Correspondence: Erin R. Hotchkiss (ehotchkiss@vt.edu)

Abstract. Streams are ecosystems organized by disturbance. One of the most frequent and variable disturbances in running waters is elevated flow. Yet, we still have few estimates of how ecosystem processes, such as stream metabolism (gross primary production and ecosystem respiration; GPP and ER), respond to high flow events. Furthermore, we lack a predictive framework for understanding controls on within-site metabolic responses to flow disturbances. Using five years of high-frequency dissolved oxygen data from an urban- and agriculturally-influenced stream, we estimated daily GPP and ER and analyzed metabolic changes across 15 isolated high flow events. Metabolism was variable from day to day, even during lower flows; median and ranges for GPP and ER over the full measurement period were 3.7 (0.0, 17.3) and -9.6 (-2.2, -20.5) g O₂ m⁻² d⁻¹. Thus, ~~w~~We calculated metabolic resistance as the magnitude of departure (M_{GPP} , M_{ER}) from the range of daily metabolism during dynamic equilibrium during antecedent lower flows (lower values of M represent higher resistance) and quantified estimated resilience as from the daytime until GPP and ER returned to the prior range of antecedent ambient dynamic equilibrium. We evaluated correlations between metabolic resistance and resilience with characteristics of each high flow event, antecedent conditions, and time since last flow disturbance. ER was more resistant and resilient than GPP. Median M_{GPP} and M_{ER} were -0.14 and 0.00, respectively. GPP was typically suppressed following flow disturbances, regardless of disturbance intensity. In contrast, the ER magnitude of departure increased with disturbance intensity. Additionally, GPP was less resilient and took longer to recover (0 to >9 days, mean = 2.2) than ER (0 to 2 days, mean = 0.6). Given the flashy nature of streams draining human-altered landscapes and the variable consequences of flow for GPP and ER, testing how ecosystem processes respond to flow disturbances is essential to an integrative understanding of ecosystem function.

Copyright statement.

1 Introduction

Disturbances can alter stream ecosystem function by changing flow while influencing carbon and nutrient inputs, transformations, and exports (Stanley et al., 2010). Stream biogeochemical cycles are altered by long-term ‘press’ disturbances, such as land use change (e.g., Plont et al. 2020), and by episodic ‘pulse’ disturbances, such as transitory changes in allochthonous inputs (e.g., Bender et al. 1984; Dodds et al. 2004; Seybold and McGlynn 2018). Here, we use the definition of disturbance from White and Pickett (1985): “any relatively discrete event in time that disrupts the ecosystem. . . and changes resources, substrate availability, or the physical environment”. Frequent disturbances generate oscillations that form a pulsing steady state dynamic ambient equilibrium (sensu Odum et al. 1995) that includes ~~ambient~~ variability in processes (Resh et al., 1988; Stanley et al., 2010). Stream disturbances come in many forms, including: rapid increases in the volume and velocity of water, drought, substrate movement, and anthropogenic alterations of channel morphology, flow, or solute chemistry (Resh et al., 1988).

Elevated flow is one of the most pervasive, frequent disturbances to streams. Flow disturbances can scour the benthos, increase turbidity, and reduce light – all of which can change stream function (Hall et al., 2015; Blaszczyk et al., 2019). However, flow is an inherent characteristic of streams and may influence stream function along a “subsidy-stress” gradient (sensu Odum et al. 1979; Figure 1). Extreme high flows can stress stream biota and induce conditions unfavorable for biotic processes, whereas more ‘normal’, frequent high flows can stimulate internal biogeochemical transformations by bringing in limiting nutrients or organic matter subsidies (Lamberti and Steinman, 1997; Roley et al., 2014; Demars, 2019). How changes in flow subsidize or stress stream functions will depend on a variety of factors, including the ecosystem process of interest.

Stream metabolism is an integrative whole-ecosystem estimate of the carbon fixed and respired by autotrophs and heterotrophs. Metabolism is most commonly estimated via diel changes in dissolved oxygen (Hall and Hotchkiss, 2017): autotrophs produce oxygen during gross primary production (GPP); autotrophs and heterotrophs consume oxygen during ~~ecosystem~~ ecosystem respiration, which we refer to as ecosystem respiration (ER) when measured at the whole-reach scale. Together, ER and GPP can elucidate whether a stream is a net producer (autotrophic; $GPP > ER$) or consumer (heterotrophic; $ER > GPP$) of carbon. Ecosystem metabolism is coupled with other ecosystem processes (e.g., nitrogen uptake, Hall and Tank 2003) and is used to monitor ~~the~~ stream health (Young et al., 2008; [Jankowski et al., 2021](#)) as well as ecosystem responses to disturbance and restoration (e.g., Arroita et al. 2019; Blersch et al. 2019; Palmer and Ruhi 2019).

Metabolism on any given day is influenced by current and past environmental factors. GPP can increase with light (Mulholland et al., 2001; Roberts and Mulholland, 2007), nutrients (Grimm and Fisher, 1986; Mulholland et al., 2001), temperature (Acuña et al., 2004), and transient storage (Mulholland et al., 2001). ER is controlled by organic carbon availability (e.g., Demars 2019), as well as the same physicochemical conditions as GPP, and consequently often mirrors GPP (e.g., Roberts et al. 2007; Griffiths et al. 2013; Roley et al. 2014). Antecedent conditions may also play a role in the variability of ecosystem responses to flow (McMillan et al., 2018; Uehlinger and Naegeli, 1998). GPP and ER respond differently to flow disturbances (O’Donnell and Hotchkiss, 2019), likely influenced by where the microbes contributing to GPP and ER reside within the heterogeneous stream benthos (e.g., Uehlinger 2000, 2006). Autotroph reliance on light for energy creates a stream bed commonly dominated by photoautotrophic algal communities and associated heterotrophs. Many heterotrophs, on the other hand, are established within the substrata and hyporheic zone, which can increase resistance and resilience of ER relative to GPP (Uehlinger, 2000; Qasem et al., 2019). Environmental drivers of metabolism fluctuate in response to disturbances (e.g., Uehlinger 2000) but also vary sub-daily to seasonally, thus inducing temporal variation in GPP and ER during base flows that are best characterized as a pulsing steady state or dynamic equilibrium (e.g., Roberts et al. 2007).

The subsidy-stress relationship between flow and ecosystem function likely induces a range of metabolic responses to and recovery from flow changes (Figure 1). Both GPP and ER may decline due to disturbance during higher er flows (Uehlinger, 2006; Roley et al., 2014; Reisinger et al., 2017); however, flow changes can also stimulate metabolism (Roberts et al., 2007; Demars, 2019). Ultimately, resistance is reflected in the capacity of microbial assemblages to withstand a flow disturbance, with metabolic processes not reduced or stimulated outside of a dynamic ambient equilibrium ~~pulsing steady state~~. Resistance captures the instantaneous response of ecosystem metabolism to a flow disturbance. We can also quantify post-disturbance ecosystem responses by estimating resilience: the time it takes for a process returns to equilibrium following a disturbance (Carpenter et al., 1992). The resilience of ER and GPP following a flow

disturbance may take anywhere from days to weeks (e.g., Uehlinger and Naegeli 1998; Smith and Kaushal 2015; Reisinger et al. 2017), and likely varies with season and the magnitude of disturbance (Uehlinger, 2006; Roberts et al., 2007). A flow event of lesser magnitude may yield higher resistance and resilience for both GPP and ER, by supplying subsidizing, limiting nutrients and organic matter from the terrestrial landscape without inducing extreme scour. Stream metabolism appears to have low resistance to disturbance but high resilience (Uehlinger and Naegeli, 1998; Reisinger et al., 2017). Understanding how different attributes of flow events (e.g., magnitude, timing) control resistance and recovery trajectories is a critical next step in characterizing metabolic responses to flow changes within and among ecosystems.

