39

40 **Abstract**

41 The element silicon (Si) is required for the growth of silicified organisms in marine
42 environments, such as diatoms, which consume vast amounts of Si together with N, P, and C,
43 connecting the biogeochemical cycles of these elements. Thus, understanding the Si cycle in
44 the ocean is critical for understanding issues such as carbon sequestration by the ocean's
45 biological pump. In this review, we show that recent advances in process studies indicate that
46 total Si inputs and outputs, to and from the world ocean, are 57 % and 18 % higher, respectively,
47 than previous estimates. We also update the total ocean silicic acid inventory value, which is
48 about 24 % higher than previously estimated. These changes are significant, modifying factors
49 such as the geochemical residence time of Si, which is now about 8,000 years and two times
50 faster than previously assumed. In addition, we present an updated value of the global annual
51 pelagic biogenic silica production ($255 \text{ Tmol-Si yr}^{-1}$) based on new data from 49 field studies
52 and 18 model outputs, and provide a first estimate of the global annual benthic biogenic silica
53 production due to sponges ($6 \text{ Tmol-Si yr}^{-1}$). Given these important modifications, we address
54 the steady state hypothesis of the Si cycle for past and modern oceans, and propose a possible
55 steady state scenario for the global ocean (inputs = outputs = $14.8 \text{ Tmol-Si yr}^{-1}$) and boundary
56 exchange zone. Case studies for future programs are highlighted, and potential impacts of
57 global change on the marine Si cycle discussed.

58

59 **1. Introduction**

60 Silicon, the seventh-most abundant element in the universe, is the second-most abundant
61 element of the Earth's crust. The weathering of the Earth's crust by CO_2 -rich rain water, a key
62 process in the control of atmospheric CO_2 , results in the generation of silicic acid (dSi; Si(OH)_4)
63 in aqueous environments. Silicifiers use dSi to precipitate biogenic silica (bSi; SiO_2) as internal
64 (Moriceau et al., 2019) and/or external (Maldonado et al., 2019) structures. They are among the
65 most important aquatic organisms, including micro-organisms (e.g. diatoms, rhizarians,
66 silicoflagellates, several species of choanoflagellates), and macro-organisms (e.g. siliceous
67 sponges). Phototrophic silicifiers, such as diatoms, globally consume vast amounts of Si
68 concomitantly with nitrogen, phosphorous and inorganic carbon, connecting the
69 biogeochemistry of these elements and contributing to the sequestration of atmospheric CO_2 in
70 the ocean (Tréguer & Pondaven, 2000). Heterotrophic organisms like rhizarians,
71 choanoflagellates and sponges produce bSi independent of the photoautotrophic processing of C
72 and N, a bSi that has been named "dark silica" (Maldonado et al., 2012, 2019).

73 Understanding the Si cycle is critical for understanding the functioning of marine food webs,
74 biogeochemical cycles, and the biological carbon pump. Herein, we review recent advances in
75 field observations and modelling that have changed our understanding of the global Si cycle
76 and provide an update of four of the six net annual input fluxes and of all the output fluxes
77 previously estimated by Tréguer & De La Rocha (2013). Taking into account numerous field
78 studies in different marine provinces and model outputs, we re-estimate the “canonical” value
79 of Si production (Nelson et al., 1995), review the potential contribution of rhizarians (Llopis
80 Monferrer et al., 2020) and picocyanobacteria (Ohnemus et al., 2016), and give an estimate of
81 the total bSi production by siliceous sponges using recently published data on sponge bSi in
82 marine sediments (Maldonado et al., 2019). We discuss the question of the balance/imbalance
83 of the marine Si biogeochemical cycle at different time scales, and propose a possible steady
84 state scenario for the modern ocean, with inputs balancing outputs at $14.8 \text{ Tmol yr}^{-1}$ (Fig. 1).
85 Finally, we address the question of the potential impact of anthropogenic activities on the global
86 Si cycle and suggest guidelines for future research endeavours.

87

88 2. Advances in input fluxes

89 As illustrated in Figure 1, silicic acid (dSi) is delivered to the ocean through six pathways,
90 which all ultimately derive from the weathering of the Earth’s crust (Tréguer & De La Rocha,
91 2013). All fluxes are given with standard deviations.

92 2.1 Riverine (F_R) and Aeolian (F_A) contributions

93 The best estimate for the riverine input (F_R) of dSi, based on data representing 60 % of the
94 world river discharge and a discharge-weighted average dSi riverine concentration of $158 \mu\text{M-Si}$
95 (Dürr et al., 2011), remains at $F_{RdSi} = 6.2 (\pm 1.8) \text{ Tmol-Si yr}^{-1}$ (Tréguer & De La Rocha,
96 2013). However, Si is transferred from the terrestrial to the riverine system, not only as dSi but
97 also as particulate Si, in either its crystallised or amorphous form (Dürr et al., 2011). According
98 to Saccone et al. (2007), the term “amorphous silica” (aSi) gathers biogenic silica (bSi, from
99 phytoliths, freshwater diatoms, sponge spicules), altered bSi, and pedogenic silicates, the three
100 of which can have similar high solubilities and reactivities to aSi. Delivery of aSi to the fluvial
101 system has been reviewed by Frings et al. (2016) and they suggested a value of $F_{RaSi} = 1.9 (\pm$
102 $1.0) \text{ Tmol-Si yr}^{-1}$. Therefore, total $F_R = 8.1 (\pm 2.0) \text{ Tmol-Si yr}^{-1}$.

103 Regarding the aeolian dust deposition into the ocean (Tegen & Kohfeld, 2006) and subsequent
104 release of dSi via dust dissolution in seawater, no progress has been made since Tréguer and
105 De La Rocha (2013), which summed the flux of particulate dissolvable silica and wet deposition
106 of dSi through precipitations. Thus, our best estimate for F_A remains $0.5 (\pm 0.5) \text{ Tmol-Si yr}^{-1}$.

107 **2.2 Dissolution of minerals (F_w)**

108 In agreement with Tréguer et al. (1995), Tréguer and De La Rocha (2013) considered benthic
109 Si fluxes from non-siliceous sediments between $\sim 10\text{-}20 \text{ mmol m}^{-2} \text{ yr}^{-1}$, which gave an estimate
110 of $F_w = 1.9 (\pm 0.7) \text{ Tmol-Si yr}^{-1}$ if extrapolated to 120 Mkm^2 zone of opal-poor sediments in the
111 global ocean.

112 About $15\text{-}20 \text{ Gt yr}^{-1}$ river-derived lithogenic particles are deposited along the margins and
113 shelves (e.g. Syvitskia et al., 2003, also see Fig. 2). Dissolution experiments with river
114 sediments or basaltic glass in seawater showed that $0.08\text{-}0.17\%$ of the Si in the solid phase was
115 released within a few days to months (e.g., Jones et al., 2012; Morin et al., 2015; Oelkers et al.,
116 2011; Pearce et al., 2013). However, the high solid-to-solution ratios in these experiments
117 increased the dSi concentration quickly to near-equilibrium conditions inhibiting further
118 dissolution, which prevents direct comparison with natural sediments. Field observations and
119 subsequent modelling of Si release range around $0.5 - 5 \text{ \% yr}^{-1}$ (e.g., Arsouze et al., 2009;
120 Jeandel and Oelkers, 2015). On the global scale, Jeandel et al. (2011) estimated the total flux
121 of dissolution of minerals to range between $0.7 - 5.4 \text{ Tmol-Si yr}^{-1}$, i.e. similar to the dSi river
122 flux, but this estimate is based on the assumption of $1 - 3 \text{ \%}$ congruent dissolution of sediments
123 for a large range of lithological composition which, so far, is not proven. A recent study by
124 Frings (2017) estimates that “non-biogenic silica” sediments (i.e. clays and calcareous
125 sediments, which cover about 78% of the ocean area) may contribute up to $44.9 \text{ Tmol-Si yr}^{-1}$
126 via benthic diffusive Si flux. However, according to lithological descriptions given in GSA
127 Data Repository 2015271 some of the “non-biogenic silica” sediment classes described in this
128 study may contain significant bSi, which might explain Frings’ high estimate for F_w .

