Sub-alpine grassland productivity increased with warmer and drier conditions, but not with higher N-deposition, in an altitudinal transplantation experiment

Abstract

Multiple global change drivers affect plant productivity of grasslands and thus ecosystem services like forage production and the soil carbon sink. Subalpine grasslands seem particularly affected and may serve as a proxy for the cold, continental grasslands of the northern hemisphere. Here, we conducted a four-year field-experiment (AlpGrass) with 216 turf monoliths, subjected to three global change drivers: warming, moisture and N-deposition. Monoliths from six different sub-alpine pastures were transplanted to a common location with six climate scenario sites (CS). CS' were located along an altitudinal gradient from 2360 to 1680 m a.s.l., representing an April - October mean temperature change of -1.4 °C to +3.0 °C, compared to $CS_{reference}$ with no temperature change and with climate conditions comparable to the sites of origin. To uncouple temperature effects along the altitudinal gradient from soil moisture and soil fertility effects, an irrigation treatment (+12-21 % of ambient precipitation) and an N-deposition treatment (+3 kg and +15 kg N ha^{-1} a^{-1}) was applied in a factorial design, the latter simulating a fertilizing air pollution effect.

Moderate warming led to increased productivity. Across the four-year experimental period, the mean annual yield peaked at intermediate CSs (+43 % at +0.7 °C and +44 % at +1.8 °C), coinciding with c. 50 % of days with less than 40 % soil moisture during the growing season. The yield increase was smaller at the lowest, warmest CS (+3.0 °C), but was still 12 % larger than at $CS_{reference}$. These yield-differences among CSs were well explained by differences in soil moisture and received thermal energy. Irrigation had a significant effect on yield (+16-19 %) in dry years, whereas atmospheric N-deposition did not result in a significant yield response. We conclude that productivity of semi-natural, highly diverse subalpine grassland will increase in the near future. Despite increasingly limiting soil water content, plant growth will respond positively to up to +1.8 °C warming during the growing period, corresponding to +1.3 °C annual mean warming.

1 Introduction

The present period of global warming is most pronounced in the cold regions of high altitude and high latitude (Core writing team, IPCC 2014). The productivity of these ecosystems is temperature-limited, and even though the temporal distribution of total annual radiation differs, they share many similarities. After the temperature decline following the Holocene climate optimum (ca. 9000 - 6000 a BP; Vinther et al., 2009), they are now experiencing a rapid rewarming.

In cold environments, the perspective on climate change is different compared to temperate and warm environments. First, mitigation of the thermal growth limitation is likely to have beneficial effects on plant growth. Second, the warming-associated drought-risk is lower. The evaporative demand is much lower and at least the initial water supply for plant growth is granted because even a small winter snowpack supplies a large soil moisture resource in spring. Third, in many regions the warming comes along with rising atmospheric nitrogen (N) deposition, originating from agriculture and fossil fuel burning. Atmospheric N deposition can be as little as <5 kg N ha^{-1} a^{-1} at remote mountain sites (Rihm and Kurz, 2001), but can reach rates >40 kg N ha^{-1} a^{-1} elsewhere in Switzerland (Rihm and Achermann, 2016). This fertilizing air pollution agent promotes plant growth and has the potential to reduce plant species diversity by favoring fast growing species (Vitousek et al., 1997; Bobbink et al., 2010; Phoenix et al., 2012). Alone and in interaction, all three factors increase the ecosystem plant productivity potential in cold regions. Given that essential ecosystem services strongly co-depend on plant productivity (e.g., forage supply for livestock and wildlife, soil erosion control and support of the biological carbon sink), an improved knowledge on how climate warming affects productivity of colder grassland systems is required.

However, previous warming experiments on plant productivity have shown inconsistent results. For example, tundra vegetation showed an up to twofold productivity increase in response to increased summer temperature (Van der Wal and Stien, 2014). In contrast, Liu et al. (2018) combined long-term observations with a manipulative experiment to find that total net primary productivity (NPP) in Tibetan grassland remained unaffected, though the relative abundance of grasses was increased at the expense of forbs and sedges by drought and warmth. In yet another meta-analysis, only 13 out of 20 experimental grassland sites revealed small increases of plant productivity due to warming (Rustad et al., 2001): while grassland ecosystems in general showed both positive and negative responses, the colder tundra systems (high latitude or altitude) with lower precipitation had positive and larger productivity responses to warming.

To make matters more complicated, evapotranspiration will increase in warming experiments. The resulting, temperature-confounded lower soil moisture makes it impossible to determine the proper temperature effect on plant growth. Only comparing the plant growth response at warming-confounded, reduced soil moisture and at experimentally mitigated soil moisture allows to distinguish warming effects from moisture effects.

A common restriction for the usability of climate change experiments for ecosystem productivity projections lies in the low number of concurrently manipulated environmental factors (Rustad 2008; but see Dukes et al., 2005 for an exception). This potentially leads to an overestimation of effects when data from several, single factor experiments are combined in meta-analyses or models (Leuzinger et al., 2011). Indeed, productivity responses to combined factors are usually less than additive in size, compared to single treatment responses (Dieleman et al., 2012; Xu et al., 2013). Not only can a low number of treatment factors, but also a low number of treatment levels invite overly simplistic interpretation of experimental results, if only a short or linear

73 segment out of a larger range of biologically possible responses is represented in the data. For example, a hump-

74 shaped response curve (2-dimensional) under atmospheric N-deposition best described the properties of a soil

75 C-sink in subalpine grassland (Volk et al., 2016). Similarly, a ridge-shaped response surface (3-dimensional),

76 driven by temperature and precipitation during 17 experimental years, was needed to explain NPP data (Zhu et

77 al., 2016). These findings demonstrate how, depending on the chosen treatment levels and their interaction with

78 the ambient climate, the vegetation in a global change productivity-experiment may respond with increasing as

79 well as decreasing growth. Combining multiple treatments with many levels might thus improve interpretation

80 of experimental outcomes and related climate change predictions.