We quantified ecosystem resistance and resilience over several years of isolated, higher flow events to examine controls on and patterns of stream metabolic responses to disturbance. We had four hypotheses (Figure 1): (H1) ER will be more resistant than GPP to flow disturbances, given the protection of many heterotrophs within the streambed; (H2) there will be a stimulation of GPP and ER at intermediate flow disturbances due to an influx of limiting carbon and nutrients; (H3) metabolic resistance and resilience will change with the size of the event, with larger flow disturbances inducing more stress due to enhanced scour; and (H4) some flow events will not push GPP and ER outside of their pulsing ambient dynamic equilibrium. In addition to testing the subsidy stress hypotheses and differences in how GPP and ER may respond to and recover from higher flow events (Figure 1), we also analyzed the relationships between environmental variables and metabolic responses, including those prior to flow disturbances that may influence how stream microbial communities respond to flow changes. We predicted recent disturbances might make microbes more vulnerable and less resistant to the next high flow disturbance. We analyzed response and recovery dynamics (i.e., resistance and resilience) relative to a pulsing a dynamic ambient equilibrium for 15 isolated flow events across 5 years in a flashy urban- and agriculturally-influenced stream. Our methods were chosen to address a lingering knowledge gap in our understanding of ecosystem processes, which motivated the three overall objectives of this work: (1) quantify how biological processes (GPP and ER) respond to and recover from discrete higher flow disturbances during storms (Figure 1, H2-H4), (2) test how the response and recovery of GPP and ER differ (Figure 1, H1), and (3) identify which environmental drivers best explain metabolic resistance and recovery. ~~We assessed which antecedent conditions or disturbance characteristics influence within-site variability in GPP and ER resistance and resilience.~~

2 Methods

2.1 Study site

Stroubles Creek is a third-order, urban- and agriculturally-influenced stream draining a 15 km² sub-watershed of the New River in Southwest Virginia in the United States (Figure A1, O'Donnell and Hotchkiss 2019). The mean annual precipitation of Stroubles Creek's catchment is 1006 mm ~~1006 mm~~, with more than half (54%) of that precipitation falling from May-October (PRISM Climate Group, 2013). Annual mean air temperature is 11.3°C (0.4-22.0°C monthly mean minimum and maximum; PRISM Climate Group 2013). The catchment draining into Stroubles Creek at our study location is 85.5% developed, 11.6% agriculture (pasture and crops), and 2.9% forested (Homer et al., 2015). Stroubles Creek has been designated an impaired waterway due to high sediment loading and has NO₃⁻ concentrations that typically exceed 1 mg/L (O'Donnell and Hotchkiss, 2019); biological oxygen demand in Stroubles Creek appears to be limited by organic carbon availability more so than inorganic nutrients (O'Donnell and Hotchkiss, unpublished data). Our study site on Stroubles is a part of the Stream 85 Research, Education, and Management Lab (StREAM Lab,

www.bse.vt.edu/research/facilities/StREAM_Lab.html), and has been monitored by Virginia Tech researchers for over 10 years.

2.2 Sensor data collection

High temporal resolution sensor data were collected from 2013-01-08 through 2018-04-14. Dissolved oxygen (DO) (mg L^{-1}), turbidity (nephelometric turbidity unit, NTU), conductivity (ms cm^{-1}), pH, and temperature ($^{\circ}\text{C}$) data were logged at 15- 90 minute intervals by an in situ YSI 6920V2 sonde (Hession et al., 2020; O'Donnell and Hotchkiss, 2019). Because a freeze event impaired DO measurements from the YSI sonde, we gap-filled missing data with calibration-checked and comparable data from an adjacent PME MiniDOT from 2017-09-01 to 2018-04-14 (Figure A2; O'Donnell and Hotchkiss 2019). ~~We obtained light data and barometric pressure measurements from a nearby weather station.~~ We obtained the data needed to model the relative change in light over 24-hours (Equation 1) from a nearby weather station (Figure A1), which also provided estimates of barometric pressure. A Campbell Scientific CS451 pressure transducer recorded stage measurements every 10 minutes. Velocity (v) and width (w) measurements were taken over multiple years to create site-specific relationships between stage, velocity, wetted width, and discharge (Q). A stage-discharge relationship was created in 2013 and updated in 2018 to allow for daily estimates of depth (z) from $Q = vwz$. Sensors were calibrated every 2-4 weeks according to best practice recommendations from the manufacturer (Hession et al. 2020) or, in the case of the PME DO sensor, with Winkler titration checks of our 100% and 0% calibration solutions (Hall and Hotchkiss 2017, O'Donnell and Hotchkiss 2019).

To remove lower-quality sensor data due to sensor error or periods of low flow, we used data cleaning and quality checks as in O'Donnell and Hotchkiss (2019). Briefly, we excluded values below the 1% and above the 99% quantile for physicochemical parameters that were heavily skewed (i.e., turbidity and conductivity). We removed physicochemical values we knew to be unreasonable (e.g., turbidity was cut off at zero). We calculated daily medians of physicochemical parameters for all days that had at least 80% of measurements over the course of the day after confirming the 80% cutoff as one that would not bias daily medians from dates without gaps in sensor measurements. Data from lower flow periods when individual sensors may have been out of water (Hession et al., 2020) were excluded when values were out of range of grab sample calibration checks.

2.3 Estimating ecosystem metabolism

We estimated GPP, ER, and K (the air-water gas exchange coefficient) from diel O_2 (DO), light, and temperature sensor data using the same inverse modeling approach and data as O'Donnell and Hotchkiss (2019). Conservative tracer additions (Hotchkiss & O'Donnell, unpublished data) suggested there are no substantial groundwater inputs to this study reach that would otherwise bias our estimates of GPP and ER (Hall and Hotchkiss 2017). We selected the streamMetabolizer R package for our analyses (Appling et al., 2018a), which uses Bayesian parameter estimation and a hierarchical state space modeling framework to generate daily estimates of GPP, ER, and K that create the best fit between modeled and observed DO data (Appling et al. 2018b; Equation 1; Table 1). We note that GPP is multiplied by the proportion of light (PAR) at the previous measurement over total daily light, so the light term in the metabolism model function is unitless.

