicted by
 294 empty black bordered squares. (d) Histogram of all conducted COS soil chamber observations with the dashed vertical lines depicting the
 295 25, 50 and 75% quantile. (e) Season plot of the modelled COS soil fluxes (F_{COSsoil}) depicted by the black circles, incident shortwave
 296 radiation reaching the soil surface ($R_{\text{SW-soil}}$) depicted by grey circles and the black dashed lines depicting the cuttings of the grassland.

297

298 3.4 COS and CO_2 ecosystem-scale fluxes

299 The grassland acted as a net sink for COS during the majority of our study period with 80 % of the COS ecosystem fluxes
 300 between $-56.0 \text{ pmol m}^{-2}\text{s}^{-1}$ and $-4.5 \text{ pmol m}^{-2}\text{s}^{-1}$ during daytime and $-37.8 \text{ pmol m}^{-2}\text{s}^{-1}$ and $9.2 \text{ pmol m}^{-2}\text{s}^{-1}$ during nighttime.
 301 We observed a net release of COS at the field site 11.2 % of the time. The net CO_2 fluxes ranged from -20.4 to $4.8 \text{ } \mu\text{mol m}^{-2}\text{s}^{-1}$
 302 $^2\text{s}^{-1}$ and -30.3 to $36.4 \text{ } \mu\text{mol m}^{-2}\text{s}^{-1}$ for 80% of all observation during day and nighttime, with daytime net emissions occurring
 303 after the cuttings of the grassland (Fig. 2 a-c and Fig. 5 a). While the COS nighttime fluxes remained unaffected by the cuts
 304 (Fig. 5 c), the daytime fluxes showed a high variability (see Fig. 5 b). Especially after the cuts we observed a strong decline
 305 in COS uptake (Fig. 4 b) and the grassland even turned into a net source for COS in middays (Fig. 2 a-c) with a highest
 306 emission flux of $26.8 \text{ pmol m}^{-2}\text{s}^{-1}$ (midday median) in August after the cut. We observed COS emissions for up to 8 days
 307 after the cut, when the dried litter had already been removed (Fig. 2 a-c). Compared to respiration processes outpacing GPP
 308 almost instantaneously after the cuts, the grassland reached its peak COS emission on the day of the cut only in July,
 309 whereas the peak was reached five days after the cut in June and August (Fig. 2 a-c). The cut in October led to a reduction in
 310 COS uptake, which declined across several days and did not recover, as the end of the season was reached (Fig. 2 d & Fig. 5
 311 b). After the fertilization of the field in October the grassland also turned into a source for COS during midday hours for one
 312 day (Fig. 5 b). Our flux measurements also included a time when the grassland was covered with snow (on the 20.05.2015),
 313 which reduced the COS (and CO_2) fluxes to values close to zero. Over the course of the season, we observed a decline in the
 314 magnitude of the daytime COS uptake from $-50.6 \pm 24.6 \text{ pmol m}^{-2}\text{s}^{-1}$ during midday in the first week of May down to $-10.3 \pm$
 315 $10.4 \text{ pmol m}^{-2}\text{s}^{-1}$ in the last week of October, which was also correlated with the decline in the CO_2 sink strength from -19.9
 316 $\pm 8.0 \text{ } \mu\text{mol m}^{-2}\text{s}^{-1}$ to $-4.4 \pm 1.5 \text{ } \mu\text{mol m}^{-2}\text{s}^{-1}$ (Fig. 5 a-b). We observed an increase in COS and CO_2 fluxes within the growing
 317 phases after the cuts only up to an LAI of ~ 4 (-) (Fig. S4-S5), which then levelled out for COS and declined for CO_2 due to
 318 ecosystem respiration compensating GPP.