129 Therefore, our best estimate for this component remains $1.9 (\pm 0.7) \text{ Tmol-Si yr}^{-1}$.

130 **2.3 Submarine groundwater (F_{GW})**

131 Since 2013, several papers have sought to quantify the global oceanic input of dissolved Si
132 (dSi) from submarine groundwater discharge (SGD), which includes terrestrial (freshwater) and
133 marine (saltwater) components (Fig. 2). Silicic acid inputs through SGD may be considerable,
134 in places similar to or in excess of riverine input. For instance, in the Bay of Bengal, Georg et
135 al. (2009) estimated this input to be $0.093 \text{ Tmol-Si yr}^{-1}$, which is $\sim 66\%$ of the Ganges-
136 Brahmaputra river flux of dSi to the ocean. At world scale, Tréguer and De La Rocha (2013)’s
137 best estimate for F_{GW} was $0.6 (\pm 0.6) \text{ Tmol-Si yr}^{-1}$. More recently, Rahman et al. (2019) used a
138 global terrestrial SGD flux model weighted according to aquifer lithology (Beck et al., 2013)
139 in combination with a compilation of dSi in shallow water coastal aquifers to derive a terrestrial
140 groundwater input of dSi to the world ocean of $0.7 (\pm 0.1) \text{ Tmol-Si yr}^{-1}$. This new estimate,

141 with its relatively low uncertainty, represents the lower limit flux of dSi to the ocean via SGD.
142 The marine component of SGD, driven by a range of physical processes such as density
143 gradients or waves and tides, is fed by seawater that circulates through coastal aquifers or
144 beaches via advective flow paths (Fig. 2; also see Fig. 1 of Li et al., 1999). This circulating
145 seawater may become enriched in dSi through bSi or mineral dissolution, the degree of
146 enrichment being determined by subsurface residence time and mineral type (Anschutz et al.,
147 2009; Ehlert et al. 2016a; Techer et al., 2001).

148 Several lines of evidence show that the mineral dissolution (strictly corresponding to net dSi
149 input) may be substantial (e.g., Ehlert et al., 2016b). Focusing on processes occurring in tidal
150 sands, Anschutz et al. (2009) showed that they can be a biogeochemical reactor for the Si cycle.
151 Extrapolating laboratory-based dissolution experiments performed with pure quartz, Fabre et
152 al. (2019) calculated that the potential flux of dissolution of quartz of sandy beaches, driven by
153 wave and tidal action, at world scale (Luijendijk et al., 2018) could be $3.2 (\pm 1.0) \text{ Tmol Si yr}^{-1}$.
154 However, this estimate, not validated by field experiments, is not well constrained (Supplement,
155 section 1). Cho et al. (2018), using a ^{228}Ra inverse model and groundwater $\text{dSi}/^{228}\text{Ra}$ ratios,
156 estimate the total (terrestrial + marine) SGD dSi flux to the ocean to be $3.8 (\pm 1.0) \text{ Tmol-Si yr}^{-1}$;
157 this represents a realistic upper limit value for SGD's contribution to the global ocean dSi
158 cycle. For the time being, without systematic data that corroborates the net input of dSi through
159 the circulation of the marine component of SGD (e.g., porewater $\delta^{30}\text{Si}$, paired dSi and ^{228}Ra
160 measurements), we estimate the range of net input of dSi through total SGD as $0.7 \text{ Tmol-Si yr}^{-1}$
161 (Rahman et al., 2019) to $3.8 \text{ Tmol-Si yr}^{-1}$ (Cho et al., 2018), with an average, i.e. $F_{\text{GW}} = 2.3$
162 $(\pm 1.1) \text{ Tmol-Si yr}^{-1}$, which is about three times larger than Tréguer & De La Rocha (2013).

163 **2.4 (Sub)polar glaciers (Fismw)**

164 This flux was not considered by Tréguer & De La Rocha (2013). Since 2013, Tréguer (2014)
165 and Hawkings et al. (2017) have identified polar glaciers as sources of Si to marine
166 environments. The current best estimate of discharge weighted dSi concentration in (sub)Arctic
167 glacial meltwater rivers lies between 20-30 μM although concentrations ranging between 3 and
168 425 μM have been reported (Meire et al., 2016; Hatton et al., 2019). Only one value currently
169 exists (Michaud et al., 2016) for dSi from subglacial meltwater in Antarctica (126 μM) and
170 iceberg dSi concentrations are poorly quantified ($\sim 5 \mu\text{M}$) (Meire et al., 2016). Glacier
171 meltwater typically contains high suspended sediment concentrations due to intense physical
172 erosion with a relatively high dissolvable aSi component (0.3-1.5% dry weight) equating to
173 concentrations of 70-340 μM (Hawkings, 2018; Hatton et al., 2019). Iceberg aSi concentrations
174 are lower (28-83 μM) (Hawkings et al., 2017). This particulate phase appears fairly soluble in

175 seawater (Hawkings et al., 2017), and large benthic dSi fluxes in glacially influenced shelf seas
176 have been observed (Hendry et al., 2019; Ng et al., 2020). Silicic acid input from (sub)polar
177 glaciers is estimated to be $0.04 (\pm 0.04)$ Tmol-Si yr⁻¹. If the aSi flux is considered then this may
178 provide an additional $0.29 (\pm 0.22)$ Tmol-Si yr⁻¹, with a total $F_{\text{ISMW}} (= \text{dSi} + \text{aSi})$ input estimate
179 of $0.33 (\pm 0.26)$ Tmol-Si yr⁻¹.

180 **2.5 Hydrothermal activity (F_{H})**

181 Tréguer & De La Rocha (2013)'s estimate for F_{H} was $0.6 (\pm 0.4)$ Tmol-Si yr⁻¹. Seafloor
182 hydrothermal activity at mid-ocean ridges (MOR) and ridge-flanks is one of the fundamental
183 processes controlling the exchange of heat and chemical species between seawater and ocean
184 crust (Wheat & Mottl, 2000). A major challenge limiting our current models of both heat and
185 mass flux (e.g. Si flux) through the seafloor is estimating the distribution of the various forms
186 of hydrothermal fluxes, including focused vs. diffuse and ridge axis vs. ridge flank fluxes.
187 Estimates of the Si flux for each input are detailed below.

188 *Axial and near axial hydrothermal fluxes settings:* The best estimate of the heat flux at ridge
189 axis (i.e. crust 0–0.1 Ma in age) is $1.8 (\pm 0.4)$ TW, while the heat flux in the near-axial region
190 (i.e. crust 0.1–1 Ma in age) has been inferred at $1.0 (\pm 0.5)$ TW (Mottl, 2003). The conversion
191 of heat flux to hydrothermal water and chemical fluxes requires assumptions regarding the
192 temperature at which this heat is removed. For an exit temperature of $350 (\pm 30)$ °C typical of
193 black smoker vent fluids, and an associated enthalpy of $1,500 (\pm 190)$ J g⁻¹ at 450–1000 bars
194 and heat flux of $2.8 (\pm 0.4)$ TW, a maximum seawater flux of $5.9 (\pm 0.8) 10^{16}$ g yr⁻¹ is required
195 (Mottl, 2003). High temperature hydrothermal dSi flux is calculated using a dSi concentration
196 of $19 (\pm 11)$ mmol kg⁻¹, which is the average concentration in hydrothermal vent fluids that
197 have an exit temperature > 300°C. This estimate is based on a compilation of > 100 discrete
198 vent fluid data, corrected for seawater mixing (i.e. end-member values at Mg=0, Edmond et al.,
199 1979) and phase separation. Although the chlorinity of hot springs varies widely, nearly all of
200 the reacted fluid, whether vapor or brine, must eventually exit the crust within the axial region.
201 The integrated hot spring flux must therefore have a chlorinity similar to that of seawater. The
202 relatively large range of dSi concentrations in high-temperature hydrothermal fluids likely
203 reflect the range of geological settings (e.g. fast- and slow-spreading ridges) and host-rock
204 composition (ultramafic, basaltic or felsic rocks). Because dSi enrichment in hydrothermal
205 fluids result from mineral-fluid interactions at depth, and is mainly controlled by solubility of
206 secondary minerals and quartz (Mottl 1983; Von Damm et al. 1991), it is also possible to obtain
207 a theoretical estimate of the concentration of dSi in global hydrothermal vent fluids. Under the

208 conditions of temperature and pressure (i.e. depth) corresponding to the base of the upflow zone
209 of high temperature (>350 - 450°C) hydrothermal systems, dSi concentrations between 16 to
210 22 mmol kg⁻¹ are calculated, which is in good agreement with measured values in end-member
211 hydrothermal fluids. Using a dSi concentration of 19 (± 3.5) mmol kg⁻¹ and water flux of 4.8
212 (± 0.8) × 10¹⁶ g yr⁻¹, we determine an axial hydrothermal Si flux of 0.91 (± 0.29) Tmol-Si yr⁻¹.
213 It should be noted, however, that high-temperature hydrothermal fluids may not be entirely
214 responsible for the transport of all the axial hydrothermal heat flux (Elderfield and Schultz,
215 1996; Nielsen et al., 2006). Because dSi concentrations in diffuse hydrothermal fluids is not
216 significantly affected by subsurface Si precipitation during cooling of the hydrothermal fluid
217 (Escoube et al., 2015), we however consider that the global hydrothermal Si flux is not strongly
218 affected by the nature (focused vs. diffuse) of axial fluid flow.