[Eqn 1 – code copied from LaTeX version for track change doc]

$$m\text{DO}_i = m\text{DO}_{\{i-\Delta t\}} + \frac{\text{GPP} \times \text{PAR}_{\{i-\Delta t\}}}{z \times \Sigma \text{PAR}} + \frac{\text{ER}_{\{z\}}}{\Delta t} + K_{\text{O}}(\text{DO}_{\{\text{sat}(i-\Delta t)\}} - m\text{DO}_{\{i-\Delta t\}}) \Delta t$$

We used most of the default model specs for streamMetabolizer. Model convergence was visualized via traceplot in the rstan package (Stan Development Team, 2019) to identify the proper number of burn-in steps (500); we saved 2000 Markov chain Monte Carlo (mcmc) steps from four chains after burn-in. We modeled GPP, ER, and K with both observation error and process error. We calculated mean daily standard error derived from the mcmc-derived distributions of GPP and ER. Additionally, to decrease the chances of equifinality between GPP, ER, and K estimates (Appling et al., 2018b), we constrained day-to-day variability in K by binning the range of possible K estimates according to discharge (O'Donnell and Hotchkiss, 2019). We divided yearly discharge into six bins, which the hierarchical modeling framework of streamMetabolizer then used to create K-Q relationships to constrain model K estimates (O'Donnell and Hotchkiss, 2019). We used nighttime linear regression of DO as another way to estimate the range in K in Stroubles (Hall and Hotchkiss, 2017) and used these estimates of K to quality check values of modeled K from streamMetabolizer (e.g., Figure A3). We quality-check metabolism model output as in O'Donnell and Hotchkiss 2019. We removed all metabolism estimates that were biologically impossible, such as negative GPP or positive ER (ER is modeled as a negative flux of O₂ consumption).

Next, we used diagnostics from fit() in stan to remove values resulting from a poor model fit or lack of chain convergence (Stan Development Team, 2019). We removed dates with poor model convergence when Rhat exceeded 1.1 and poor model fit when N_eff (effective sample size) ended at or exceeded the product of the number of chains (4) and the number of saved mcmc steps (2000) specified for our model. Additionally, to avoid using biased estimates of metabolism, we removed K values below the 1% (< 3.38 d⁻¹) and above the 99% (> 27.21 d⁻¹) quantile of model estimates. 246 days of metabolism estimates were ultimately removed due to these QA/QC criteria, resulting in 1375 days (of 1621 total from 2013-01-08 to 2018-04-14) of quality-checked GPP and ER for further analyses.

2.4 Selection of isolated flow events

To identify flow events for our analyses of metabolic resistance and resilience, we calculated the percent change in cumulative daily discharge (Q) relative to the day prior (Equation 2).

[Eqn 2 – code copied from LaTeX version for track change doc]

$$\% \Delta Q = \frac{Q_i - Q_{i-1}}{Q_{i-1}} \times 100$$

where Q_i is the discharge of the day of interest and Q_{i-1} is the discharge during the prior day. We selected isolated flow events that had a greater than 50% Q change relative to the antecedent cumulative daily Q. We defined isolation as a period of three days before and three days after a high flow event where no other flow events exceeding 10% Q change occurred. In total, there were 15 isolated flow events across all 5 years that met our criteria for isolated flow events and had quality-checked metabolism estimates (Figure 2). Hydrograph and metabolism time series for each isolated flow event are available in Appendix Figures 4 - 18.

The designation of 50% change in flow for high flow events ensured analyzed events were outside of the range of baseline flows. We defined a flow event as >10% change in Q when comparing the high flow changes to prior metabolic rates, as smaller changes in Q may still influence metabolism. In testing different thresholds of flow change and different discharge metrics, we settled on our current method to optimize the thresholds for a change in Q that resulted in the highest number of quality-checked events while ensuring differences between classifications of ambient stream flow and higher flow events.

The goal of this work was to assess how metabolism responded to and recovered from higher flow events that were also isolated flow events. We focused on quality over quantity when selecting for and analyzing stream metabolism results before, during, and after high flow events. After all appropriate quality checking measures, we had 1375 days of metabolism estimates over five years (as reported in O'Donnell & Hotchkiss, 2019). To calculate resistance and recovery, we needed consecutive days of high-quality metabolism estimates, which further limited the number of high flow events appropriate for our analyses. For example, in 2016: there were 52 (out of 352) days with quality-checked sensor data that had a 50% flow change relative to the day prior. After looking at these 52 storms and selecting those that had three days before and three days after without any other flow events, we had 12 that were isolated. After quality-checking our metabolism estimates for all of those days, we had four high flow events from 2016 that passed all quality-checking steps required for this analysis.

2.5 Characterizing metabolic resistance and resilience

To acknowledge the ~~pulsing~~, ambient day-to-day variability of GPP and ER, we used metabolism estimates from three days prior to define a range of antecedent metabolism for each isolated flow event. We quantified metabolic responses to flow disturbances by comparing the pre-event metabolic range with event and post-event metabolism rates. To assess resistance, we estimated metabolic magnitude of departure (M) during events to quantify the resistance of GPP and ER to disturbance. We calculated M per isolated flow event by comparing the difference between GPP and ER to the nearest value of the antecedent range (Equation 3; Figure 3),

[Eqn 3 – code copied from LaTeX version for track change]

$$M = 1 - \frac{X_{\text{event}}}{X_{\text{prior}}}$$

where X_{event} is either GPP or ER ($\text{g O}_2 \text{m}^{-2} \text{d}^{-1}$) on the day of the isolated flow event. X_{prior} is the maximum or minimum value of GPP or ER from the antecedent range, depending on if the isolated flow event resulted in a stimulated (increased) or ~~repressed~~ suppressed (reduced) metabolic response. For instance, if GPP declined ~~was repressed~~ during a flow event, M was calculated as the difference between GPP for the isolated flow event and the minimum value from the antecedent 3-day range (Figure 3). We use the maximum or minimum values instead of the median or mean because this approach allowed us to better capture the full range of average metabolism estimates in ways that summarizing pre-storm rates to means or medians would exclude. If the estimate of GPP or ER on the event day did not fall outside of the antecedent range, the magnitude of departure was zero, thus indicating high resistance. A negative magnitude of departure (M) represents a suppression, and a positive M a stimulation, of GPP or ER relative to the antecedent equilibrium.

To quantify the resilience of GPP and ER, we estimated recovery intervals (RI) by counting the number of days until metabolic rates returned to within the range of pre-event values, signifying a return to antecedent ~~dynamic~~ ambient equilibrium (Figure 3). If metabolism from the isolated flow event did not fall outside of the antecedent range and M is was zero, there was no RI (metabolism cannot recover if it never shifts outside the ambient range ~~of normality~~). To ensure additional flow events did not obscure the recovery interval of GPP or ER, we stopped counting RI the day before the next event (i.e., if another flow event happened four days later, we stopped counting RI at 3 ~~three~~ days), and have noted this in our results as days+ ~~and used different symbols in data figures~~. To test for statistically significant differences between ER and GPP recovery intervals (RI_{ER} and RI_{GPP}) and ER and GPP magnitude of departure (M_{ER} and M_{GPP}), we ran Welch's t-tests in R (R Core Team, 2018).

While limiting our assessment to isolated flow events significantly decreased the number of suitable events for analysis, our choice of methods allowed us to focus on metabolic response and recovery to discrete disturbances and avoid biased comparisons of multiple high flow (but not isolated) events that encompass time periods long enough (e.g., weeks) where pre/post comparisons are less meaningful. Because flow was so variable, we chose three days to balance best practices from past work on metabolic responses to storms (e.g., four days of prior stable baseflow, Reisinger et al., 2017) while ensuring we could analyze as many events with appropriately quality-checked data as possible.