81 Here, we present four years of results from a field experiment in the Swiss Alps. Turf monoliths from a variety

82 of grassland communities at six different sites of origin were transplanted to one common experimental site to

83 test for a plant productivity response that is not restricted to a specific species composition. At the common site,

84 transplanted turf monoliths were distributed over six levels of altitude to generate a climate gradient. Doing so,

85 we included not only the temperature change, but also the changing length of the growing period. The between-

86 year weather variability created a large variety of climate situations within the range of potential growth

87 conditions. Additionally, to uncouple temperature effects along the altitudinal gradient from soil moisture and

88 soil fertility effects, a two-level irrigation treatment and a three-level atmospheric N-deposition treatment were

89 set up in a factorial design. We hypothesized that

90   1) The effect of warming on plant growth would be beneficial at moderate warming levels, but detrimental at

91   high warming levels.

92   2) Increased soil water content would mitigate the detrimental effects of excessive warming levels.

93   3) N-deposition would exhibit a generally favorable effect on plant growth. This effect would further

94   increase with higher temperatures and irrigation due to their mitigating effect on thermal and water co-

95   limitations.

2 Materials and Methods

This experiment (AlpGrass experiment) used grassland monoliths to investigate climate change effects on subalpine pasture ecosystems in the central Alps. At six different sites in the Canton Graubünden, Switzerland, areas of 1 ha on southerly exposed, moderate slopes were selected at an altitude of ca. 2150 m a.s.l. to serve as 'sites of origin'. All six sites were mountain grassland used for summer livestock grazing, within ≤ 55 km distance of each other, but their soil (typical depth 20-30 cm) developed either on basic or on acidic bedrock. Thus, the sites of origin shared very similar climatic conditions, but represented a wide range of soil properties and plant communities. Plant communities at the sites of origin were generally dominated by grass and sedge species, but comprised also a substantial share of forbs and a few legume species. Two of the summer pastures were characterized by Sesleretalia vegetation (with *Sesleria caerulea*, *Anthyllis vulneraria*, *Helianthemum nummularium* present at both); the other four were dominated by Nardetalia vegetation (with typical species *Nardus stricta*, *Leontodon helveticus*, and *Potentilla aurea*). *Nardus stricta*, *Polygonum viviparum*, and *Carex sempervirens* were present in almost all monoliths, regardless of grassland type. Detailed information on soil properties and species composition of the different origins can be found in Wüst-Galley et al. (2020).

In June 2012 a total of 252 monoliths (6 sites of origin × 42 monoliths) of 0.1 m² surface area (L × W × H = 37 × 27 × 22 cm) were excavated at the sites of origin. Randomly generated X-Y-coordinates were used to choose the location of excavation. If a distinct location had sufficiently deep soil and no rocks, if bare soil and woody species were < 10 %, and if there was no apparent dominance of single plant species, then monoliths were extracted. Else, the next pair of coordinates was probed. Monoliths were placed into precisely-fitting, well-drained plastic boxes to facilitate future transport and avoid potential side effects of experimental treatments applied later (Appendix Fig. A1). To minimize the disturbance of temperature and moisture conditions, monoliths were immediately reinserted into the ground at their respective site of origin.

Half a year later, in November 2012, 36 monoliths were transported from each site of origin to the common AlpGrass experimental site, while 6 monoliths each remained at their original site to allow for an assessment of the transplanting effect. Standardizing harvests were done in 2012 and 2013 to homogenize the canopy of the previously grazed monoliths that had more heterogeneous canopies than mown grassland.

2.1 Experimental site and treatment design

The AlpGrass experimental site is located on the south slope of Piz Cotschen (3029 m), above Ardez in the Lower Engadine valley (Graubünden, Switzerland). The site as a whole covers a 680 m altitudinal gradient, characterized by a vegetation change from montane forest (WGS 84 N 46.77818°, E 10.17143°) to subalpine grassland (WGS 84 N 46.79858°, E 10.17843°). Along the gradient, six separate climate scenario sites (CS) were located at different altitudes (CS1: 2360 m, CS2: 2170 m, CS3: 2040 m, CS4: 1940 m, CS5: 1830 m, CS6: 1680 m a.s.l.). Photographs of the environment can be found in the Appendix (Photographs A 1-4). Because CS2 had a similar altitude as the sites of origin, it was chosen as a reference site (hereafter $CS2_{reference}$).

$CS2_{reference}$ and sites of origin are all characterized by cold winters with permanent snow cover. The snow-free period lasts approximately from May to October, with a mean April – October air temperature of 6.5 °C during the experiment (Tab. 1). Annual mean temperature at $CS2_{reference}$ was 3.2 °C and mean precipitation sum was 748 mm (Tab. 2).

At each of the 6 CS, 6 monoliths from each of the six sites of origin were installed in the ground within their drained plastic boxes, flush with the surrounding grassland surface, resulting in 36 monoliths per CS and a total of 216 transplanted monoliths (Appendix Figs. A2-A4). Monoliths in their containers were arranged side by side without a separating gap or buffer zone. The grassland surrounding the monoliths was frequently mown to prevent the introduction of new species/genotypes by seed dispersal.

At each CS, an irrigation and an N-deposition treatment were set up in a full-factorial design. One half of the 36 monoliths (3 monoliths per site of origin) received only ambient precipitation and no additional water, the other half received additional water during the growing season. Within each irrigation treatment, monoliths were subjected to an N treatment representing three levels of atmospheric N-deposition (treatment details below, and see Appendix Tab. A1 for a schematic description). At each CS, irrigation and N treatments were arranged in a randomized complete block design (six blocks each containing all six irrigation × N treatment combinations). Moreover, monoliths of the six sites of origin were assigned to the six blocks by restricted randomization so that an equal distribution of sites of origin to all blocks was ensured.