219 *Ridge flank hydrothermal fluxes:* Chemical fluxes related to seawater-crust exchange at ridge
220 flanks has been previously determined through direct monitoring of fluids from low-
221 temperature hydrothermal circulation (Wheat and Mottl, 2000). Using basaltic formation fluids
222 from the 3.5 Ma crust on the eastern flank of the Juan de Fuca Ridge (Wheat and McManus,
223 2005), determined a global flux of 0.011 Tmol-Si yr⁻¹ for warm ridge flank. This estimate is
224 based on the measured Si anomaly associated with warm spring (0.17 mmol kg⁻¹) and a ridge
225 flank fluid flux determined using oceanic Mg mass balance, therefore assuming that the ocean
226 is at steady-state with respect to Mg. More recent results of basement fluid compositions in cold
227 and oxygenated ridge flank settings (e. g. North Pond, Mid-Atlantic Ridge) also confirms that
228 incipient alteration of volcanic rocks may result in significant release of Si to circulating
229 seawater (Meyer et al., 2016). The total heat flux through ridge flanks, from 1 Ma crust to a
230 sealing age of 65 Ma, has been estimated at 7.1 (± 2) TW. Considering that most of ridge-flank
231 hydrothermal power output should occur at cool sites (< 20°C), the flux of slightly altered
232 seawater could range from 0.2 to 2 × 10¹⁹ g yr⁻¹, rivaling with the flux of river water to the ocean
233 of 3.8 × 10¹⁹ g yr⁻¹ (Mottl, 2003). Using this estimate and Si anomaly of 0.07 mmol-Si kg⁻¹
234 reported in cold ridge flank setting from North Pond (S18), a Si flux of 0.14 to 1.4 Tmol-Si yr⁻¹
235 for cold ridge flank could be determined. Because of the large volume of seawater interacting
236 with oceanic basalts in ridge flank settings, even a small chemical anomaly resulting from
237 reactions within these cold systems could result in a globally significant elemental flux. Hence,
238 additional studies are required to better determine the importance of ridge flanks to oceanic Si
239 budget.

240 Combining axial and ridge flank estimates, the best estimate for F_H is now $1.7 (\pm 0.8)$ Tmol-Si
241 yr^{-1} , about three times larger than Tréguer & De La Rocha (2013)'s estimate.

242 **2.6 Total net inputs** (Table 1A)

243 Total Si input = $8.1 (\pm 2.0)$ ($F_{R(\text{dSi}+\text{aSi})}$) + $0.5 (\pm 0.5)$ (F_A) + $1.9 (\pm 0.7)$ (F_W) + $2.3 (\pm 1.1)$ (F_{GW})
244 + $0.3 (\pm 0.3)$ (F_{ISMW}) + $1.7 (\pm 0.8)$ (F_H) = **$14.8 (\pm 2.6)$ Tmol-Si yr^{-1} .**

245 The uncertainty of the total Si inputs (and total Si outputs, section 3) has been calculated using
246 the error propagation method (Bevington and Robinson, 2003). This has been done for the total
247 fluxes and the individual flux estimates.

248

249 **3. Advances in output fluxes**

250 **3.1 Long-term burial of planktonic biogenic silica in sediments (F_B)**

251 Long-term burial of bSi, which generally occurs below the top 10-20 cm of sediment, was
252 estimated by Tréguer & De La Rocha (2013) to be $6.3 (\pm 3.6)$ Tmol-Si yr^{-1} . The burial rates are
253 highest in the Southern Ocean (SO), the North Pacific Ocean, the equatorial Pacific Ocean, and
254 in the coastal and continental margin zone CCMZ (DeMaster et al., 2002; Hou et al., 2019;
255 Rahman et al., 2017).

256 Since DeMaster (2002) the burial rate in the open ocean remains unchanged at $>1.04 (\pm 0.34)$
257 Tmol-Si yr^{-1} . Pichevin et al. (2014) have shown that bSi burial may also be enhanced in Fe
258 limited regions in the open ocean, which include the SO, warranting further study on the
259 physical and chemical factors that control the form of burial output fluxes of Si. For the SO,
260 particularly in the “opal belt” zone (Geibert et al., 2005), to correct for processes like
261 winnowing and focusing (leading to under- and over-estimation of uncorrected sedimentation
262 and burial rates), the burial rates are typically normalized using the particle reactive nuclide
263 ^{230}Th (Geibert et al., 2005). Chase et al. (2015) has revised upward Tréguer & De La Rocha
264 (2013)'s estimate. According to these authors the best estimate for the SO burial rate, south of
265 40°S , is now $2.3 (\pm 1.0)$ Tmol-Si yr^{-1} .

266 Regarding the CCMZ, estimates of silica burial rates have been usually determined from carbon
267 burial rates using a Si : C ratio of 0.6 (DeMaster 2002). However, we now have independent
268 estimates of marine organic C and of total initial bSi burial (e.g. Aller et al., 1996; Aller et al.,
269 2008; Galy et al., 2007; Rahman et al., 2016, 2017). It has been shown that the initial bSi burial
270 in sediment evolved as unaltered bSi or as authigenically formed alumino-silicate phase
271 (Rahman et al., 2017). The Si : C burial ratios of residual marine plankton post-remineralization
272 in tropical and subtropical deltaic systems are much greater (2.4 - 11) than the 0.6 Si:C burial

273 ratio assumed for continental margin deposits (DeMaster, 2002). Therefore, the sedimentary
274 Si:C preservation ratios are suggested to depend on differential remineralization pathways of
275 marine bSi and C_{org} under different diagenetic regimes (Aller et al., 1996). Partitioning of ^{32}Si
276 activities between bSi and mineral pools in tropical deltaic sediments indicate rapid and near-
277 complete transformation of initially deposited bSi to authigenic clay phases (Rahman et al.,
278 2017). For example, in subtropical/temperate deltaic and estuarine deposits, ^{32}Si activities
279 signal approximately ~50% of initial bSi_{opal} delivery to sediments (Rahman et al., 2017). Using
280 the ^{32}Si technique Rahman et al. (2019) provided an updated estimate of bSi burial for the
281 CCMZ of $3.7 (\pm 2.1) \text{ Tmol-Si yr}^{-1}$, higher than Tréguer and De La Rocha (2013)'s estimate of
282 $3.3 (\pm 2.1) \text{ Tmol-Si yr}^{-1}$ based on the Si:C method of DeMaster (2002).

283 Combining DeMaster (2002)'s burial rate of the open ocean zone with these new estimates for
284 the SO and the CCMZ gives a revised global total burial flux, F_b , of $> 7.0 (\pm 2.4) \text{ Tmol-Si yr}^{-1}$,
285 11 % larger than Tréguer and De La Rocha (2013)'s estimate.