320

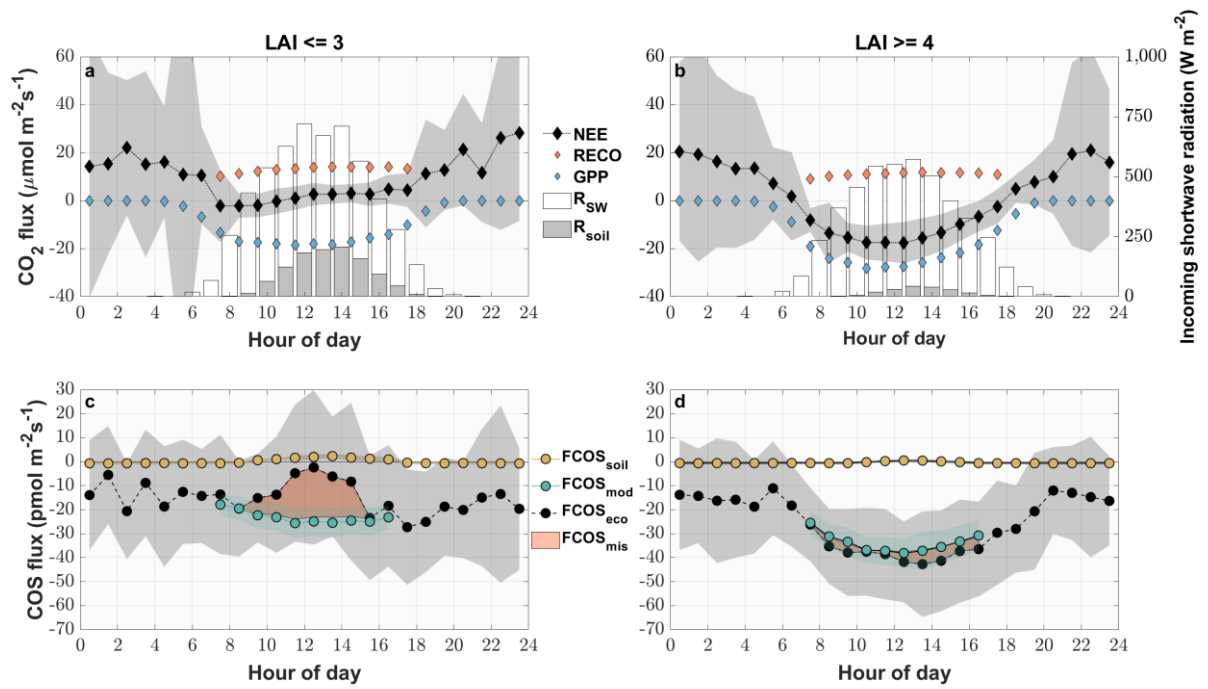

321 **Figure 5:** Seasonal cycle of the half hourly CO₂ (a), COS daytime (b) and COS nighttime (c) ecosystem fluxes in $\mu\text{mol m}^{-2}\text{s}^{-1}$ and $\text{pmol m}^{-2}\text{s}^{-1}$ depicted by black circles if they are above the limit of detection (LOD) and grey x's if they are below (Langford et al., 2015). The red
 322 s^{-1} depicted by black circles if they are above the limit of detection (LOD) and grey x's if they are below (Langford et al., 2015). The red
 323 circles depict the mean fluxes between 11 a.m. and 2 p.m. CET for (a & b) and between 11 p.m. and 2 a.m. for (c) that are above the LOD,
 324 while the red x's indicate means below the LOD. The red error bars depict the ± 1 standard deviation of the mean. The blue lines depict the
 325 running mean (5 days) for the mean fluxes. The black dashed lines depict the cuttings of the grassland.

326

327 The seasonal pattern of a decrease in COS sink strength was similar for nighttime fluxes ($-18.0 \pm 29.6 \text{ pmol m}^{-2}\text{s}^{-1}$ to $-10.6 \pm$
 328 $18.2 \text{ pmol m}^{-2}\text{s}^{-1}$) (Fig. 5c). The mean nighttime respiration also decreased over the course of the season from 15.9 ± 28.2
 329 $\mu\text{mol m}^{-2}\text{s}^{-1}$ to $9.4 \pm 17.5 \mu\text{mol m}^{-2}\text{s}^{-1}$ between May and October (Fig. 5a).