| Site | Alt. (m) | Air temp. (Mean, °C) ±1SE | | | | Δ T (°C) | $DD0°C_{total}$ | | Pre-harvest period | |
		Apr. – Oct.		annual		Apr. – Oct.	Mean ±1SE		# Days	±1SE
CS1	2360	5.1	±0.17	1.6	±0.20	-1.4	1156	±50	78	±4.3
$CS2_{reference}$	2170	6.5	±0.17	3.2	±0.23	0.0	1440	±43	91	±3.8
CS3	2040	7.2	±0.17	3.7	±0.20	0.7	1649	±67	107	±4.4
CS4	1940	8.0	±0.16	4.7	±0.25	1.5	1746	±71	104	±2.8
CS5	1830	8.3	±0.17	4.6	±0.21	1.8	1829	±10	97	±3.4
CS6	1680	9.5	±0.17	5.8	±0.21	3.0	2095	±14	104	±3.5

Table 1 Climatic parameter means across years (±1SE) at the climate scenario sites (CS) during the experiment: Mean air temperature from April to October and for the whole year, April – Oct. air temperature difference (Δ T) of respective CS' compared to $CS2_{reference}$. Degree days above 0 °C for the snow free period between annual harvests ($DD0°C_{total}$). Pre-harvest period length is the number of days between snow-melt and harvest.

| Site | Alt. (m) | Precipitation (sum, mm) | | | | Dry days (%) | | Harvest |
		Apr. – Oct.		annual		not irrigated	irrigated	Date (Ø)
CS1	2360	674	±18	752	±20	27 ±5.3	17 ±5.1	12 Aug
$CS2_{reference}$	2170	656	±27	748	±27	31 ±1.7	20 ±2.7	26 July
CS3	2040	629	±26	732	±21	42 ±5.2	24 ±4.3	22 July
CS4	1940	614	±20	739	±22	33 ±2.2	24 ±3.5	14 July
CS5	1830	628	±20	780	±17	55 ±4.4	41 ±5.0	09 July
CS6	1680	570	±19	687	±21	73 ±3.1	53 ±4.5	05 July

Table 2 Precipitation sums for the climate scenario sites, aggregated from April to October and annually. For comparison: The closest Swiss Federal Office for Meteorology station (Scuol, 1303 m a.s.l., 9 km distance) reported 662 mm mean annual precipitation during the experiment. Dry days (%) indicates the percentage of

158   days during the pre-harvest period with SWC <40 %. The phenology triggered harvest date reflects the delayed

159   vegetation development at higher altitudes.

2.2 Climate scenario site (CS) climate change treatment

The different altitudes of the CSs created a climate change scenario treatment, commencing in November 2012, when the monoliths were installed at the AlpGrass site, and ending in 2017 with the final harvest. The difference in altitude between the sites of origin and the respective CS at the AlpGrass experimental site determined the change of climatic conditions that the transplanted monoliths experienced. These conditions include the mean growing period temperature, from April to October. We assumed the evenly moderate temperature (ca. 0 °C) under the winter snow cover to be of little importance for differences in ecosystem productivity. The CS temperature treatment was specified as the deviation from $CS2_{reference}$ temperature. The available thermal energy was expressed as degree days (DD) above a threshold of 0 °C (DD0°C). To derive DD, the sum of hourly temperature means above 0°C during one day was calculated and then divided by 24 hours. To quantify the total thermal energy available for growth, DD during the snow-free period between the annual harvests (DD0°Ctotal) was summed up, considering that the perennial vegetation continues to grow after mowing.

Differences in volumetric soil water content (SWC) were quantified as the proportion of days during the growing period with a SWC < 40 % (hereafter 'dry days'). This < 40 %-threshold does not necessarily imply plant growth limitation, but it was developed to reliably contrast the soil moisture status between the CSs and between years. Thus, more time below the threshold indicates a 'drier period' in relative terms.

2.3 Irrigation treatment

An irrigation treatment with two levels was set up to distinguish the warming effect from the soil moisture effect, driven by warming. In several applications throughout the growing period, precipitation equivalents of 20 mm were applied to the monoliths under the irrigation treatment. The total amount of water added per monolith was 80, 120, 120 and 80 mm in 2014, 2015, 2016 and 2017, respectively. These amounts were equivalent to 12-21 % of the recorded precipitation sum during the growing periods.

2.4 N-deposition treatment

The N-deposition treatment consisted of three levels. Atmospheric N-deposition from air pollution was simulated to amount to a deposition of 3 and 15 kg N ha^{-1} a^{-1}, on top of the present background deposition. We used a 200 ml ammonium nitrate (NH_4^- NO_3^+)/water solution per monolith, which was applied in twelve, ca. bi-weekly fractions, covering the growing period. Monoliths without additional N-deposition received water without ammonium nitrate.

2.5 Meteorology

At all six CS we measured air temperature, relative humidity (Hygroclip 2 in an unaspirated radiation shield, Rotronic, Switzerland), and precipitation (ARG100 tipping bucket raingauge, Campbell Scientific, UK). Soil temperature and SWC were measured at 8 cm depth in 6 monoliths each at topmost CS1 and intermediate CS3, CS4 and CS5, using a SWC reflectometer with 12 cm rods (CS655, Campbell Scientific, UK). At $CS2_{reference}$ and lowest CS6 these values were measured in 18 monoliths and two points in the surrounding grassland. The measurement interval for all parameters was 10 minutes originally and was later integrated for longer periods as necessary.

199 At each site of origin, we installed Hobo U12-008 data loggers with TMC-HD sensors (Onset Computer

200 Corporation, USA) in three monoliths and one spot in the undisturbed, surrounding grassland for comparison

201 with the reference climate scenario site $CS2_{reference}$.

202 Ambient wet N-deposition was measured at $CS2_{reference}$ and lowest CS6 using bulk samplers (VDI 4320 Part 3,

203 2017; c.f. Thimonier et al., 2019) between April 2013 and April 2015. Nitrate (NO_3^-) in rainwater and melted

204 snow was analyzed by ion chromatography (ICS-1600, Dionex, USA) and NH_4^+ was analyzed using a flow

205 injection analyzer (FIAstar 5000, Foss, Denmark) with gas diffusion membrane, detection was completed with

206 UV/VIS photometry (SN EN ISO 11732).

207

208 **2.6 Plant productivity**

209 All plant material (including mosses and lichens) of the monoliths was cut 2 cm above the soil surface once per

210 year at canopy maturity. This plant removal serves as a proxy for the short, but intensive summer grazing period

211 of the traditional management. As a result of the phenology-triggered harvests (anthesis of *Festuca rubra*), the

212 topmost CS1 was cut on average 38 days later than the lowest CS6. Plants were dried at 60 °C, allowed to cool

213 in a desiccator and weighed to determine dry matter yield (hereafter biomass yield).