2.5-16 Testing controls on metabolic resistance and resilience

Quantifying how different antecedent conditions induce variable responses from GPP and ER is critical to furthering our understanding of stream ecosystem responses to flow disturbances. We assessed three categories of potential predictors of metabolic resistance and resilience: antecedent conditions, characteristics of the isolated flow event, and characteristics of the most recent prior flow event. Antecedent conditions included median GPP, and ER ($\text{g O}_2 \text{m}^{-2} \text{d}^{-1}$), turbidity (NTU), water temperature ($^{\circ}\text{C}$), and light PAR ($\mu\text{mol m}^{-2} \text{s}^{-1}$). Antecedent medians for turbidity were estimated from seven days prior due to missing sensor data. We had to remove poor-quality data from the turbidity dataset and chose to set methods that would accommodate inclusion of the most storms for our analysis. We compared the outcome of changing the number of days prior for events with turbidity data available for both three- and seven-day analyses and found no difference in the results. For all other variables, we estimated median values from three days prior to the flow event for correlations between metabolism M and RI. Flow event characteristics included flow magnitude (% change of cumulative daily discharge; $\text{m}^3 \text{d}^{-1}$; Equation 2), time (HH:MM) of peak discharge ($\text{m}^3 \text{s}^{-1}$), and environmental conditions (e.g., light, temperature, turbidity, season) on the event day. Characteristics of the most recent flow event included the magnitude of and days since the last flow event. We visually identified the most recent flow event (% change in cumulative daily discharge > 50) prior to each isolated flow event. We ran bivariate correlation analyses to quantify the strength and directions of linear relationships between predictor variables and metabolic resistance and resilience using the R cor.test function (R Core Team, 2018). We interpreted correlation strengths as: negligible ($r = 0.0-0.3$), low ($0.3-0.5$), moderate ($0.5-0.7$), or high ($0.7-1.0$) (Hinkle et al., 2003). All modeling and analyses were conducted in R (R Core Team, 2018).

3 Results

3.1 Flow and metabolism

Stroubles Creek is a hydrologically flashy stream, with frequent high flow events (Figure 2). Cumulative daily discharge for days with quality-checked metabolism estimates ranged from 66 to 114,408 $\text{m}^3 \text{d}^{-1}$, with a median of 6,230 $\text{m}^3 \text{d}^{-1}$. The 15 isolated flow events selected for analyses were within the mid-high range of all cumulative daily discharge values, and were of magnitudes that occurred multiple times a year (Table 2, Figure 2). We identified isolated flow events of interest based on percent changes in flow, so changes in cumulative daily discharge are proportional across seasons. During the entire measurement period, GPP ranged from 0.002 to 17.3 $\text{g O}_2 \text{m}^{-2} \text{d}^{-1}$ (median = 3.7 \pm 4.0); ER ranged from -0.4 -2.2 to -20.5 -27.2 $\text{g O}_2 \text{m}^{-2} \text{d}^{-1}$ (median = -9.6) (Figure 4; O'Donnell and Hotchkiss, 2019). Stroubles was heterotrophic ($|\text{ER}| > \text{GPP}$), except for 38 days (3%) where $\text{GPP} > \text{ER}$, all of which occurred in spring except for one day in the fall.

3.2 Metabolic resistance and resilience

GPP most often declined following an isolated flow event, whereas ER rarely deviated from the antecedent equilibrium during higher flows. The magnitude of departure for GPP (M_{GPP}) ranged

from -0.92 to 0.09, with a median of -0.14 (Table 3; Figure 5). GPP was inhibited during 11 and stimulated during two 2 of 15 isolated flow events. The magnitude of departure for ER (M_{ER}) ranged from -0.59 to 0.22, with a median of 0.00 (Table 3; Figure 5). Three of 15 flow events stimulated ER, five repressed reduced ER, and ER did not deviate from the antecedent equilibrium for seven events (i.e., M_{ER} was zero). Overall, the direction of ER response to elevated flow was more variable than that of GPP.

Although GPP exhibited stronger responses across isolated flow events than ER, M_{GPP} and M_{ER} were positively correlated ($R^2 = 0.39$, $p = 0.007$, Figure 5) and not significantly different ($p = 0.06$, $\alpha = 0.05$). M_{GPP} was less than M_{ER} for nearly all flow events, except for one in which M_{GPP} and M_{ER} were both zero and two where M_{GPP} and M_{ER} were both small (Figure 5, Figure A19). The isolated flow event that induced the greatest stimulation of GPP ($M_{GPP} = 0.09$) also stimulated ER ($M_{ER} = 0.05$). Of the other two events that stimulated ER, one had no GPP response ($M_{GPP} = 0$) and the other had a minor GPP reduction ($M_{GPP} = -0.06$). Similarly, the only other event that stimulated GPP ($M_{GPP} = 0.03$) had no ER response, suggesting many flow disturbances may decouple GPP and ER.

Both GPP and ER typically recovered from flow-related stimulation or reduction in less than three days (Table 3). There were many isolated flow events where GPP took multiple days to recover but ER never departed from the antecedent dynamic equilibrium (i.e., $M = 0$; Figure 5). When M_{GPP} and M_{ER} were both greater than zero, ER almost always recovered faster than GPP. RI_{GPP} ranged from 1-9+ d, with an average of 2.5 d (Table 3). RI_{ER} ranged from 1-2 d, with an average of 1.1 d (Table 3). There was only one isolated flow event where GPP recovered before ER. While ER always recovered before another flow event occurred, GPP did not recover before another flow event for four 4 of 15 analyzed events. Excluding the four 4 of 15 events when GPP did not recover, recovery intervals for GPP and ER were not correlated (Figure 5) or significantly different ($p = 0.12$, $\alpha = 0.05$).

3.3 Controls on metabolic resistance and resilience after a flow disturbance

Although GPP and ER are linked processes, the variables that were moderate or strong predictors of resistance or resilience ($r > 0.5$) differed between ER and GPP (Table 4; Figure A21 6). There were no predictors with moderate or stronger relationships for both M_{GPP} and RI_{GPP} . Because the median RI_{ER} was zero, bivariate correlations could not be used to determine potential predictors of ER resilience. Peak discharge of the flow event was negatively correlated with M_{ER} ($r = -0.59$). The magnitude of each disturbance, characterized by the % change in cumulative daily discharge, was negatively correlated with M_{GPP} ($r = -0.46$, $p = 0.08$) and M_{ER} ($r = 0.66$, $p = 0.01$, $\alpha = 0.05$) (Figure 6 7), but was not significantly correlated with RI_{GPP} ($p = 0.54$; $\alpha = 0.05$). Overall, there were multiple environmental controls on metabolic resistance or resilience that were strongly correlated with either GPP or ER, but no significant drivers of both GPP and ER resistance and resilience (Table 4).

4 Discussion

4.1 Metabolic resistance and resilience

GPP and ER responded differently to isolated flow events in a heterotrophic stream draining a heterogeneous urban-agricultural landscape. Notably, ER was more resistant than GPP (Figure 4-Figures 5,6). Of the fifteen high flow events analyzed here, three events stimulated ER and there were two instances of minor GPP stimulation (Table 3). The flow disturbance of heterotrophic activity was likely balanced by increased inputs of organic carbon from terrestrial sources that stimulated respiration (Roberts et al., 2007; Demars, 2019). The potential balance between subsidy and stress that buffered changes in ER during higher flows was a pattern that emerged in an analysis of metabolism at Stroubles Creek across all flows: We found similar

differences in how GPP and ER change with discharge across all days with metabolism estimates from Stroubles Creek (instead of event-specific analyses presented in this paper); GPP decreased but ER was relatively constant on days with higher than median flow (O'Donnell and Hotchkiss, 2019). While we do not discuss net ecosystem production results in the context of this work because the patterns mirror those for ER (O'Donnell and Hotchkiss, 2019), we note that during the time periods of different GPP and ER responses and recovery to higher flow, Stroubles Creek was even more heterotrophic due to the higher resistance and resilience of ER relative to GPP. How often and when GPP and ER respond similarly to flow disturbances may differ among ecosystems as a function of their metabolic balance (GPP:ER), nutrient limitation status, and history of flow disturbance. Ultimately, flow-induced changes disproportionately disturbed GPP relative to ER, even in a stream like Stroubles Creek with frequently dynamic flows and relatively short recovery times.