330 Periods between May and August of low (after cuts) and high (before cuts) LAI were compared as diel courses (Fig. 5). Over
 331 the course of the day, both periods were characterized by a mean uptake of COS (Fig 6 c & d). Even though the uptake was
 332 similar during nighttime, the daytime pattern differed considerably. The modelled contribution of the soil to the ecosystem
 333 scale COS flux under high LAI conditions (Fig. 6 d) was minor, contributing between 1.3 % and 5.5/5.7 % of the ecosystem
 334 flux during midday and morning/evening, respectively. In contrast, during low LAI conditions the soil contribution to the
 335 ecosystem fluxes increased during daytime and contributed up to 82.4% of the mean hourly COS ecosystem flux (Fig 6. c).
 336 While the grassland acted as a stronger sink for COS during daytime at a high LAI, reaching peak mean uptake values of up
 337 to $-41.8 \text{ pmol m}^{-2}\text{s}^{-1} \pm 16.8 \text{ pmol m}^{-2}\text{s}^{-1}$ during midday, the mean daytime sink strength weakened and we observed close to
 338 zero fluxes during midday in periods of low LAI. The magnitude of the soil flux ($2 \pm 1 \text{ pmol m}^{-2}\text{s}^{-1}$) was not high enough to
 339 explain the difference of up to $26.0 \text{ pmol m}^{-2}\text{s}^{-1}$ between the measured COS ecosystem flux and COS flux resulting from the
 340 FP+ model (Fig 6 c), suggesting a missing COS source. For phases of high LAI we saw a good agreement between hourly
 341 averaged modelled and measured COS ecosystem fluxes (Fig 6 d). While the grassland acted as a net sink for CO₂ during
 342 periods of high LAI (Fig. 6 b), a combination of a decline in GPP and an increase in daytime RECO, as more incoming
 343 radiation was heating the soil surface, turned it into a net source during midday in periods of low LAI (Fig. 6 a).

344

346

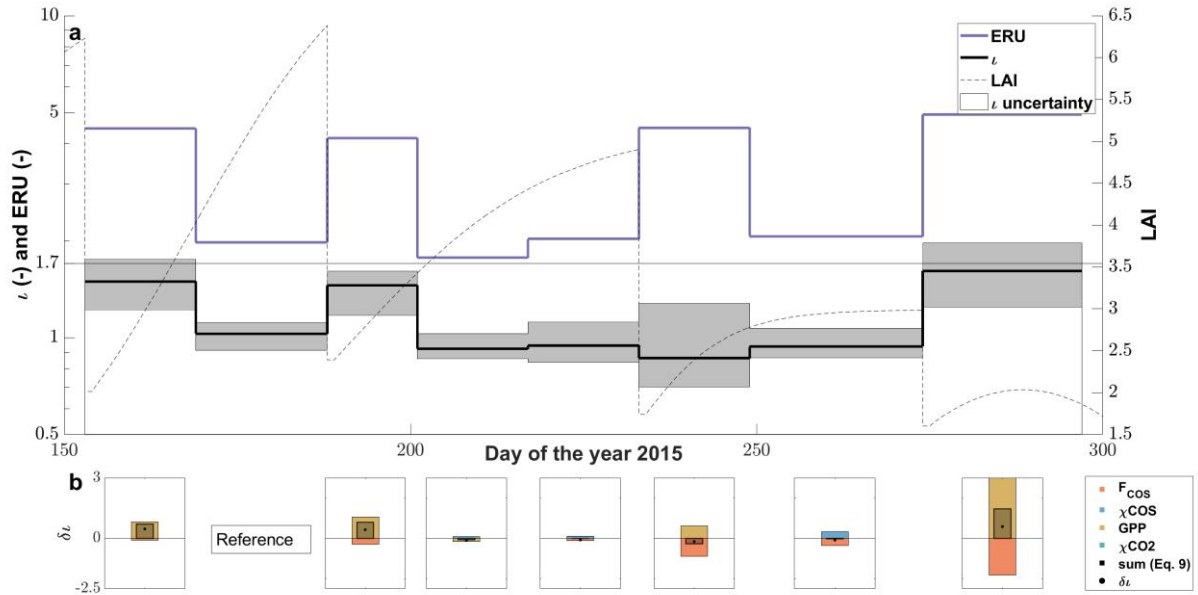

347 **Figure 6.** Mean diel variation of the measured and modelled CO₂ (a & b) and COS (c & d) fluxes for phases of low (LAI ≤ 3) (a & c) and
 348 high (LAI ≥ 4) (b & d) from May to August. The carats depict the modelled gross primary productivity (blue), the modelled ecosystem
 349 respiration (red) and the measured CO₂ ecosystem fluxes (black) in μmol m⁻²s⁻¹. The circles depict the modelled COS soil flux (yellow),
 350 the modelled COS ecosystem flux (turquoise) and the measured COS ecosystem fluxes (black) in pmol m⁻²s⁻¹. The red area depicts the
 351 difference between the measured ecosystem flux and the sum of the modelled fluxes. The grey areas depict the ±1 standard deviation of
 352 the mean for all the measured fluxes. The white bars depict the diel mean total incoming shortwave radiation (W m⁻²) while the grey bars
 353 indicate the diel mean shortwave radiation reaching the soil surface.