214

215 **2.7 Data analyses**

216 Data were analyzed by linear mixed-effects models. First, we were interested in the overall response of biomass

217 yield over years as affected by the treatment factors. To this aim, biomass yield was averaged across the four

218 experimental years (2014-2017) and was modeled as function of CS (factor of 6 levels), irrigation (factor of 2

219 levels), and N-deposition (factor of 3 levels), including all interactions. 'Site of origin' (6 sites) and block (36

220 levels: 6 CS × 6 blocks) were modeled as random factors (random intercepts). Restricted maximum likelihood

221 was used for parameter estimation. For the inference on fixed effects, the Kenward–Roger method was applied

222 to determine the approximate denominator degrees of freedom (Kenward and Roger 1997), and the marginal

223 and conditional R^2 of the model were computed following Nakagawa and Schielzeth (2013). Differences in

224 biomass yield between single CSs and the $CS_{reference}$ were tested based on the model contrasts (post-hoc *t*-tests,

225 without using multiple comparisons). To receive additional insight into within year treatment effects, this very

226 same model was also applied to data of each of the four individual years.

227 Second, to consider the time effect and the repeated structure of the data, biomass yield of all four years was

228 modeled as function of year (factor of 4 levels), CS, irrigation, and N-deposition (factor levels as described),

229 including all interactions. Here, random factors consisted of an identifier for monolith (216 levels) to consider

230 the potential correlation of monoliths' biomass yield over years (modeled as random intercept). In addition, the

231 model included the random factor 'site of origin' and allowed for a separate block term at each of the four years

232 (details as described). Residuals of all models were evaluated for normality and homoscedasticity and fulfilled

233 assumptions of linear mixed-effects models. Finally, to gain insight into effects of thermal energy and drought

234 on plant productivity, biomass yield was modeled as function of each $DD0°C_{total}$ and percent days with less soil

235 moisture ('dry days') using generalized additive models (GAM). Generalized additive models had to be used as

236 simple linear models could not appropriately handle these relationships. The GAMs included the fixed factor

237 irrigation and a smooth term for the continuous variables $DD0°C_{total}$ and percent dry days, respectively, for both

238 levels of the irrigation treatment. Model validation revealed that the assumptions of GAMs were met; more

239   information on the model specification is given in the Appendix. All data was analyzed with the statistics

240   software R, version 4.0.2 (R Core Team 2020) and packages lme4 for linear-mixed effect models (Bates et al.,

241   2015) and mgcv for GAMs (Wood, 2017).

3. Results

3.1 Climate scenario site (CS) environmental conditions

3.1.1 Low atmospheric background N-deposition

Total N-deposition was 3.3 kg N ha^{-1} a^{-1} at CS2$_{reference}$ and 4.3 kg N ha^{-1} a^{-1} at the lowest CS6. The seasonal distribution showed peak deposition rates in June and July.

3.1.2 Consistent temperature, precipitation and drought changes with altitude

The mean Apr. – Oct. temperature gradient of up to +3 °C compared to CS2$_{reference}$, distributed over four altitudinal levels (CS3 – CS6), constituted the warming treatment. Conversely, temperature at the topmost CS1 constituted a cooling treatment (Δ temp. -1.4 °C), extending the range of temperature responses tested (Δ temp., Tab. 1). As intended, the DD0°C$_{total}$ steadily increased from CS2$_{reference}$ to lowest CS6. The pre-harvest period (PHP) length was fairly similar among CSs, because the early snow-melt at the lower CS was compensated by an early harvest (Tab. 1).

We observed a small, non-linear increase of precipitation with altitude during April – October. The recorded annual precipitation sum was somewhat larger than the sum for the growing period (Tab. 2).

The length of the period with less soil moisture (% dry days) doubled along the altitudinal gradient: At the two top CSs only one third of the pre-harvest period was dry, compared to two thirds of the time at the lowest site CS6 (compare Tables 1 & 2). The irrigation treatment reduced the incidence of days with < 40 % soil moisture to 60-80 % of the non-irrigated situation (Tab. 2).

3.1.3 Small transplantation effects on soil temperature and moisture

At the sites of origin, the mean April – October soil temperatures in the undisturbed grassland were 8.8 ° (±0.3) compared to 8.9 °C (±0.3) in the monoliths. At CS2$_{reference}$ this difference was 9.2 ° vs. 9.5 °C. Thus, the surrounding grassland at CS2$_{reference}$ site was on average 0.4 °C warmer than at the sites of origin, and monoliths at CS2$_{reference}$ were 0.3 °C warmer than the undisturbed grassland surrounding the experiment. Volumetric SWC in the undisturbed grassland was 1 % lower on average compared to SWC in the monoliths at CS2$_{reference}$ and lowest CS6.

3.2. Yield

3.2.1 Insignificant transplantation effect

The mean annual yield was 20 % larger at CS2$_{reference}$ (control treatment monoliths), compared to the origins (162 g m^{-2}; ±12.7), but not significantly different ($P = 0.19$; paired, two-sided t-test). Equally important, the difference showed no trend, as in some years the yield at CS2$_{reference}$ was higher, in some years it was lower compared to the sites of origin.