ER was also more resilient than GPP. Differences in ER and GPP resilience were likely a result of flow-induced changes to physicochemical parameters (e.g., increasing turbidity with higher flows) that can also enhance the physical disturbance of flow on GPP (O'Donnell and Hotchkiss, 2019). For instance, sustained periods of high turbidity following a flow disturbance can prolong the recovery of GPP by inhibiting light attenuation (Blaszczak et al., 2019). In contrast, higher resilience of ER is likely a function of greater resistance of ER to disturbances (i.e., smaller M ; Table 3) as well as flow-induced ER stimulation. The correlation of M_{GPP} and M_{ER} , but a lack of correlation between RI_{GPP} and RI_{ER} (Figure 5, Table 3), suggests GPP and ER were temporarily decoupled while recovering, despite similar initial responses of GPP and ER to flow disturbances.

The dynamic nature of stream metabolism, even during low flow periods, must guide how we quantify metabolic responses to disturbance. When we estimated ~~quantified~~ resistance as a deviation from an antecedent average (e.g., Reisinger et al. 2017; Roley et al. 2014), few only a subset of analyzed flow events yielded 100% resistance and every metabolism estimate was classified as a reduction or stimulation. Without acknowledging the ~~"pulsing steady state"~~ dynamic ambient equilibrium of stream metabolism in many streams and rivers, we may overestimate disturbances in ecosystem function. In assessing metabolic responses and recovery from smaller flow events relative to the dynamic equilibrium of metabolism during ambient flows at baseflow, we found some of the shortest metabolic recovery intervals recorded in the literature (Figure 8; Table A1). Incorporating the ~~pulsing equilibrium~~ dynamic nature of metabolism and standardizing calculations of metabolic recovery dynamics will enable more robust, cross-site comparisons of complex ecosystem response to changes in flow.

Our analysis of only 15 isolated flow events provided examples of all four hypothesized changes in metabolism with flow (Figure 1; H1-H4). ER was more resistant than GPP to most flow disturbances (H1). At small-to-intermediate sized flow disturbances, the response of metabolism was variable (H2,H3), with the greatest range of metabolic stimulation or reduction (i.e., subsidy or stress) observed at smaller flow changes (Figure 6). ER and GPP also did not increase or decrease relative to their ambient equilibrium during several high flow events (H4). With increasing intensity of flow disturbance, stress and replacement may indeed scale with intensity (H3). We note that many smaller streams, even those draining heavily modified landscapes, may continue to play an important role in carbon cycling and nutrient removal, especially during smaller flow disturbances. Further work exploring when and why metabolism-flow dynamics adhere to predicted disturbance responses is critical for a predictive understanding of disturbances and ecosystem health.

4.2 Controls on metabolic resistance and resilience after a flow disturbance

In addition to testing potential subsidy-stress responses of metabolism to higher flow disturbances, a major objective of this work was to identify potential controls metabolic resistance and resilience. While GPP responded similarly to flows regardless of magnitude, ER was more resistant to smaller magnitude isolated flow events. Our hypothesis prediction that isolated flow events of greater magnitudes (i.e., larger % change in cumulative daily discharge) would result in less resistance and higher M_{GPP} and M_{ER} , due to increased scouring, was supported only for M_{ER} . GPP appears to have low resistance to flow disturbances, regardless of flow magnitude (Table 4, Figure 7 & 8; Reisinger et al. 2017; Roley et al. 2014). Of the other stream metabolism studies that provided results suitable to include in our comparison of % reduction in GPP or ER and metabolic recovery intervals (RI_{GPP} , RI_{ER} ; Figure 7), two were from streams draining more heavily urbanized watersheds (Reisinger et al. 2017, Qasem et al. 2019), and one was from a stream draining an agriculturally-dominated landscape (Roley et al. 2014). It appears streams draining more urbanized landscapes have larger reductions in metabolism and longer recovery intervals after higher flow disturbances; additional analyses at sites covering a range of land cover types and flow regimes will provide exciting opportunities to see if the trends in Figure 7 are more broadly applicable.

The different responses of GPP and ER to variable flow may be attributed to differences in energy sources and locations of autotrophs and heterotrophs (Uehlinger, 2000, 2006). Primary producers reside in exposed areas on the streambed to access light required for photosynthesis, and are thus more vulnerable to scour than heterotrophic biofilms tucked within, and protected by, substrates in the streambed, sediments, and hyporheic zone (Uehlinger, 2000). At some threshold of higher flows that disturb more protected areas within and below streambeds, we expect ER will decline as flow-induced stress exceeds flow-induced carbon and nutrient subsidies. Analyses of the interactions between flow-induced changes in shear stress, water depth, and light availability may provide additional insights to tests of predicted subsidy-stress dynamics related to stream metabolism. Future analyses that include event duration may also provide new insights into flow-metabolism dynamics: Do sustained, higher flows change GPP and ER in the same way as a more instantaneous, intense flow event? As is common of long-term characterizations of metabolism in streams, many high flow days had metabolism model outputs that did not hold up to quality checks and thus were not included in our analyses. Overcoming the logistic and computational challenges of estimating metabolism during extreme flows that disturb deeper substrates will also allow us to better test predictions relating flow magnitude with ecosystem functions.

Quantifying how different antecedent conditions induce variable responses from GPP and ER is critical to furthering our understanding of stream ecosystem responses to flow disturbances. Contrary to our predictions Contrary to our prediction that past scouring might reduce future resistance to disturbances, the size of the most recent antecedent flow disturbance had a positive relationship with M_{GPP} and M_{ER} (Figure A19, A21). M_{GPP} was smaller and GPP was more resistant when the most recent flow events were larger. Similarly, the % change in cumulative daily discharge from the last event was positively correlated with M_{ER} . Stream biota still recovering and regenerating biomass lost from scour might respond differently to flow events depending on successional stage (Peterson and Stevenson, 1992). Furthermore, biomass growth initially stimulated by a preceding event may have been limited by one or more nutrients later supplied by the isolated flow event. We ultimately do not know what caused the unexpected negative relationships between the magnitude of the most recent event and M_{GPP} as well as M_{ER} in Stroubles Creek; quantifying the interactions between successional recovery and changes in nutrient limitation across multiple flow events may provide improved insights into the mechanisms behind elucidate this interesting relationship.