286 **3.2 Deposition and long-term burial of sponge silica (F_{SP})**

287 Tréguer and De La Rocha (2013)'s estimate for F_{SP} , the net sink of sponge bSi in sediments of
288 continental margins, was $3.6 (\pm 3.7) \text{ Tmol Si yr}^{-1}$. The longevity of sponges, ranging from years
289 to millennia, temporally decouples the process of skeleton production from the process of
290 deposition to the sediments (Jochum et al., 2017). While sponges slowly accumulate bSi over
291 their long and variable lifetimes (depending on the species), the deposition to the sediments of
292 the accumulated bSi is a relatively rapid process after sponge death, lasting days to months
293 (Supplement, section 2). Tréguer and De La Rocha (2013)'s estimate was calculated as the
294 difference between the sponge dSi demand on continental shelves ($3.7 (\pm 3.6) \text{ Tmol Si yr}^{-1}$) —
295 estimated from silicon consumption rates available for few sublittoral sponge species
296 (Maldonado et al., 2011) —, and the flux of dSi from the dissolution of sponge skeletons in
297 continental shelves ($0.15 (\pm 0.15) \text{ Tmol Si yr}^{-1}$). This flux was tentatively estimated from the
298 rate of dSi dissolution from a rare, unique glass sponge reef at British Columbia (Canada) (Chu
299 et al., 2011) and which is unlikely to be representative of the portion of sponge bSi that dissolves
300 back as dSi after sponge death and before their burial in the sediments. To improve the estimate,
301 Maldonado et al. (2019) used microscopy to access the amount of sponge silica that was actually
302 being buried in the marine sediments using 17 sediment cores representing different marine
303 environments. The deposition of sponge bSi was found to be one order of magnitude more
304 intense in sediments of continental margins and seamounts than on continental rises and central
305 basin bottoms. By assuming that the rate of sponge silica deposition in each core had been
306 approximately constant through the Holocene, the new best estimate (Maldonado et al. (2019)

307 for F_{SP} is $1.7 (\pm 1.6) \text{ Tmol-Si yr}^{-1}$, i.e. two times smaller than Tréguer and De La Rocha's
308 preliminary estimate.

309 **3.2 Reverse Weathering flux (F_{RW})**

310 The previous estimate for this output flux, provided by Tréguer & De La Rocha (2013), $F_{RW} =$
311 $1.5 (\pm 0.5) \text{ Tmol-Si yr}^{-1}$, was determined using indirect evidence since the influence of reverse
312 weathering on the global Si cycle prior to 2013 was poorly understood. For example, reverse
313 weathering reactions at the sediment–water interface were previously thought to constitute a
314 relatively minor sink ($0.03 - 0.6 \text{ Tmol-Si yr}^{-1}$) of silica in the ocean (DeMaster, 1981). The
315 transformation of bSi to a neoformed aluminosilicate phase, or authigenic clay formation, was
316 assumed to proceed slowly ($> 10^4 - 10^5$ years) owing principally to the difficulty of
317 distinguishing the contribution of background lithogenic or detrital clays using the common
318 leachates employed to quantify bSi (DeMaster, 1981). Recent direct evidence supporting the
319 rapid formation of authigenic clays comes from tropical and subtropical deltas (Michalopoulos
320 & Aller, 1995; Rahman et al., 2016, 2017; Zhao et al., 2017) and several geochemical tools
321 show that authigenic clays may form ubiquitously in the global ocean (Baronas et al., 2017;
322 Ehlert et al., 2016a; Michalopoulos & Aller, 2004). Activities of cosmogenic ^{32}Si ($t_{1/2} \sim 140$
323 yrs), incorporated into bSi in the surface ocean, provide demonstrable proof of rapid reverse
324 weathering reactions by tracking the fate of bSi upon delivery to marine sediments (Rahman et
325 al., 2016). By differentiating sedimentary bSi storage between unaltered bSi (bSi_{opal}) and
326 diagenetically altered bSi ($\text{bSi}_{\text{altered}}$) in the proximal coastal zone, ^{32}Si activities in these pools
327 indicate that $3.7 \text{ Tmol-Si yr}^{-1}$ is buried as unaltered bSi_{opal} (also see Supplement, section2) and
328 $4.7 (\pm 2.3) \text{ Tmol-Si yr}^{-1}$ as authigenic clays (bSi_{clay}) on a global scale. Here, we adopt 4.7 Tmol-
329 Si yr^{-1} for F_{RW} representing about three times the Tréguer & De La Rocha (2013)'s value.

330 **3.3 Total net output (Table 1A)**

331 Total Si output = $7.0 (\pm 2.3) (F_{B(\text{net deposit})}) + 4.7 (\pm 2.3) (F_{RW}) + 1.7 (\pm 1.6) (F_{SP}) = \mathbf{13.4 (\pm 3.7)}$
332 **Tmol-Si yr⁻¹.**

333

334 **4. Advances in biological fluxes**

335 **4.1 bSi annual pelagic production**

336 **4.1.1 from field data**

337 The “canonical” value for global gross marine bSi pelagic production is $240 (\pm 40) \text{ Tmol-Si yr}^{-1}$
338 (Nelson et al., 1995). Since 1995, the number of field studies of bSi production (using either
339 the ^{30}Si tracer method, Nelson & Goering (1977) or the ^{32}Si method (Tréguer et al., 1991;
340 Brzezinski & Phillips, 1997), has grown substantially from 15 (1995) to 49 in 2019, allowing

341 the first estimate based on empirical silica production rate measurements (Fig. 3, and
342 Supplement, section 3). It is usually assumed that the silica production, as measured by the
343 above methods, is mostly supported by diatoms, with some unknown (but minor) contribution
344 of other planktonic species.

345 The silica production rates measured during 49 field campaigns were assigned to Longhurst
346 provinces (Longhurst, 2007; Longhurst et al., 1995) based on location, with the exception of
347 the Southern Ocean, where province boundaries were defined according to Tréguer & Jacques
348 (1992). Extrapolating these “time-and-space-limited” measurements of bSi, spatially to a
349 biogeographic province, and annually from the bloom phenology for each province (calculated
350 as the number of days where the chlorophyll concentration is greater than the average
351 concentration between the maximum and the minimum values) results in annual silica
352 production estimates for 26 of the 56 world ocean provinces. For the “ocean basin” estimate
353 (Table 2), the annual production of all provinces in a basin were averaged, and then extrapolated
354 by basin area. For the “domain” estimate (Table 2), the averages from provinces were
355 subdivided among coastal, Southern Ocean, and open ocean domains, and extrapolated based
356 on the area of each domain. Averaging the “ocean basin” and the “domain” annual estimates
357 (Table 2), our best estimate for the global marine bSi production is $267 (\pm 18) \text{ Tmol-Si yr}^{-1}$
358 (Table 2).

359 **4.1.2 bSi annual pelagic production from models**

360 Estimates of bSi production were also derived from satellite productivity models, and from
361 global ocean biogeochemical models (GOBMs).

362 For the estimates based on satellite productivity models, we used global net primary production
363 (NPP) estimates from the carbon-based productivity model (Westberry et al., 2008) and the
364 vertically generalized productivity model (VGPM) (Behrenfeld & Falkowski, 1997). NPP
365 estimates from these models were divided into oligotrophic ($< 0.1 \mu\text{g Chl a L}^{-1}$), mesotrophic
366 ($0.1 - 1.0 \mu\text{g Chl a L}^{-1}$) and eutrophic ($> 1.0 \mu\text{g Chl a L}^{-1}$) areas (Carr et al., 2006). The fraction
367 of productivity by diatoms in each area was determined using the DARWIN model (Dutkiewicz
368 et al., 2015) resulting in diatoms accounting for 29% of the global production. Each category
369 was further subdivided into High Nutrient Low Chlorophyll (HNLC) ($>5 \mu\text{M}$ surface nitrate,
370 World Ocean Atlas 2015, Garcia et al., 2014), coastal ($< 300 \text{ km}$ from a coastline) and open
371 ocean (remainder) regions for application of Si:C ratios to convert to diatom silica production.
372 Si:C ratios were 0.52 for HNLC regions, 0.065 for the open ocean and 0.13 for the coastal
373 regions, reflecting the effect of Fe limitation in HNLC areas (Franck et al. 2000), of Si
374 limitation for uptake in the open ocean (Brzezinski et al., 1998, 2011; Brzezinski & Nelson,

1996; Krause et al., 2012), and of replete conditions in the coastal zone (Brzezinski, 1985). Silica production estimates were then subdivided between coast (within 300 km of shore), open ocean and Southern Ocean (northern boundary 43°S from Australia to South America, 34.8°S from South America to Australia) and summed to produce regional estimates (Table 2). From satellite productivity models our best estimate for the global marine bSi production is 207 (± 23) Tmol-Si yr⁻¹ (Table 2).