3.2.2 Strongest climate scenario site effect at intermediate CS

Across the four years, we found a highly significant effect of the CS on aboveground biomass yield (Tab. 3). At intermediate sites, yields increased by +43 %, +18 % and +44 % (CS3, CS4 and CS5, respectively; Tab. 4, $P \leq$ 0.05 at least), related to +0.7, +1.5, and +1.8 °C of the warming component of the respective CS (compare Table

1). Even at the warmest site CS6 the yield was still +12 % larger compared to the CS2$_{reference}$ site ($\Delta T = +3$ °C, $\Delta DD0$°C$_{total} = 655$). The coldest site CS1 was not less productive than CS2$_{reference}$. In the year of the overall maximum productivity (2016), also the coldest site CS1 and the warmest site CS6 produced their respective record yield (Tab. 4). Overall, the yields of the 24 combinations of year × CS varied by a factor of 2.1 (yields averaged across irrigation and N-deposition treatments). The yield response to CSs differed between years (Appendix Tab. A2, year × CS interaction: $P < 0.001$) in that the CS effect became weaker towards the end of the experiment (Appendix Tab. A3).

Variable	df$_{num}$	df$_{den}$	F-value	P
Climate Scenario (CS)	5	29.1	14.9	< 0.001
Irrigation	1	145.2	6.5	0.012
N	2	145.2	1.3	0.287
CS × Irrigation	5	145.2	1.1	0.352
CS × N	10	145.2	0.5	0.864
Irrigation × N	2	145.2	1.1	0.348
CS × Irrigation× N	10	145.2	1.3	0.241

df$_{num}$: degrees of freedom of term; df$_{den}$: degrees of freedom of error (which can be fractional in restricted maximum likelihood analysis)

Table 3 Summary of analyses for the effects of climate scenario site (CS), irrigation and N deposition on aboveground biomass yield of subalpine grassland. Data were averaged across the four experimental years (total $n = 216$). F-tests refer to the fixed effects of the linear mixed-effects model. The marginal and conditional R^2 were 0.41 and 0.50, respectively.

299   **Table 4** Aboveground biomass yield (means ±1SE) per CS and year, averaged across irrigation, N-deposition treatments, and site of origin. Within each year, significance

300   tests are against CS2$_{reference}$, based on contrasts derived from linear mixed-effects models (see Table 3 and Appendix Tab. A1, for the respective model summaries). Shaded

301   values indicate the CS with the greatest aboveground biomass yield per year and across years.

 3.2.3 Irrigation effect in dry years

303 Despite a mere +7.7 % average yield increase (Fig. 1 b), irrigation turned out to be a significant factor across years

304 (Table 3). Yet, the effect of irrigation differed between years (Appendix Tab. A2, year × irrigation interaction: *P* <

305 0.001), and single years analysis detected positive effects of irrigation only in 2015 (+15.8 %) and 2017 (+18.8 %)

306 (Appendix Tab. A3). In these years, the percentage of days with < 40 % soil moisture was highest.

307

308 **3.2.4 No nitrogen deposition effect**

309 Five years of experimentally increased atmospheric nitrogen deposition (+3 and +15 kg N ha^{-1} a^{-1}) did not cause a

310 significant response of biomass yield. Moreover, there was no significant interaction detected between the N-

311 treatment and the factors CS or irrigation (Fig. 1 a; Tab. 3). Single years analysis, to test for a late response to

312 accumulating amounts of N, revealed a marginally significant effect only in 2016 (Appendix Tab. A3).
313

314 **Figure 1 a, b** Aboveground biomass yield as a function of the altitude of CSs. Data were averaged across years;

315 circles denote means ±1 SE. Warming and dry days (%) increase with decreasing altitude from left to right. **a)** Yield

316 values grouped by N-deposition treatment (0, 3 and 15 kg N ha^{-1} a^{-1}, in addition to 4-5 kg N background deposition).

317   **b)** Yield values grouped by irrigation treatment. Overlapping means and SEs are shifted horizontally to improve

318   their visibility.

319

320   **3.2.5 Yield at climate scenario sites strongly relates to changes in thermal energy and soil moisture**

321   Biomass yield at the different CSs was significantly related to thermal energy, expressed as growing $DD0°C_{total}$.

322   Here, intermediate CSs (CS3, CS5) had greatest yields at intermediate values of $DD0°C_{total}$, indicated by the

323   curvature of the predicted line in particular under irrigated conditions (Fig. 2 a, Appendix Tab. A4, smooth term for

324   $DD0°C_{total}$: $P < 0.001$).

325   Similarly, biomass yield was significantly related to days with soil moisture < 40 % ('dry days') during the growing

326   season, with intermediate CS3 and CS5 having highest yields at around 50 % of dry days under no irrigation and at

327   around 30 % dry days under additional irrigation (Fig. 2 b, Appendix Tab. A5, smooth term for dry days: $P <$

328   0.001). Under unirrigated conditions, in parallel with a doubling of dry days (from 27 % at topmost CS1 to 55 % at

329   intermediate CS5), yield consistently rose and only fell at the driest and warmest site CS6, with 73 % dry days.