Environmental conditions on the day of isolated flow events that promote biomass growth, such as high light and temperature, were not significant predictors of ER or GPP recovery intervals. Metabolic recovery trajectories often increase with temperature and light PAR (Uehlinger and Naegeli, 1998; Uehlinger, 2000), and consequently may change also display a seasonally component, with faster recoveries in spring and slower recoveries in winter (Uehlinger, 2000, 2006). We found a negative relationship between RI_{GPP} and both temperature and season (Figure A20), suggesting that under colder conditions and in winter months, GPP takes longer to recover. While we did not find strong predictors of RI_{ER} among the environmental variables in our dataset, changes in the source, magnitude, and biological reactivity ~~ability~~ of organic matter inputs may alter RI_{ER} (Roberts et al., 2007). How do changes in nutrients and organic matter govern the resistance and resilience of GPP and ER? Combining high-frequency nutrient and organic matter quality measurements with metabolic resistance and resilience estimates will offer an improved understanding of how changing resources mediate metabolic responses to flow changes.

~~We did not find evidence to support a single subsidy stress response of metabolic changes during and after high flow events (Figure 1). ER was more resistant than GPP to most flow disturbances (H1). At small intermediate sized flow disturbances, the response of metabolism was variable (H2,H3), with the greatest range of metabolic stimulation or reduction (i.e., subsidy or stress) observed at smaller flow changes (Figure 7). ER and GPP did not increase or decrease relative to their antecedent "pulsing equilibrium" during several high flow events (H0). Light, temperature, or turbidity may control the variability in metabolic response to smaller flow disturbances. With increasing intensity of flow disturbance, stress and replacement may indeed scale with intensity (H3).~~

5 Conclusions

Metabolic regimes are punctuated by high flow events that create frequent pulses of stimulated or repressed reduced GPP or ER (e.g., Uehlinger 2006; Beaulieu et al. 2013; Bernhardt et al. 2018). As such, changes in flow play an influential role in the trends and variability in daily metabolism. While geomorphology and disturbance regimes may control metabolic resistance across sites (Uehlinger, 2000; Blaszcak et al., 2019), within-site variability of M and RI may be controlled by the characteristics of each flow event. Differences between ER and GPP response and recovery to flow disturbances at our study site were controlled by higher resistance and resilience of ER relative to GPP. Within this study, our prediction that ER would be more resistant than GPP to flow disturbances was supported, as ER frequently did not even deviate from the antecedent ambient equilibrium. However, ER had less resistance to events of greater magnitude: M_{ER} was negatively correlated with the % change in discharge of flow event, whereas M_{GPP} was not, suggesting that GPP responded similarly to changes in flow regardless of flow magnitude. Metabolic responses s to small and intermediate flow disturbances were was variable: GPP and ER were both stimulated and suppressed. We suggest there may be a resistance threshold to flow disturbances, where controls other than flow magnitude (e.g., season, light, turbidity) might regulate metabolic responses to lower flow changes. Using segmented process-discharge relationships to quantify a resistance threshold of processes to flow disturbances (O'Donnell and Hotchkiss, 2019) may support a more predictive understanding of metabolic response to flow disturbances, as it provided insights on how patterns of water quality parameters and metabolism changed across the full range of flow, thus supporting the inferences we were able to make from storm-specific analyses in this paper.

One motivation of our work was to better understand metabolic dynamics in less pristine ecosystems, where flashy hydrology makes estimating metabolism more challenging, and further decreased the number of events with appropriate data for our analysis. Despite only

analyzing 15 high flow events, many of the past analyses on related topics included a similar or fewer number of events over a shorter time period. Our work fills in substantial knowledge gaps: we analyzed across seasons (not only summer months or a short sensor deployment period) and high flow magnitudes (not only base flow or the highest flow disturbances), which allowed us to show a suite of different metabolic responses to changing flow. We are also left with questions about how ecosystem processes respond to discrete changes: how might environmental drivers of metabolic subsidy or stress determine thresholds of resistance and timelines of recovery? How do recent high flow events facilitate improved resistance to flow disturbances? What is the role of flow duration in altering metabolism within and after high flow events? Ultimately, we are entering an era of metabolic data opportunity (e.g., Bernhardt et al. 2018). As time series of metabolism lengthen and modeling tools improve, we envision exciting opportunities to better assess the consequences of isolated flow events as well as the impacts of multiple, sequential high flow disturbances that did not meet our criteria for analyzing isolated flow events in this paper. While the short time periods between high flow events in many streams and rivers make isolating and quantifying functional resistance and resilience an ongoing challenge, including dynamic flow in our assessment of metabolic regimes is a critical next step toward a more holistic understanding of frequently disturbed ecosystems.

Code and data availability. All data and results are included in the Appendices of this paper. Supplemental data files and metadata (not embedded in this document) can be downloaded at <https://tinyurl.com/RMetab>

Author contributions. BO developed the ideas for this manuscript with ERH. BO led the data analyses and development of resistance/resilience indices with ERH. BO and ERH wrote and edited the manuscript.

Figure 1. Potential metabolic responses along a subsidy-stress gradient of stream flow (adopted from Odum et al. 1979). Flow is on the x-axis. The y-axis represents ecosystem metabolism (i.e., gross primary production and ecosystem respiration; GPP and ER), scaled to the same "normal" starting values for comparison, and is broken into four categories as proposed by Odum et al. (1979): (1) subsidy (when subsidization flow replenishes carbon and nutrients dominates and metabolism increases), (2) normal (periods of dynamic equilibrium metabolic pulsing equilibrium under ambient flow), (3) stress (when ecosystem processes are repressed suppressed by disturbance), and (4) replacement (when there is a severe reduction in metabolism and communities are scoured or replaced). H1-H4 labels correspond to different hypotheses about how GPP and ER may respond differently to flow (H1) and how metabolism might change with flow (H2-H4), and are described further in the main text of the introduction. The inset graph next to the 'normal' bracket depicts how ambient process rates are best represented by a pulsing dynamic ambient equilibrium rather than a fixed point of stability (sensu Odum et al. 1995).

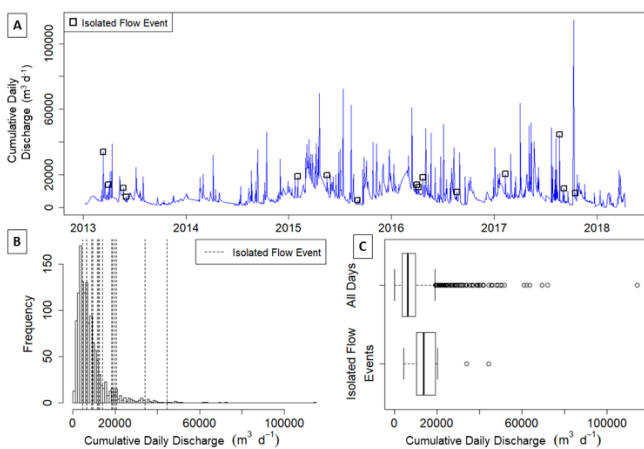

Figure 2. (A) Time series of cumulative daily discharge (m^3d^{-1}) on all days with quality-checked metabolism estimates from 2013-01-08 to 2018-04-14. The 15 isolated flow events analyzed for metabolic responses to higher flow are represented by open squares. (B) Frequency distribution of cumulative daily discharge for days with quality-checked metabolism estimates. Vertical dashed lines denote the cumulative daily discharge values of the 15 different isolated flow events. (C) Box plots of cumulative daily discharge (m^3d^{-1}) for all days with metabolism estimates versus from isolated flow event days that fit our criteria for analyzing metabolic resistance and resilience.