A second model-based estimate of silica production considered 18 numerical GOBMs models of the marine silica cycle that all estimated global silica export from the surface ocean (Aumont et al., 2015; Bernard et al., 2011; De Souza et al. 2014; Dunne et al., 2007; Dutkiewicz et al., 2015; Gnanadesikan et al., 1999; Heinze et al., 2003; Holzer et al., 2014; Jin et al., 2006; Matsumoto et al., 2013; Pasquier & Holzer, 2017; Roshan et al., 2018; Sarmiento et al., 2007; Usbeck, 1999; Ward et al., 2012; Wischmeyer et al., 2003). These models include variants of the MOM, HAMOCC OCIM, DARWIN, cGENIE and PICES models. Export production was converted to gross silica production by using a silica dissolution-to-production (D:P) ratio for the surface ocean of 0.58 for the open ocean and 0.51 for coastal regions (Tréguer & De La Rocha, 2013). Model results were first averaged within variants of the same model, and then averaged across models to eliminate biasing the average to any particular model. From GOBMs our best estimate for the global marine bSi production is 276 (± 23) Tmol-Si yr⁻¹ (Table 2). Averaging the estimates calculated from satellite productivity models and GOBMs give a value of 242 (± 49) Tmol-Si yr⁻¹ for the global marine bSi production (Table 2).

4.1.3 Best estimate for bSi annual pelagic production

Using a simple average of the “field” and “model” estimates, the revised best estimate of global marine gross bSi production, mostly due to diatoms, is now $F_{P_{gross}} = 255 (\pm 52)$ Tmol-Si yr⁻¹, not significantly different from the Nelson et al. (1995)’s canonical value.

In the Southern Ocean (SO), a key area for the world ocean Si cycle (DeMaster, 1981), there is some disagreement among the different methods of estimating bSi production. Field studies give an estimate of 67 Tmol-Si yr⁻¹ for the annual gross production of silica in the SO, close to the estimate calculated using satellite productivities models (Table 2). However, the SO estimate calculated from numerical models of the global silica cycle (Dutkiewicz et al., 2015; Gnanadesikan et al. 1999; Holzer et al, 2014; Jin et al. 2006; Matsumoto et al., 2013; Roshan et al., 2018; Sarmiento et al., 2007), is about two times larger than that calculated from silica production studies (Table 2). GOBMs include a very limited number of functional groups of phytoplankton, with some only including two: small phytoplankton and diatoms. As such these

408 models are likely to overestimate the role that diatoms play, especially in the SO. See also
409 Supplement, section 4.

410 **4.1.4 Estimates of the bSi production of other pelagic organisms**

411 Regarding phytoplanktonic organisms other than pelagic diatoms, extrapolations from field and
412 laboratory work show that the contribution of picocyanobacteria (like *Synechococcus*, Baines
413 et al. 2012, Brzezinski et al., 2017; Krause et al., 2017) to the world ocean accumulation of bSi
414 is $< 20 \text{ Tmol-Si yr}^{-1}$.

415 According to Llopis Monferrer et al. (2020), the gross silica production of rhizarians, siliceous
416 protists, in the 0-1000 m layer might range between 2 – 58 Tmol-Si yr^{-1} , about 50% of it
417 occurring in the 0-200 m layer.

418 Note that these preliminary estimates of bSi accumulation or production by picocyanobacteria
419 and rhizarians are within the uncertainty of our best estimate of F_{Pgross} .

420 **4.2 Estimates of the bSi production of benthic organisms**

421 Note that the above updated estimate of the pelagic production does not take into account bSi
422 production by benthic organisms like benthic diatoms and sponges. Our knowledge of these
423 production terms is not well developed for benthic diatoms and no robust estimate is available
424 for bSi annual production of benthic diatoms at global scale (Supplement, section 4).

425 Recently, substantial progress has been made for silica deposition by siliceous sponges.
426 Laboratory and field studies reveal that sponges are highly inefficient in the molecular transport
427 of dSi and, consequently in the bSi production, compared to diatoms and particularly when dSi
428 concentrations are lower than $75 \mu\text{M}$, a situation that applies virtually to most ocean areas
429 (Maldonado et al., 2020). On average, sponge communities are known to produce bSi at rates
430 that are about 2 orders of magnitude smaller than those measured for diatom communities
431 (Maldonado et al., 2012). Because sponge populations are not homogeneously distributed on
432 the marine bottoms, and extensive, poorly mapped and unquantified aggregations of heavily
433 silicified sponges occur in deep sea of all oceans, the global standing crop of sponges is very
434 difficult to be constrained and the annual bSi production attained by such standing crop even
435 more difficult to estimate. A first tentative estimate of bSi production for sponges on continental
436 shelves, where sponge biomass can be more easily approximated, ranged widely, from 0.87 to
437 $7.39 \text{ Tmol-Si yr}^{-1}$, because of persisting uncertainties in estimating sponge standing crop
438 (Maldonado et al., 2012). A way to estimate the global annual bSi production by sponges
439 without knowing their standing crop is to retrace bSi production values from the amount of
440 sponge bSi that is annually being deposited to the ocean bottom, after assuming that, in the long
441 run, the standing crop of sponges in the ocean is in equilibrium (i.e, it is neither progressively

442 increasing nor decreasing over time). The deposition rate of sponge bSi has been estimated at
443 $49.95 (\pm 74.14) \text{ mmol-Si m}^{-2} \text{ yr}^{-1}$ on continental margins, at $0.44 (\pm 0.37) \text{ mmol-Si m}^{-2} \text{ yr}^{-1}$
444 in sediment of ocean basins where sponge aggregations do not occur and at $127.30 (\pm 105.69)$ in
445 deep-water sponge aggregations (Maldonado et al., 2019). By considering that the sponge
446 aggregations occupy not more than 2% of seafloor at ocean basin, a corrected sponge bSi
447 deposition rate for ocean basins is estimated at $2.98 (\pm 1.86) \text{ mmol Si m}^{-2} \text{ yr}^{-1}$ (Maldonado et
448 al., 2019). When the average sponge bSi deposition rate for continental margins and seamounts
449 (representing 108.02 Mkm^2 of seafloor) and for ocean basins (253.86 Mkm^2) is scaled up
450 through the extension of those bottom compartments, a total value of $6.15 (\pm 5.86) \text{ Tmol-Si yr}^{-1}$
451 can be estimated for the global ocean. If the production bSi that is being accumulated as
452 standing stock in the living sponge populations annually is assumed to become constant in a
453 long term equilibrium state, the global annual deposition rate of sponge bSi can be considered
454 as a reliable estimate of the minimum value that the annual bSi production by the sponges can
455 reach in the global ocean. The large associated SD value do not derive from the approach being
456 little reliable but from heterogeneous spatial distribution on the marine bottom, with some ocean
457 areas being very rich in sponges and sponge bSi in sediments while others are not.

458

459 **5. Discussion**

460 **5.1 Overall residence times**

461 The overall geological residence time for Si in the ocean (τ_G) is equal to the total amount of dSi
462 in the ocean divided by the net input (or output) flux. We re-estimate the total ocean dSi
463 inventory value derived from the Pandora model (Peng et al. 1993), which according to Tréguer
464 et al. (1995) was $97,000 \text{ Tmol-Si}$. An updated estimate of the global marine dSi inventory was
465 computed by interpolating the objectively analyzed annual mean silicate concentrations from
466 the 2018 World Ocean Atlas (Garcia et al., 2018) to the OCIM model grid (Roshan et al., 2018).
467 Our estimate is now $120,000 \text{ Tmol-Si}$, i.e. about 24 % higher than Tréguer et al. (1995)'s
468 estimate. Taking this updated estimate of the total dSi inventory into account, Tables 1B and 3
469 show updated estimates of τ_G of Tréguer et al. (1995) and of Tréguer & De La Rocha (2013).
470 Our updated budget (Fig. 1, Table 1B, Table 3A) reduces past estimates of τ_G (Tréguer et al.,
471 1995; Tréguer and De La Rocha, 2013) by more than half, from ca.18 kyr to ca. 8 kyr (Table
472 3C). This brings the ocean residence time of Si closer to that of nitrogen (< 3 kyr, Sarmiento &
473 Gruber, 2006) than phosphorus (30 – 50 kyr, Sarmiento & Gruber, 2006).

474 The overall biological residence time, τ_B , is calculated by dividing the total dSi content of the
475 world ocean by gross silica production. Given the large uncertainty on our estimate of the bSi

476 production by sponges it has been calculated from the bSi pelagic production only. τ_B is ca. 470
477 years (Table 1B, Table 3). Thus, Si delivered to the ocean passes through the biological uptake
478 and dissolution cycle on average 17 times (τ_G / τ_B) before being removed to the sea floor (Table
479 1B, Table 3C).