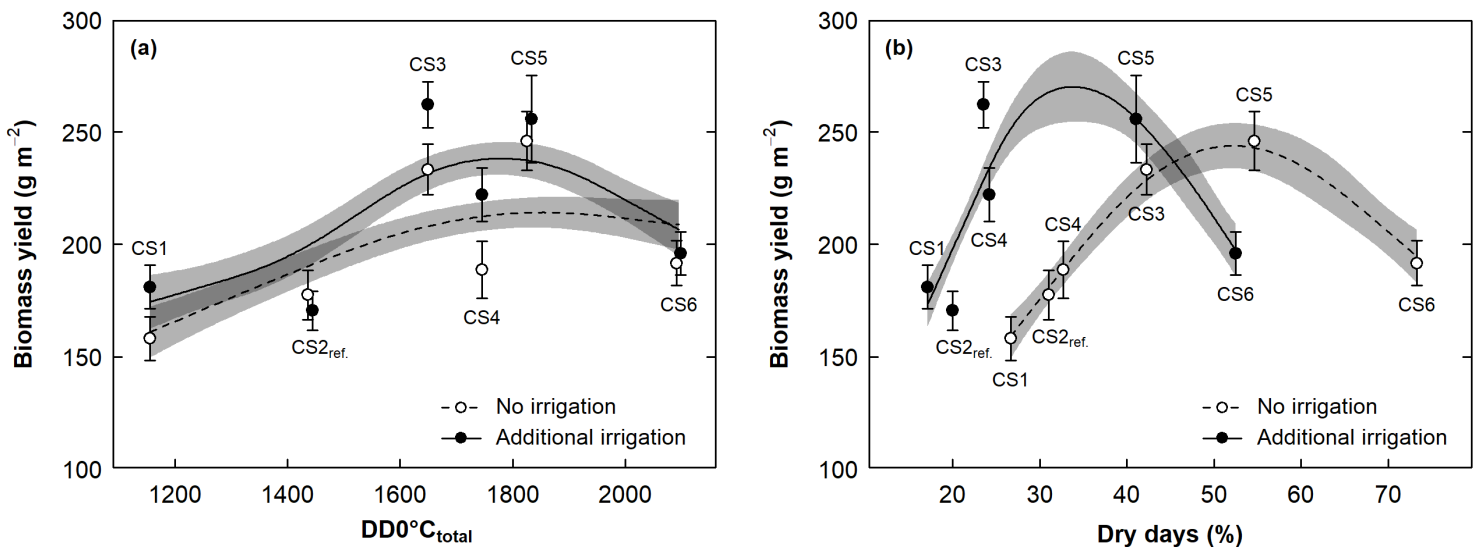
330

331   **Figure 2 a, b** Aboveground biomass yield at the six CS as **a)** a function of total received thermal energy

332   ($DD0°C_{total}$), and **b)** percent of days with dry soil (SWC < 40 %) during the growing season (dry days %). Data were

333   averaged across years; circles denote means ±1 SE per CS and irrigation treatment. The predicted line is based on a

334   generalized additive model using all data (±1 SE light grey shaded). Dark grey indicates the cross-section of the two

335   SE bands. Overlapping means and SEs in (a) are shifted horizontally to improve their visibility.


4 Discussion

We found a substantial and significant positive effect of climate scenarios, equivalent to warming of up to + 1.8 °C (Apr. – Oct. mean), on aboveground biomass of subalpine grasslands (up to +44 % yield). Contrary to expectation, additional resource supply through irrigation and N-deposition had only marginal (water) or no effects (N) on yield, respectively. Our transplanting experiment proved to be efficient in assessing several linked climate change drivers in their effect on plant growth.

4.1 Climate scenario temperature effects

The phenology-triggered harvest opened the possibility to extend the growing period in cool years and shorten the exposure to drought stress in warm years. Thus, beneficial thermal effects were maximized, while detrimental drought effects were minimized. As a consequence, we displayed the yield over a continuous x-axis of degree days between harvests ($DD0°C_{total}$, Fig. 2 A). This represents the available thermal resource, associated with a particular yield, much better than mean temperatures of CS, or categorical values for CS1-CS6.

In cold environments, the warming is so important because the metabolic growth processes, which utilize the assimilated energy, are strongly temperature dependent, much more so than the assimilation process *per se* (Körner 2003). In a meta-analysis of grassland responses to warming that included 32 sites, distinctly positive warming effects on growth were found in the colder portion of those ecosystems (Rustad et al., 2001), very similar to responses in the subalpine grassland of the current study. Interestingly, also the response size of our effects is in the same range as that reported by Rustad et al., (2001).

Plant growth at the intermediate climate scenarios that represented a warming of 0.7 °C, 1.5 °C and 1.8 °C (Apr.-Oct.) clearly benefitted from greater warmth. However, the increase of responses was somewhat inconsistent (CS4 ca. +18 %, CS3 and CS5 both > +40 %), matching only partly our first hypothesis. The erratic response of intermediate CS4 is likely the result of an interaction of micro-topography effects on climate that were not detected by our meteorological measurements, cockchafer infestation (*Melolontha melolontha*: bug whose larvae fed on roots), or the occurrence of mast years in some species at that CS. In the extreme treatment at lowest CS6 (+3 °C Apr.-Oct., +2.4 °C annual mean) the positive response to warming finally ceased to increase, but yield was still somewhat larger than at $CS2_{reference}$. This comparatively low growth response suggests that the water supply at CS6 had already reached critically low levels; yet, the larger thermal energy resource must have partly compensated for the radically smaller soil water resource, leading also to some growth benefit at CS6 (compare Figure 2 a & b).

Despite substantial cooling at topmost CS1, coinciding with a temperature decline of -1.4 °C, the mean yields for CS1 and $CS2_{reference}$ were very similar (Tab. 4, Fig. 1). This is indicative of a plant community that is well cold-adapted. Indeed, local historical records from the Swiss Federal Office for Meteorology (MeteoSwiss) show that only 100 years ago the local April-October mean air temperature was 1.4-1.5 °C lower than today (30 a running mean, courtesy P. Calanca using MeteoSwiss data from Segl-Maria site at 1804 m a.s.l.). In effect, the cooling upward-transplantation represented a climatic time travel of 100 years into the past, and the similar yield responses between CS1 and $CS2_{reference}$ indicate that subalpine grassland productivity may not have changed much during the past century. Moreover, the dramatic temperature dynamics during the past 12,000 years of the Holocene

373   interglacial suggest that temperature adaptations in modern plant genotypes may actually match not only today's

374   weather, but also warmer and cooler climate conditions. From this perspective, and with respect to the genetic

375   memory of plants, the undiminished productivity at topmost CS1 illustrates that assumed 'control' temperatures in

376   warming experiments only represent the most recent point of an extremely dynamic climatic history.

377

378   **4.2 Climate scenario soil moisture effects**

379   The differences in soil moisture content that resulted naturally from 24 different climatic situations (6 CS/altitude

380   levels × 4 years) created a hump-shaped response curve of yield over drought (Fig. 2 b). This does imply that, with

381   decreasing altitude and increasing warmth, productivity rose despite more days with soil moisture < 40 %.

382   The importance of soil moisture for plant growth has been shown predominantly in much drier grasslands, e.g., in

383   warmer prairie (Xu et al., 2013) or cold alpine grassland (Wang et al., 2013), where release from drought stress

384   benefitted growth. For example, along a temperature and altitude gradient in semiarid Tibetan alpine grassland,

385   productivity increased with altitude due to reduced drought stress, but despite decreasing temperatures. Only after an

386   800 m rise in altitude, productivity eventually became smaller, and further reduced drought stress did not constitute

387   a further advantage on plant growth (Wang et al., 2016).