Figure 3. Example calculations of metabolic resistance (M) and resilience (RI). Daily gross primary production (GPP) was estimated for the three days before, one day during (grey square), and two days following an isolated flow event that occurred on 2017-02-09. Dashed horizontal lines represent the maximum and minimum GPP estimates from three days prior to the flow event. In this case, GPP declined was repressed, and the magnitude of departure (M with grey arrow) is the difference between minimum GPP estimate from the antecedent range (bottom dashed line) and GPP during the event. After this flow event, GPP recovered to its antecedent range on day in 2 two days; recovery interval days (RI) are represented by the grey boxed numbers next to GPP estimates.

Figure 4. Gross primary production (GPP, top) and ecosystem respiration (ER, bottom) in Stroubles Creek, VA from 2013-01-08 to 2018-04-14. ER is represented here as a negative rate because it is the consumption of oxygen. Dashed vertical lines mark the isolated flow events that fit our criteria for analyzing metabolic responses to flow change (Figure 2).

Figure 5. (A) Resistance (i.e., magnitude of departure; left) and (B) resilience (i.e., recovery interval; right) of gross primary production (GPP) versus ecosystem respiration (ER) in Stroubles Creek, VA. Dashed lines are is the 1:1 lines; solid line is the linear model fit through all data (p-value = 0.007, $R^2 = 0.39$). Black circles are isolated flow events that did recover to antecedent equilibrium, or were unresponsive (i.e., $M = 0$). Grey squares are the isolated flow events that did not recover to antecedent equilibrium before another flow event occurred. R_i values are jittered along the x-axis (the points are slightly scattered around their value to visualize overlapping values); each recovery interval was calculated at the daily scale.

[Image moved to A21]

Figure 6. Pearson correlation coefficients for tested controls on ecosystem respiration magnitude of departure (M_{ER}), gross primary production magnitude of departure (M_{GPP}), and recovery interval of GPP (RI_{GPP}). Variables are divided into three groups (left-right): median antecedent conditions, disturbance characteristics, and characteristics of the most recent flow event. For units of variables, see Table 4.

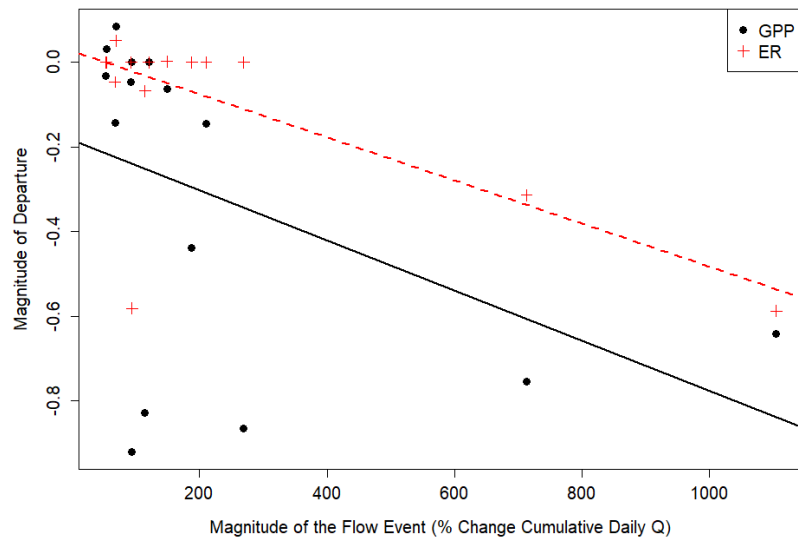

Figure 67. Flow event magnitude (% change in cumulative daily discharge relative to the day prior) was negatively correlated with magnitude of departure (M) for gross primary production (GPP; $R^2= 0.15$, $r = -0.46$, $p = 0.08$) and ecosystem respiration (ER; $R^2= 0.39$, $r = -0.66$, $p = 0.01$, $\alpha = 0.05$). The solid black line is the regression for the relationship between M_{GPP} and % change in discharge, while the dashed red line is the regression for the relationship between M_{ER} and % change in discharge. % change in cumulative daily discharge was significantly negatively correlated with M_{ER} , but not significantly correlated with M_{GPP} .

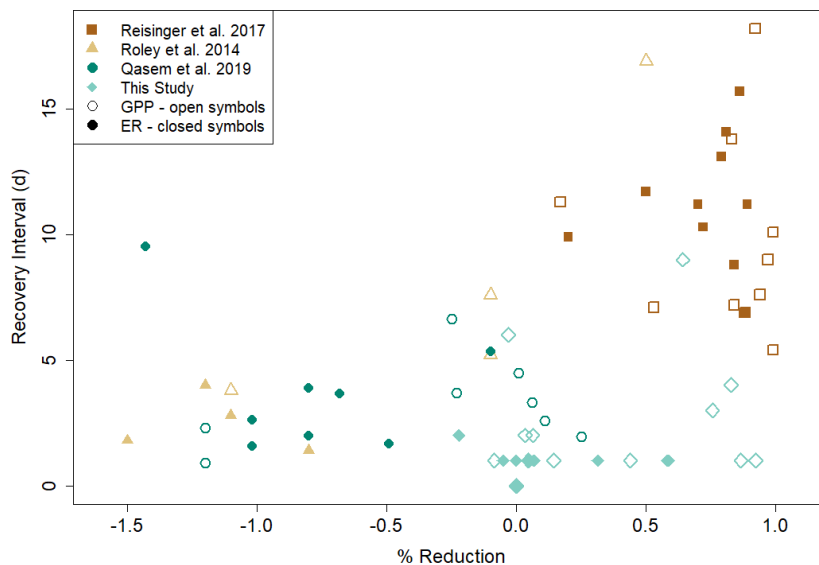

Figure 7-8. A synthesis of metabolic recovery intervals (days) and % reduction of gross primary production (GPP) and ecosystem respiration (ER) in response to flow disturbances. Open symbols represent GPP response, and closed symbols signify ER response. A negative % reduction is a stimulation. Included in Supplemental Table A1 are additional studies that have reported either recovery intervals, or % metabolic reduction in response to flow disturbances, but not both, and consequently could not be included here.

Table 1. Parameter symbols, descriptions, and units used in Equation 1

[coded in LaTeX; no changes]

Table 2. Cumulative daily discharge (CDQ), % change in CDQ relative to the prior day, metabolism (gross primary production (GPP), ecosystem respiration (ER)), and air-water gas exchange (K) of isolated flow events analyzed for metabolic recovery

[coded in LaTeX; no changes]

Table 3. Magnitude of departure (M, unitless) and recovery intervals (RI, days) of gross primary production (GPP) and ecosystem respiration (ER) during and after fifteen isolated flow events between 2013-01-08 and 2018-04-14. A negative M represents a suppression, and a positive M a stimulation, where GPP or ER increase relative to the antecedent equilibrium. If GPP did not recover before the next flow event, RI is noted with a "*" and those events are not included in recovery interval correlation analyses. n/a is "not applicable", and is used to note times when ER or GPP did not deviate from its antecedent range, and therefore had no recovery interval.

[coded in LaTeX; no changes outside of legend text]

Table 4. Pearson correlations (r) between predicted drivers of gross primary production (GPP) and ecosystem respiration (ER) magnitudes of departure (M) and recovery intervals (RI) of isolated flow events. Predictor variables with moderate or stronger relationships ($r > 0.5$) are bolded. p-values are included in parentheses.