480 The new estimate for the global average preservation efficiency of bSi buried in sediments is
481 (7.0 / 255) = 2.8 %, similar to Tréguer and De La Rocha (2013)'s estimate, and ~20 times larger
482 than carbon preservation efficiency, making bSi in sediments a potential proxy for export
483 production (Tréguer et al., 2018).

484 **5.2 The issue of steady state**

485 Over a given time scale, an elemental cycle is at steady state if the outputs balance the inputs
486 in the ocean, and the mean concentration of the dissolved element remains constant.

487 **5.2.1 Long time scales ($> \tau_G$)**

488 Over geologic time scales, the average dSi concentration of the ocean has undergone drastic
489 changes. A seminal work (Siever, 1991) on the biological – geochemical interplay of the Si
490 cycle showed a factor of 100 decline in ocean dSi concentration from 550 Myr to the present.
491 This decline was marked by the rise of silicifiers like radiolarian and sponges during the
492 Phanerozoic. Then, during the mid-Cenozoic, diatoms took control of a Si cycle previously
493 dominated by inorganic and diagenetic processes. Taking into account the impact of the
494 evolution of biosilicifying organisms (including bacterial-related metabolism), Conley et al.,
495 (2017) hypothesized that biological processes might also have influenced the dSi concentration
496 of the ocean at the start of oxygenic photosynthesis. Demonstrated skeletal underdevelopment
497 (Maldonado et al., 1999), and low performance in dSi consumption (Maldonado et al., 2020) in
498 sponges when using dSi at the relatively modest concentrations typical of most environments
499 in the modern ocean, also testify for sponges persisting maladapted to the important decrease
500 in the average dSi concentration of the global ocean during the peak of molecular diversification
501 and ecological expansion of diatoms over the Late Jurassic. Note that with a geological
502 residence time of Si of about 8,000 years, the Si cycle can fluctuate over glacial-interglacial
503 time scale.

504 **5.2.2 Short time scales ($< \tau_G$)**

505 In the modern ocean, as shown above, the main control over silica burial and authigenic
506 formation rate is the bSi production rate of (pelagic + benthic) silicifiers. The gross production
507 of bSi due to diatoms is not Si-limited or not severely limited in several zones of the world
508 ocean, which include the coastal zones, and the HNLC zones (Tréguer & De La Rocha, 2013).
509 Thus, on short timescales, there are no strong negative feedbacks, between supply rates and

510 production or burial rates, which would necessarily keep the marine Si cycle in balance. For
511 this reason, climatic changes or anthropogenic impacts that affect dSi inputs to the ocean by
512 rivers and/or other pathways, could lead to an imbalance of Si inputs and outputs in the modern
513 ocean.

514 **5.2.3 A possible steady-state scenario**

515 Within the limits of uncertainty, the total net inputs of dSi and aSi are $14.8 (\pm 2.6)$ Tmol-Si yr⁻¹
516 ¹, and are approximately balanced by the total net output flux of Si with the conservative value
517 of $13.4 (\pm 3.7)$ Tmol-Si yr⁻¹. Figure 1 shows a possible scenario for the Si cycle at steady state
518 in the modern ocean, based on a balance of inputs and outputs at 14.8 Tmol-Si yr⁻¹, compatible
519 with the geochemical and biological fluxes of Table 1. Raising the mean output flux up to 14.8
520 Tmol-Si yr⁻¹ makes sense because of potential underestimation of different components of the
521 present best-estimate total output flux. First, the value of F_B may be underestimated because
522 the commonly used alkaline attack method (DeMaster, 1981) is not always effective at digesting
523 all the bSi present in sediments, particularly bSi in highly silicified diatom frustules, radiolarian
524 tests, or sponge spicules that are abundant in sediments (Maldonado et al., 2019). Second, our
525 value of 4.7 Tmol-Si yr⁻¹ value for F_{RW} is for the proximal coastal zone. However, reverse
526 weathering reactions occur ubiquitously at the sediment water interface in the distal coastal
527 zone, slope, and open ocean regions (Baronas et al., 2017; Ehlert et al., 2016a; Chong et al.,
528 2016), suggesting that our present value for F_{RW} is an underestimate.

529 Consistent with Fig. 1, Figure 4 shows a possible steady-state scenario for the Si cycle in the
530 coastal and continental margins zone (CCMZ), often called the “boundary exchange” zone
531 which, according to Jeandel (2016) and Jeandel & Oelkers (2015), plays a major role in the
532 land-to-ocean transfer of material (also see Fig. 2). Figure 4 illustrates the interconnection
533 between geochemical and biological Si fluxes, particularly in the CCMZ. In agreement with
534 Laruelle et al. (2009), Figure 4 also shows that the “open ocean” bSi production is mostly fueled
535 by dSi inputs from below (94.3 Tmol-Si yr⁻¹) and not by the CCMZ (2.9 Tmol-Si yr⁻¹)
536 (Supplement section 5).

537 **5.3 Specific cases and unresolved questions**

538 In the past three decades, best estimates for the net inputs or outputs of Si in and from the world
539 ocean (Tréguer et al., 1995; Tréguer & De La Rocha, 2013) have increased by a factor of two.
540 This is not only due to better spatial and temporal coverage of Si stocks and fluxes in the
541 different regions of the world ocean, but also to a better understanding of the processes that
542 control the Si cycle, such as SGD and reverse weathering (see discussion above). The two case

543 studies herein presented illustrate the need to improve our understanding of the different
544 contributions of dSi inputs in the coastal zone and the deep Pacific Ocean.

545 **5.3.1 Chinese seas**

546 In many respects, the Chinese marginal seas, composed of the Bohai Sea (BS), Yellow Sea
547 (YS), East China Sea (ECS), and South China Sea (SCS), are a unique and interesting system
548 to study the cycling of Si in the marine environment. Firstly, the dSi SGD inputs largely exceed
549 the dSi riverine inputs by a factor of about 3-16 times for the BS, YS, and ECS (e.g. Ding et al.,
550 2019; Liu et al., 2017a; Liu et al., 2017b; Wang et al., 2018b; Wu et al., 2017). Secondly,
551 the bSi production seem to be mostly (62-90%) maintained by the recycling of Si (Li et al.,
552 2019; Liu et al., 2005; Liu et al., 2016; Wu et al., 2017; Wu et al., 2020), which is unusual for
553 coastal systems (Tréguer & De La Rocha, 2013). Thirdly, most (63-75%) of the bSi that reaches
554 the sediment-water interface is accumulated in sediments (Li et al. 2019; Liu et al. 2005; Liu et al.
555 2016; Wu et al., 2017; Wu et al. 2020). Finally, reverse weathering as a sedimentary sink in
556 the YS and in the SCS, could be a large component to the Si budget (Zhao et al., 2017). To date,
557 preliminary Si budgets have been published for BS, YS and ECS (Li et al., 2019; Liu et al.,
558 2005; Liu et al., 2016; Wu et al., 2017; Wu et al., 2020), but the estimates are still unbalanced
559 since key fluxes, such as reverse weathering, are lacking. In addition, the relatively high load
560 of lithogenic material in the Chinese marginal seas sediments, due to massive entrainment of
561 siliceous soils through the hydrographic network of large rivers (Ding et al., 2019), make it
562 difficult to quantify the bSi content in this system using a classic alkaline leach (DeMaster,
563 1981). We therefore recommend additional attention be paid to the cycling of Si within the
564 Chinese marginal seas system in the near future.

565 **5.3.2 The North-East Pacific dSi anomaly**

566 Maximum dSi values Southern Ocean bottom waters are about 130 μM , but they are over 160-
567 165 μM in the Pacific Ocean when the conveyor belt crosses the latitude of Hawaii. This dSi
568 progressive enrichment is classically explained by recycling from siliceous debris in association
569 with the biological pump. In the northern ($> 50^\circ\text{N}$) Sea of Okhotsk, dSi concentrations exceed
570 200 μM at depths $> 1,800$ m, in a nitrate ($> 40 \mu\text{M}$) layer almost depleted in dissolved dioxygen.
571 This Okhotsk system, acting as a natural sediment trap and biogeochemical processes, can fully
572 account for this nutrient richness and O_2 depletion in bottom water. Exceptionally high dSi
573 concentrations have been measured (e.g. PI WOCE section at 47°N) on the eastern side of the
574 North Pacific, where a large dSi rich plume contains concentrations $> 200 \mu\text{M-Si}$ (Talley et al.
575 1992). The dSi total inventory of this plume is estimated at 164 Tmol-Si (Johnson et al., 2006),
576 i.e. about 0.14 % of the world ocean inventory and it corresponds to an advective flux ranging

577 between 1 and 2 Tmol-Si yr⁻¹. The process that feeds this dSi flux has not been identified yet,
578 but possibilities include the dissolution of biogenic material accumulated on the deep valleys
579 of this area, or hydrothermal fluids. Alternatively, this N-E Pacific dSi plume might be due to
580 the remobilization of relatively old bSi that accumulated over a long time interval, a process
581 that requires further studies as it would be considered as a net input for the Si cycle.