388   In our experiment, soil moisture values and its proxies integrate information on moisture *and* temperature. Thus, the

389   two-dimensional growth response curve along the altitudinal gradient, peaking at the least detrimental situation

390   between moisture limitation and thermal limitation (Fig. 2 b), is analogous to the three-dimensional response surface

391   found in the Jasper Ridge experiment (Zhu et al., 2016). Unfortunately, our experiment did not produce a sufficient

392   number of data points for a 3-D presentation. Based on these results, we infer that a joint evaluation of soil moisture

393   and temperature is mandatory to assess reliably warming effects of climate change on plant growth in the subalpine

394   environment.

395

396   **4.3 Irrigation treatment**

397   We had assumed that increased SWC would mitigate detrimental effects of excessive warming. Surprisingly

398   however, the overall irrigation effect on yield was not very substantial, despite large differences in the percentages

399   of days with soil moisture < 40% during the growing season (Table 2, Fig. 2 b). Moreover, the positive responses

400   did not increase consistently with warmth, but were strongest at the intermediate CS3 and CS4 (Fig. 1 b). Analyses

401   of individual years showed that the two significant responses of annual yield to irrigation coincided with the two

402   driest years. This evidence suggests that maximum mitigation of (low) temperature limitation requires simultaneous

403   release of water limitation, while at the same time the amount of water applied in our study was insufficient to

404   compensate for increased evapotranspiration at CS5 and the warmest site CS6.

405

406   **4.4 N-deposition treatment**

407   We hypothesized a generally positive effect of N-deposition on plant growth, but found no significant overall effect

408   of N-deposition on yield after four years and only a marginal effect in one year. Historically, the responsiveness of

409   (sub-)alpine vegetation to improved nutrient supply was considered to be restricted due to an overriding effect of

410   thermal energy limitation. Yet, studies with very high rates of N application (40-100 kg N ha^{-1} a^{-1}; Körner et al.,

411   1997; Heer and Körner 2002) showed substantial yield responses, also at alpine sites. Low N-dose responses of total

412   plant yield may require N-accumulation over years or a compound interest effect in plant biomass. For example,

413   only in the seventh treatment year a strong, +31 % total yield growth response to 5 kg N ha^{-1} a^{-1} was reported by

414   Volk et al., (2014) from subalpine grassland.

415   Low dose experiments (5-30 kg N ha^{-1} a^{-1}), however, can induce a species composition change (Bowman et al.,

416   2012), indicating a growth benefit for some species at the expense of others. Yet, such single species responses may

417   be only transient: a strong *Carex* species response to as little as 5 kg N ha^{-1} a^{-1} in similar subalpine vegetation was

418   recently found to cease after five years (Bassin et al., 2009 and 2013). Taken together, we conclude that the cold-

419   adapted, mature and low productivity grassland either responds with a >4 year time lag, or that the N-deposition

420   treatment was below the critical load for aboveground biomass responses.

421

422   **4.5 Transplantation**

423   The turf monoliths at CS2$_{reference}$ were only slightly warmer and moister compared to the sites of origin, suggesting a

424   low transplantation impact (we have found no transplantation effect data from other experiments to compare with).

425   However, within the experimental site similar temperature increases between CS2$_{reference}$ and CS3 caused a much

426   larger productivity increase (+43 %). We reason that this incongruence can be explained by the difference in melt-

427   out time, which was on average only 3 days earlier at CS2$_{reference}$ (julian day 118) than at the sites of origin, but 21

428   days earlier at CS3 than at CS2$_{reference}$. We thus assume that the substantially earlier start of the growing season

429   caused the stronger growth response, despite a similar temperature change. This effect, induced by the

430   transplantation of the grassland monoliths along the altitudinal gradient, demonstrates the importance of integrating

431   multiple drivers in climate change experiments to allow for a multi-factor driven plant response.

432   In our study, the effect of altitude on photosynthesis substrate limitation was considered negligible, compared to the

433   climate effects. The assimilation conditions of alpine plants have been the subject of investigation for decades. Since

434   the theoretical considerations of Gale (1972) and the field studies by Körner and Diemer (1987) and Körner et al.,

435   (1988), a predominant 'altitude-tolerance' of photosynthesis is widely accepted. Relevant environmental parameters

436   that change with altitude (temperature, CO_2 and O_2 partial pressure, vapor-pressure deficit and photosynthetic

437   photon flux density) have antagonistic effects on assimilation efficiency (see Wang et al., (2016) for a recent

438   discussion on the topic).

5 Conclusions

Despite dwindling soil water content, the subalpine grassland growth increased to up to +1.8 °C warming during the growing period (corresponding to +1.3 °C annual mean), compared to present temperatures. Even at the maximum warming (corresponding to +2.4 °C annual mean) the yield was larger than at the reference site. At the same time -1.4 °C cooling during the growing period (corresponding to -1.7 °C annual mean) did not reduce plant growth. These results suggest that the productivity of the subalpine grasslands in our study has likely not yet increased during the past century warming. But the positive response to warming treatments suggests, that despite growing soil moisture deficits, productivity will increase with continued warming in the near future.

Author contribution

MV and SB designed the experiment, MV, ALW and SB conducted field work. MV and MS analyzed the data. MV led the writing of the manuscript, with significant contribution from MS. All authors contributed critically to the drafts and gave final approval for publication.

Data availability

The data analyzed for the current study are available in the Dryad Digital Repository at ...

Competing interests

The authors declare that they have no conflict of interest.

Table A1 Schematic layout of monolith arrangement at each CS of the AlpGrass experimental site. At each CS, six monoliths from each of six sites of origin were transplanted, resulting in 36 monoliths. Two irrigation and three N-deposition treatments were set up in a factorial design, resulting in six irrigation × N treatment combinations, which were assigned to each of the six monoliths per site of origin. The six irrigation × N treatment combinations were arranged in a randomized complete block design of six blocks. Regarding sites of origin, the monoliths were assigned to the six blocks in a restricted randomization, so that an equal distribution of sites of origin to all blocks was ensured. It follows that the six monoliths from each site of origin received all irrigation × N treatment combinations and were evenly distributed on the site. Displayed is a possible randomization of irrigation and N treatments per block; at each CS separate randomizations were performed.