354

355 3.5 Leaf and ecosystem relative uptake

356 The LRU at high-light conditions, τ , which we calculated using the FP+ algorithm increased from relatively stable pre-cut
 357 levels of 0.9-1. (-) before the 2nd and the 1st cut to up to 1.6 (-) after the 4th cut (Fig. 7a). After the decrease in τ between the
 358 2nd and the 3rd cut, τ increased steadily until the 4th cut, with the 3rd cut seemingly not having an effect. The reason for the
 359 increase in τ after the 2nd and 4th cut was a stronger decrease in GPP than the COS uptake, while both decreased more evenly
 360 after the 3rd cut (Fig. 7b). We observed τ in the period before the 4th cut to be influenced not only by a decrease in COS
 361 uptake, but also by a decrease in COS mixing ratio (Fig 7b). The mean midday ERUs varied between 2.0 ± 0.1 (-) before and
 362 4.5 ± 0.4 (-) after the cuts. The larger difference between the ERU and τ after the cuts reflect that we observed similar
 363 respiration rates at low and high LAI (Fig 6a-b).

364 Under low light conditions, the LRU increased during pre- and post-cut phases in a similar manner with the last 15-day
 365 period in October showing an earlier increase in the morning and evening (see Fig. S7).

367

368 **Figure 7.** (a) The seasonal cycle of ι (black line) with the 95% confidence interval (gray area) resulting from the FP+ model and the
 369 midday mean (11 a.m. – 2 p.m. at PAR > 800 $\mu\text{mol m}^{-2} \text{s}^{-1}$) ecosystem relative uptake (ERU) (blue line) using the CO₂ ecosystem flux for
 370 the calculation windows (~15 days adjusted to cuts). The dashed black line depicts the progression of the leaf area index (LAI) of the
 371 grassland. (b) The contribution of the drivers (F_{COS} , χ_{COS} , GPP and χ_{CO_2}) to the changes in ι between all calculation windows and the
 372 reference period (DOY 169-188) resulting from the linear perturbation analysis compared to the observed change in ι ($\delta\iota$).

373 4 Discussion

374 4.1 COS mixing ratios

375 The continuous seasonal decrease in above-canopy χ_{COS} was within the range of published records observing mixing ratios to
 376 decrease from 465 (in summer) to 375 ppt (in winter) (Kuhn et al., 1999). This pattern is typical for the northern hemisphere
 377 and the COS drawdown by terrestrial ecosystems (Montzka et al., 2007). We found the lowest χ_{COS} at the end of September,
 378 which coincides with the lowest ambient mixing ratios of COS, measured in Ireland, the closest COS observation site Mace
 379 Head (MHD) of NOAA, on the 6th of October (Fig. S6).

380 The extremely low COS canopy mixing ratios we observed within the canopy, have also been reported by Rastogi et al.
 381 (2018), who measured a mean χ_{COS} minimum of 152 ppt at 1 m above the soil within an old growth forest. Compared to the
 382 consistent decrease of COS below the canopy level during day and nighttime, the gradient for CO₂ reverses during nighttime
 383 due to ongoing respiration processes while plants are not photosynthetically active. Even though the COS mixing ratio at the
 384 layer closest to the soil were higher during day than during nighttime, the absolute decrease in COS was lower during
 385 nighttime due to partial stomatal closure (Kooijmans et al., 2017; Campbell et al., 2017). The absolute difference in
 386 concentrations during day and nighttime originate from changes in the height of the planetary boundary layer (PBL). While
 387 the PBL is shallow during nighttime and the COS mixing ratio decreases due to sink strength of the grassland, at the onset of
 388 the day, the PBL layer height increases fast and COS rich air is transported down to the ecosystem (Fig. S12) (Campbell et
 389 al., 2017). A similar steep increase until midday has also been observed by Rastogi et al. (2018). Even though CO₂ and COS
 390 share a similar pathway into plants, reflected by their respective decrease in the mixing ratios within the canopy, we saw a
 391 difference at the lower levels of our gradient analysis during daytime. We only observed an increase in CO₂ mixing ratios,
 392 caused by the release of CO₂ through respiration processes in the soil, whereas COS mixing ratios further declined down to
 393 the soil surface. This supports our soil model, which predicted only minor COS fluxes under conditions of high LAI, when
 394 only a small portion of incident radiation reaches the soil surface.