582 **5.4 The impacts of global change on the Si cycle**

583 As illustrated by Fig. 1 and 4, the pelagic bSi production is mostly fueled from the large, deep
584 ocean recycled pool of dSi. This lengthens the response time of the Si cycle to changes in dSi
585 inputs to the ocean due to global change (including climatic and anthropogenic effects),
586 increasing the possibility for the Si cycle to be out of balance.

587 **5.4.1 Impacts on riverine inputs of dSi and aSi**

588 Climate change at short time scale during the 21st century impacts the ocean delivery of riverine
589 inputs of dSi and aSi (F_R) and of the terrestrial component of the submarine groundwater
590 discharge (F_{GW}), either directly (precipitations and subsequent dSi and aSi weathering and
591 transport), or indirectly by affecting forestry and agricultural dSi export. So far, impacts of
592 climate change and the terrestrial Si cycle have been reported for boreal wetlands (Struyf et al.,
593 2010), North American rivers (Opalinka & Cowling, 2015), and for Arctic rivers which includes
594 western Canadian Arctic (Phillips, 2020), and the tributaries of the Laptev and East Siberian
595 Seas (Charette et al., 2020), but not for tropical environments. Tropical watersheds are the key
596 areas for the transfer of terrestrial dSi to the ocean, as approximately 74% of the riverine Si
597 input is from these regions (Tréguer et al., 1995). Note that, according to model predictions
598 (Chou et al., 2004, 2008), under global warming, the precipitations in tropical regions usually
599 follow “the rich-get-richer” mechanism. In other words, in tropical convergence zones rainfall
600 increase with large climatological precipitations, but it is the reverse in tropical subsidence
601 regions, with contradictory impacts for weathering of tropical soils. So, if the predicted global
602 predictions of temperature rise and variations in precipitations of the IPCC are correct (IPCC,
603 2018), it is not sure that F_R or F_{GW} , two major components of dSi and aSi inputs, will increase
604 at global scale by climate change during this century. Consistent with these considerations are
605 the conclusions of Phillips (2020)’s first tentative to model the impacts of climate change on
606 the riverine delivery of dSi to the ocean, using a machine learning. Using a model based on 30
607 environmental variables including temperature, precipitation, land cover, lithology, and terrain,
608 Phillips (2020) predicts that within the end of this century, if dSi mean yield could increase
609 regionally (for instance in the Arctic region), the global mean dSi yield is projected to decrease.

610 **5.4.2 Abundance of marine and pelagic and benthic silicifiers**

611 Over the period 1960-2009, a change in diatom abundance was not seen on the North Atlantic
612 from Continuous Plankton Recorder (CPR) data (Hinder et al., 2012). However, studies have
613 cautioned that many fields (e.g. Chl) will take several decades before these changes can be
614 significantly measured beyond natural variability (Henson et al 2010; Dutkiewicz et al 2019).
615 Note that regarding the impact of climate change on benthic silicifiers, the melting of Antarctic
616 ice platforms has been corroborated to trigger impressive population blooms of highly silicified
617 sponges (Fillinger et al. 2013).

618 **5.4.3. Predictions for the ocean phytoplankton production and bSi production**

619 In the 21st century, climate change affects ocean circulation, stratification and upwelling thus
620 affecting the cycles of nutrients (Aumont et al., 2003; Bopp et al., 2005, 2013). With increase
621 stratification, reduced dSi supply from below (Fig. 1 and 4) leads to less siliceous phytoplankton
622 production in surface compartments of lower latitudes and possibly the North Atlantic (Tréguer
623 et al., 2018). The impact of climate change on the phytoplankton production or polar seas as is
624 highly debated as melting of sea ice decreases light limitation. Regarding the Arctic Sea,
625 increase nutrients (at the least for silicic acid) availability will occur through the Transpolar
626 Drift delivering nutrient rich river- and shelf derived waters as potential sources for primary
627 production, including bSi production (e.g. Charette et al., 2020). Regarding the Southern Ocean,
628 bSi production is likely to increase in the coastal and continental shelf zone as iron availability
629 increases due to ice – shelf and icebergs melting (Boyd et al., 1016; Hutchins & Boyd, 2016;
630 Tréguer et al., 2018). Globally, it is therefore possible that a warmer and acidified ocean alters
631 the pelagic bSi production rates, thus modifying the export production and outputs of Si at short
632 time scales.

633 Although uncertainty is substantial, model studies (Bopp et al., 2005; Dutkiewicz et al., 2019;
634 Laukötter et al, 2015) suggest regional shifting of bSi pelagic production due to climate change.
635 Climate change models suggest a global decrease in diatom biomass and productivity over the
636 course of the 21st century (Bopp et al., 2005, Dutkiewicz et al., 2019, Laufkötter et al., 2015),
637 which would lead to a reduction in the pelagic biological flux of silica. Regional responses
638 however differ, with most models suggesting a decrease in diatom productivity in the lower
639 latitudes and many predicting an increase in diatom productivity in the Southern Ocean
640 (Laufkötter et al, 2015). Holzer et al. (2019) suggest that changes in supply of dFe will alter bSi
641 production mainly by inducing floristic shifts, not by relieving kinetic limitation. Increased
642 primary productivity come from reduction in sea-ice and the faster growth rates with warmer
643 waters and longer growing seasons in the high latitudes. However, many models have very
644 simple ecosystems including only diatoms and a small phytoplankton. In these models,

645 increased primary production in the Southern Ocean is mostly from diatoms. Some models with
646 more complex ecosystem (i.e. including additional phytoplankton groups) suggest that
647 increased primary productivity in the future Southern Ocean will be due to other phytoplankton
648 types (e.g. pico-eukaryote) and that diatoms biomass will decrease (Dutkiewicz et al, 2019; also
649 see model PlankTOM5.3 in Laufkötter et al, 2015), except in regions where sea-ice has melted.
650 Differences in the complexity of the ecosystem and parameterizations, in particular in terms of
651 temperature dependences of biological process, between models lead to widely varying
652 predictions (Dutkiewicz et al., 2019; Laufkötter et al., 2015). These uncertainties suggest we
653 should be cautious in our predictions of what will happen with the silica biogeochemical cycle
654 in a future ocean.

655 **5.4.2 Other anthropogenic impacts**

656 For decades if not centuries, anthropogenic activities directly or indirectly altered the Si cycle
657 in rivers, and the CCMZ (Bernard et al., 2010; Conley et al. 1993; Derry et al. 2005; Humborg
658 et al., 2006; Ittekkot et al., 2000, 2006; Laruelle et al. 2009; Liu et al., 2012; Yang et al., 2015;
659 Wang et al., 2018; Zhang et al., 2019). Processes involved include eutrophication and pollution
660 (Conley et al., 1993; Liu et al., 2012), river damming (Ittekkot, 2006; Ittekkot et al., 2000; Yang
661 et al., 2015; Wang et al., 2018), deforestation (Conley, 2008), changes in weathering and in
662 river discharge (Bernard et al. 2010; Yang et al. 2015), and deposition load in river deltas (Yang
663 et al., 2015).