Block 1			Block 2			Block 3		
W0.N15	W1.N0	W0.N3	W0.N3	W0.N0	W1.N15	W1.N15	W0.N0	W1.N0
W0.N0	W1.N3	W1.N15	W1.N3	W0.N15	W1.N0	W1.N3	W0.N15	W0.N3

W1.N15	W1.N0	W0.N0	W1.N3	W0.N3	W1.N0	W0.N0	W1.N0	W0.N15
W0.N3	W0.N15	W1.N3	W0.N0	W1.N15	W0.N15	W1.N3	W1.N15	W0.N3
Block 4			Block 5			Block 6		

W0: no additional water (ambient precipitation only), W1: additional water during growing period; N0: no N fertilizer, N3: 3 kg N ha^{-1} a^{-1}, N15: 15 kg N ha^{-1} a^{-1}

585 **Table A2** Summary of analyses for the effects of climate scenario (CS), irrigation, and N deposition on
586 aboveground biomass yield of subalpine grassland over four experimental years. *F*-tests refer to the fixed
587 effects of a linear mixed-effects model that included all four years for a repeated measures analysis. The
588 marginal and conditional R^2 were 0.68 and 0.80, respectively.

589

Variable	df_{num}	df_{den}	*F*-value	*P*
Year	3	45.5	66.2	< 0.001
Climate Scenario (CS)	5	198.0	18.3	< 0.001
Irrigation	1	166.6	6.2	0.014
N	2	166.6	1.2	0.304
Year × CS	15	63.0	9.6	< 0.001
Year × Irrigation	3	450.5	13.6	< 0.001
Year × N	6	450.5	0.9	0.492
CS × Irrigation	5	166.6	1.1	0.380
CS × N	10	166.6	0.5	0.882
Irrigation × N	2	166.6	1.0	0.365
Year × CS × Irrigation	15	450.5	2.9	< 0.001
Year × CS × N	30	450.5	0.8	0.749
Year × Irrigation × N	6	450.5	1.4	0.199
CS × Irrigation × N	10	166.6	1.2	0.275
Year × CS × Irrigation × N	30	450.5	1.4	0.066

590 df_{num}: degrees of freedom of term; df_{den}: degrees of freedom of error (which can be fractional
591 in restricted maximum likelihood analysis)

592 **Table A3** Summary of analyses for the effects of climate scenario (CS), irrigation, and N deposition on aboveground biomass yield of subalpine grassland at each of

593 four experimental years (2014 – 2017). *F*-tests refer to the fixed effects of a linear mixed-effects model to each of the four years.

594

Variable	df_{num}	2014				2015			2016			2017		
		df_{den}	*F*-value	*P*		df_{den}	*F*-value	*P*	df_{den}	*F*-value	*P*	df_{den}	*F*-value	*P*

595 df_{num}: degrees of freedom of term; df_{den}: degrees of freedom of error (which can be fractional in restricted maximum likelihood analysis)

596

597 **Table A4** Summary of analyses for the effects of total received thermal energy ($DD0°C_{total}$) on aboveground
598 biomass yield of subalpine grassland under two irrigation treatments. Data were averaged across the four
599 experimental years (total n = 216). *F*-values and approximate *P*-values refer to a generalized additive model that
600 used a smooth term for each irrigation treatment.

601

Parametric terms	df	*F*-value	*P*
Irrigation	2	1613.0	< 0.001
Smooth terms	edf	*F*-value	*P*
$s(DD0°C_{total})$ – No irrigation	1.72	7.7	< 0.001
$s(DD0°C_{total})$ – Additional irrigation	2.34	10.2	< 0.001

602 df: degrees of freedom; edf: effective degrees of freedom (which can be fractional
603 in smooth terms of generalized additive models)
604 s: smoothing function applied on term

605
606
607
608
609

610 **Table A5** Summary of analyses for the effects of percent days with soil moisture < 40% during the growing
611 season (dry days %) on aboveground biomass yield of subalpine grassland under two irrigation treatments. Data
612 were averaged across the four experimental years (total n = 216). *F*-values and approximate *P*-values refer to a
613 generalized additive model that used a smooth term for each irrigation treatment.

614

Parametric terms	df	*F*-value	*P*
Irrigation	2	402.9	< 0.001
Smooth terms	edf	*F*-value	*P*
s(Dry days %) – No irrigation	2.55	11.3	< 0.001
s(Dry days %) – Additional irrigation	2.59	8.1	< 0.001

615 df: degrees of freedom; edf: effective degrees of freedom (which can be fractional
616 in smooth terms of generalized additive models)
617 s: smoothing function applied on term

Appendix Photographs

618

619   **Photograph A1** Monolith produced at site of origin "Alp Nova" (46.72786°N, 9.72609°E) in June 2012. After

620   monoliths were excavated in the close surroundings, they were fitted tightly into plastic containers. A total of

621   216 monoliths was produced at six such sites of origin, for later use at the altitudinal transplantation site of the

622   AlpGrass Experiment.

623

624

625   **Photograph A2** Topmost climate scenario site CS1 (2360 m, 46.79859°N, 10.17840°E). Monoliths are in the

626   right part of the fenced area. Monolith arrangement in two double rows of nine allows easy access and equal

627   distribution of edge-effects.

628 **Photograph A3** Control climate scenario site CS2$_{reference}$ (2170 m, 46.79264°N, 10.17714°E). Along the

629 altitudinal transplantation gradient this CS is representative of the sites of origin, because the share the same

630 altitude.

631

632

633 **Photograph A4** Lowest climate scenario site CS6 (1680 m, 46.77818°N, 10.17143°E). Due to its low altitude

634 this CS is the warmest and driest site along the altitudinal transplantation gradient.