[coded in LaTeX; p values added in parentheses next to r values as requested by a reviewer. Units for different parameters tested, which were already provided in the main text, were removed to allow space for p values.]

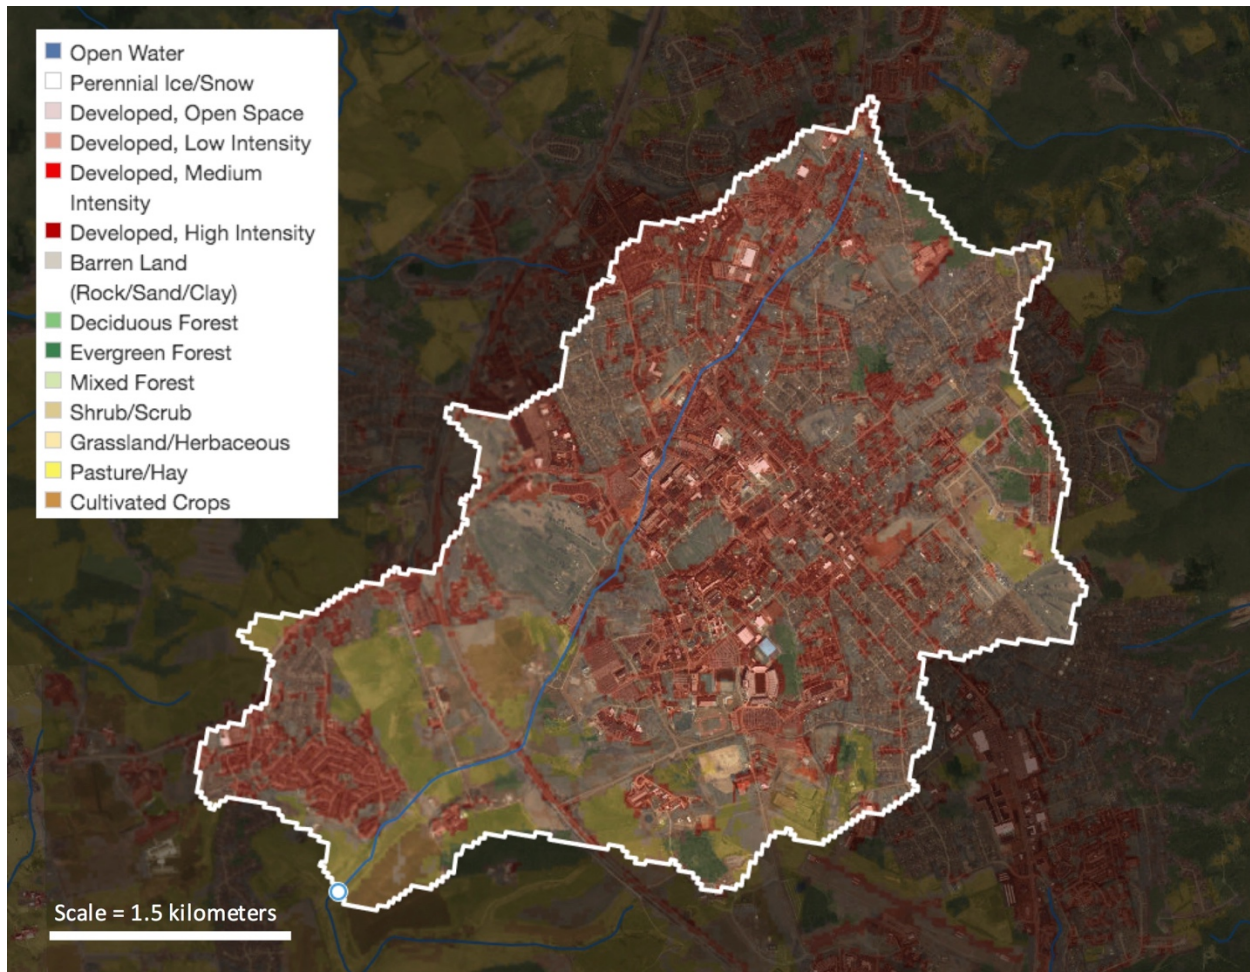

Figure A1. Stroubles Creek watershed and land cover types in the area that drains to the StREAM Lab monitoring site at Bridge 1, Blacksburg, VA, U.S.A. [The nearby weather station used for these analyses is just west of the watershed boundary and within the same valley.](#) We created this map using ArcGIS, NHDplus version 2.1, and the U.S. Geological Survey's 2011 National Land Cover Database.

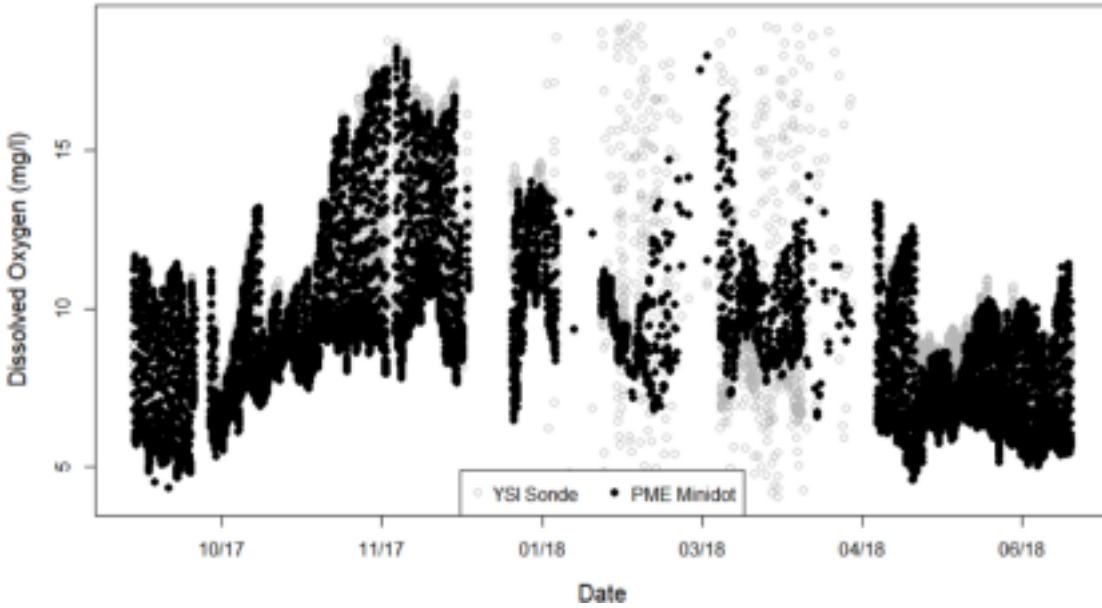

Figure A2. Dissolved oxygen measurements from the two sensors – YSI Sonde and PME Minidot - at Bridge 1 on Stroubles Creek. The spread of YSI Sonde values spanning from the end of January to mid-April was likely a result of a freeze event. We used PME data during the period of record when YSI data did not pass our quality assurance checks.

Figure A3. Example of data used to confirm modeled K_{600} (d⁻¹) using a regression of the nighttime dissolved oxygen saturation deficit versus changes in saturation (as in Hall and Hotchkiss 2017). These data are from 2017-09-04, when the estimated value for K_{600} was 22 d⁻¹.