664 Among these processes, river damming is known for having the most spectacular and short
665 time-scale impacts on the Si delivery to the ocean. In principle, river damming favours
666 enhanced biologically mediated absorption of dSi in the dam reservoir, thus resulting in drastic
667 decreases in dSi concentration downstream. Indeed, drastic perturbations on the Si-cycle and
668 downstream ecosystem have been shown (Ittekkot, 2006; Ittekkot et al. 2000; Humborg et al.
669 2006; Zhang, 2019), particularly downstream of the Nile (Mediterranean Sea), the Danube
670 (Black Sea) and the fluvial system of the Baltic Sea. This is critical for major rivers of the
671 tropical zone (Amazon, Congo, Changjiang, Huanghe, Ganges, Brahmaputra, etc.), which carry
672 74 % of the global exorheic dSi flux (Dürr et al., 2011; Tréguer et al., 1995). Among these
673 major rivers, the course of Amazon and Congo are, so far, not affected by a dam or, if so for
674 the Congo river, the consequence of Congo damming for the Si cycle in the equatorial african
675 coastal system has not been studied. The case for Changjiang (Yangtze), one of the major world
676 players on dSi delivery to the ocean, is of particular interest. Interestingly, the Changjiang
677 (Yangtze) river dSi concentrations decreased dramatically from 1960s to 2000 (before the
678 building of the Three Gorge Dam, TGD). As explained by Wang et al. (2018) this decrease is

679 due a combination of natural and anthropogenic impacts. Paradoxically, since the achievement
680 of the TGD (2006 - 2009) no evidence of additional retention of dSi by the dam has been
681 demonstrated (Wang et al., 2018).

682

683 **6. Conclusions/recommendations**

684 The main question that still needs to be addressed is whether the contemporary marine Si cycle
685 is at steady state, which requires the uncertainty in total inputs and outputs to be minimized.
686 For the output fluxes, it is clear that the commonly used method for bSi determination
687 (DeMaster, 1981) in sediments does not fully account for the bSi contribution of siliceous
688 sponges and rhizarians, consequently the present value for silica burial is likely underestimated.
689 Quantitative determination of bSi is particularly difficult for lithogenic or silicate-rich
690 sediments (e.g. estuarine and coastal), for example those of the Chinese seas. An analytical
691 effort for the quantitative determination of bSi from a variety of sediment sources and the
692 organization of an international comparative analytical exercise are of high priority for future
693 research. It is also clear that reverse weathering processes are at work not only in estuarine or
694 coastal environments, but also in the distal coastal zone, slope, and open ocean regions of the
695 global ocean. Careful use of geochemical tools (e.g. ^{32}Si , Ge/Si, $\delta^{30}\text{Si}$) to trace partitioning of
696 bSi between opal and authigenic clay phases may further elucidate the magnitude of this sink,
697 particularly in understudied areas of the ocean.

698 For the input fluxes, more effort is required to quantify groundwater input fluxes, particularly
699 using geochemical techniques to identify the recycled marine flux from other processes that
700 generate a net input of dSi to the ocean. Studies addressing these uncertainties at the regional
701 scale are critically needed. Further, better constraints on hydrothermal inputs (for the North-
702 East Pacific specific case), aeolian inputs, and inputs from ice melt in polar regions are required.
703 Finally, in light of laboratory experiments by Fabre et al. (2019) demonstrating low temperature
704 dissolution of quartz in clastic sand beaches, collective multinational effort should address to
705 examine whether sandy beaches are major global dSi sources to the ocean.

706 This review highlights the significant progress that has been made in the past decade toward
707 improving our quantitative and qualitative understanding of the sources, sinks and internal
708 fluxes of the marine Si cycle. Filling the knowledge gaps identified in this review is also
709 essential if we are to anticipate changes in the Si cycle, and their ecological and biogeochemical
710 impacts, in the future ocean.

711

712

713 *Data availability:* All data used in this review article are available in the referenced articles.
714 Data of biogenic pelagic production are shown in Supplement (Annex 1).

715

716 *Supplement:* The supplement related to this article is available on line at...XXX

717

718 *Author contributions.* PJT & JNS defined the manuscript content and wrote the paper. MAC,
719 CE, JH, SR, OR & PT wrote the inputs section. JS, CE, SR, & MM wrote the outputs section.
720 MB, TD, SD, AL, & PT wrote the pelagic production section. MLA & MM wrote the sponge
721 subsections. SML, LR, & PT wrote the discussion section. Every author re-read and approved
722 the review article.

723

724 *Competing interests.* The authors declare that they have no conflict of interest.

725

726 *Acknowledgements.* The idea for this manuscript was conceived during a conference of the
727 SILICAMICS Network, held in June 2018 at the University of Victoria (Canada). This work
728 was supported by the French National Research Agency (18-CEO1-0011-01). Thanks are due
729 to Sébastien Hervé (LEMAR-IUEM, Plouzané) for his art work.

1222 (5) recalculated from our updated dSi inventory value

1223

1224

1225 **Figure 1:** Schematic view of the Si cycle in the modern world ocean (input, output, and
1226 biological Si fluxes), and possible balance (total Si inputs = total Si outputs = $14.8 \text{ Tmol-Si yr}^{-1}$)
1227 ¹) in reasonable agreement with the individual range of each flux (F), see Tables 1 and 2. The
1228 white arrows represent fluxes of net sources of silicic acid (dSi) and/or of dissolvable
1229 amorphous silica (aSi) and of dSi recycled fluxes; Orange arrows correspond to sink fluxes of
1230 Si (either as biogenic silica and or as authigenic silica); Green arrows correspond to biological
1231 (pelagic) fluxes. All fluxes are in teramoles of silicon per year (Tmol-Si yr^{-1}). Details in
1232 Supplement section 1.

1233 **Figure 2.** Schematic view of the low temperature processes that control the dissolution of
1234 (either amorphous or crystallized) siliceous minerals in seawater in and to the coastal zone and
1235 in the deep ocean, feeding F_{GW} and F_{w} . These processes correspond to both low and medium
1236 energy flux dissipated per volume of a given siliceous particle in the coastal zone, in the
1237 continental margins, and in the abysses, and to high-energy flux dissipated in the surf zone.
1238 Details in Supplement section 1.

1239 **Figure 3.** Biogenic silica production measurements in the world ocean. Distribution of
1240 stations in the Longhurst biogeochemical provinces (Longhurst, 2007; Longhurst et al., 1995).
1241 All data are shown in Supplement, section 4 (Annex 1).

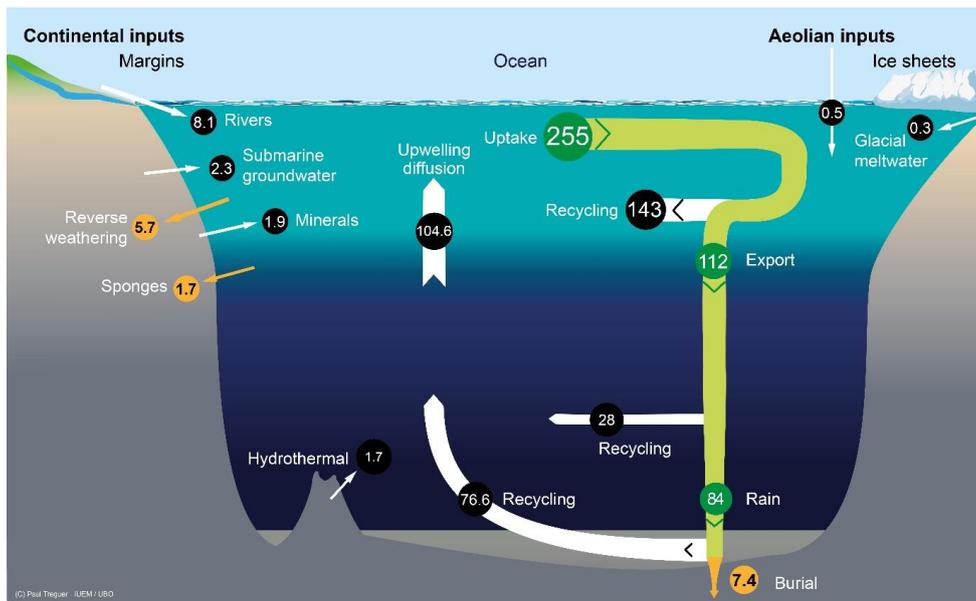

1242 **Figure 4.** Schematic view of the Si cycle in the coastal and continental margin zone (CCMZ),
1243 linked to the rest of the world ocean (« open ocean » zone, including upwelling and polar
1244 zones). In this steady-state scenario, consistent with Fig. 1, total inputs = total outputs = 14.8
1245 Tmol-Si yr^{-1} . This figure illustrates the links between biological, burial and reverse weathering
1246 fluxes. It also shows that the “open ocean” bSi (pelagic) production ($F_{\text{P(gross)}} = 222 \text{ Tmol-Si yr}^{-1}$)
1247 ¹) is mostly fueled by dSi inputs from below ($94.3 \text{ Tmol-Si yr}^{-1}$), the CCMZ only providing 2.9
1248 Tmol-Si yr^{-1} to the “open ocean”.