395 4.2 Soil fluxes

396 The nighttime soil chamber measurements compare well in terms of magnitude with the COS fluxes resulting from studies
397 using dark chambers in agricultural and grassland sites (Whelan et al., 2018;Maseyk et al., 2014;Whelan and Rhew,
398 2016;Liu et al., 2010) and indicate the soil to be a small sink for COS. The current understanding of COS soil exchange links
399 the COS consumption to soil biota e.g. bacteria and fungi, possessing the ubiquitous enzyme CA (Kesselmeier et al.,
400 1999;Meredith et al., 2019). The origin of COS in soils on the other hand is still highly debated, but comparisons of
401 untreated and sterilized soils suggest yet unknown abiotic processes (Meredith et al., 2019;Kitz et al., 2019).

402 The high COS emissions resulting from the soil chambers during daytime lie at the upper end of recently stated values of
403 agricultural and grassland sites (Whelan et al., 2018;Kitz et al., 2017;Maseyk et al., 2014;Liu et al., 2010). Partly, this can be
404 attributed to the type of chambers we used and their deployment. We allowed the full spectrum of incoming radiation to
405 reach the soils surface, whereas most other studies used dark chambers. Therefore we were able to capture the influence of
406 COS emission processes coupled to thermo- and photo production on our COS soil fluxes (Whelan and Rhew, 2015;Kitz et
407 al., 2019;Meredith et al., 2018). This also led to lower peak soil emissions of COS at the end of the season, when the
408 incoming radiation declined.

409 The low COS mixing ratios observed in the lowermost canopy layers just above the soil surface emphasize the importance of
410 using air from within the canopy for soil chamber measurements and not COS richer air from above the canopy, which
411 would increase the COS gradient and thus increase the uptake/decrease emission of COS to/from the soil.

412 Our modelled COS soil fluxes peak at about 12% of the maximum emissions retrieved from the soil chambers. This is owed
413 to the difference in incident radiation reaching the soil surface between the fluxes resulting from chamber measurements and
414 our model. For the chambers, the aboveground biomass was removed, whereas our modelled fluxes were adjusted for
415 undisturbed canopy conditions.

416 Another factor contributing to the high COS soil emissions might be the yearly fertilization using slurry, as high nitrogen
417 content in soils has been linked to a higher source strength of COS (Kaisermann et al., 2018). This agrees well with the study
418 of Kitz et al. (2019), who found a correlation between increased soil nitrogen content and soil COS emission in a laboratory
419 experiment with samples taken from the grassland at two different dates (i.e. June and September).
420

421 4.3 Ecosystem fluxes

422 Our observations show that the agriculturally used grassland acted as a major sink for COS during the growing season. The
423 fluxes fit well within or even exceeded the COS uptake rates of published grassland and agricultural sites during their
424 growing phases (Billesbach et al., 2014;Whelan and Rhew, 2016;Geng and Mu, 2004). The late snow event that occurred in
425 the peak growing season almost completely inhibited the exchange of CO₂ and COS, as the snow acted as a diffusion barrier
426 for these compounds (Björkman et al., 2010).

427 The cuttings and the consecutive drying of the above ground plant material at the site had a major influence on the COS
428 exchange. COS emissions of a similar magnitude have also been reported at agricultural fields in phases of senescence
429 (Maseyk et al., 2014;Billesbach et al., 2014). Although the soil was a strong source for COS, caused by the high R_{soil} and
430 T_{soil} (Whelan and Rhew, 2015;Kitz et al., 2019;Meredith et al., 2018), and the sink strength of the grassland was low due to
431 the reduced aboveground biomass, soil fluxes did not explain the emission on ecosystem level (see Fig. 6a). As plants
432 contain precursors involved in COS emission processes, e.g. methionine and cysteine (Meredith et al., 2018), the plant litter
433 and dying plant parts remaining at the site after the cuts might be the missing source of COS. Laboratory tests of the soil of
434 the grassland have shown that a mixing of dried litter and soil lead to a strong but short-lived emission peak of COS (Kitz et
435 al., 2019). We did not observe strong COS emissions after the last cut, as the incoming solar radiation, which we hypothesize
436 to amplify the degradation of sulfur containing compounds of plants, was reduced at the end of the season. Alternatively, the

437 cutting of the grassland might induce stress mediated COS production in the remaining living plant parts (Bloem et al.,
438 2012; Gimeno et al., 2017). The delay in the peak COS emissions at ecosystem scale after the cuts could indicate that some
439 yet unknown biotic or abiotic processes take several days to release COS.

440 The short-lived COS emission by yet unknown biotic or abiotic processes after the fertilization of the grassland towards the
441 end of the growing season was likely triggered by the increase of available nitrogen (Kaisermann et al., 2018) and COS
442 precursors introduced to the soil in the form of cattle slurry (Hörtnagl et al., 2018).

443 Due to the independence of CA to catalyze COS without R_{PAR} (Stimler et al., 2011), the grassland remained a sink for COS
444 during nighttime. Again, the soil sink was too small to explain the total COS exchange (Fig. 6), which indicates that the plant
445 stomata were not fully closed (Kooijmans et al., 2017) and were responsible for the majority of the COS uptake. The
446 minimum or residual stomatal conductances at the field site in Neustift have been reported to be between 10 and 65 mmol m^{-2}
447 s^{-1} depending on the species (Wohlfahrt, 2004).

448 The large variability in COS nighttime fluxes (Fig. 5c) is due to the combination of low wind speeds and stable stratification,
449 which results in highly intermittent CO_2 (Wohlfahrt et al., 2005) and COS fluxes compared to daytime. On half-hourly basis,
450 even a nighttime net uptake of CO_2 has been reported at the field site, which is typically compensated for by large CO_2
451 emissions in a subsequent averaging period (Wohlfahrt et al., 2005). We also observed this pattern for COS.

452 Although we observed phases of high VPD and low SWC (Fig. 1), they did not lead to a decrease in CO_2 and COS
453 ecosystem fluxes (Fig. S1-S2), which has already been observed for the grasslands CO_2 and H_2O fluxes between 2001 and
454 2009. The species located at the site were insensitive to progressive drought conditions (Brilli et al., 2011).

455

456 **4.4 LRU**

457 The parameter τ of this study is placed at the lower end of a recent compilation of published leaf-level LRUs, that put 95% of
458 all data between 0.7 (-) and 6.2 (-) with a median of 1.7 (-) (Whelan et al., 2018) and also lower than the LRU of 2.53 (-)
459 estimated for grasslands by Seibt et al. (2010). Even the higher τ after the cuts was low compared to these studies. The
460 seasonal trend of τ was strongly influenced by the cutting of the grass and can be attributed mainly to changes in the ratio of
461 COS uptake to GPP. However, we also observed a strong decline in the ambient mixing ratio of COS, which also had an
462 equally strong influence on the change in τ as the COS flux for the 15 day window before the last cut (Fig 7 b).

463 Even though the changes in τ can be explained, it is important to keep in mind that the grassland was a source for COS on
464 ecosystem level after the cuts. For the calculation of LRUs we had to remove the canopy flux data containing COS and/or
465 CO_2 emissions since they would yield negative values for ERU and LRU (see Eq.8). This indicates that the unknown source
466 strength after cuts likely decreases the post-cut τ 's.

467 **5 Conclusion**

468 Due to the management interventions at the grassland site, the leaf area development was decoupled from seasonal changes
469 in environmental forcing. This allowed us to measure concurrent CO_2 and COS fluxes at soil and ecosystem level for
470 multiple growing periods within one season. The LAI on seasonal scale as well as incoming solar radiation on hourly to
471 seasonal scales determined whether soils were a source or a sink for COS. The incoming shortwave radiation reaching the
472 soil surface had a decisive influence on the COS soil surface flux and thus supports our hypothesis H4. The covariance
473 between the daytime CO_2 and COS fluxes on daily to seasonal level was high and the fluxes only diverged after the cuts,
474 leading to higher LRUs. Beside the perturbations of the ecosystem, the sink strength of the grassland was high for COS and
475 declined over the course of the season (H1). The COS emissions at ecosystem scale shortly after the cuts, which could not be
476 explained by the soil source, raise questions about other unknown mechanisms of COS production within ecosystems (H2).

477 With the exception of short periods after the cuts, the LRUs under high light conditions were relatively constant during the
478 season, indicating a good correlation between the COS flux and GPP under stable conditions (H3).
