25 **Abstract**

26 ~~In many temperate ecosystems, nitrogen (N) limits productivity, meaning anthropogenic N~~
27 ~~deposition can stimulate plant growth and subsequently carbon (C) sequestration. Phosphorus~~
28 ~~(P) and N-P co-limited grasslands are widespread, yet there is limited understanding of their~~
29 ~~responses to N deposition.~~ Phosphorus (P) limited ecosystems are widespread, yet there is
30 limited understanding of how these ecosystems may respond to anthropogenic deposition of
31 nitrogen (N), and the interconnected effects on the biogeochemical cycling of carbon (C), N and
32 P. Here, we investigate the consequences of enhanced N addition on the C-N-P pools of two P-
33 limited grasslands; one acidic and one limestone, occurring on contrasting soils and explore their
34 responses to a long-term nutrient-manipulation experiment. We do this by combining data with
35 an integrated C-N-P cycling model (N14CP). We explore the role of P-access mechanisms by
36 allowing these to vary in the modelling framework, and comparing model plant-soil C-N-P
37 outputs to empirical data. Combinations of organic P access and inorganic P availability most
38 closely representing empirical data were used to simulate the grasslands and quantify their
39 temporal response to nutrient manipulation. The model suggested that access to organic P is a
40 key determinant of grassland nutrient limitation and responses to experimental N and P
41 manipulation. A high rate of organic P access allowed the acidic grassland to overcome N-
42 induced P limitation, increasing biomass C input to soil and promoting SOC sequestration in
43 response to N addition. Conversely, poor accessibility of organic P for the limestone grassland
44 meant N provision exacerbated P-limitation and reduced biomass input to the soil, reducing soil
45 carbon storage. Plant acquisition of organic P may therefore play an important role in reducing
46 P-limitation, and determining responses to anthropogenic changes in nutrient availability. We
47 conclude that grasslands differing in their access to organic P may respond to N deposition in
48 contrasting ways, and where access is limited, soil organic carbon stocks could decline. ~~and~~
49 ~~stress that should N deposition shift ecosystems toward stronger P-limitation, a globally~~
50 ~~important carbon sink risks degradation.~~

51 **1. Introduction**

52 Grasslands represent up to a third of terrestrial net primary productivity (NPP) [Hoekstra *et al.*, 2005]
53 and potentially hold over 10% of the total organic carbon stored within the biosphere [Jones and
54 Donnelly, 2004]. The ecosystem services provided by grasslands, such as carbon storage, are highly
55 sensitive to perturbations in their nutrient cycling, including the perturbation of nitrogen (N) inputs
56 from atmospheric deposition [Phoenix *et al.*, 2012].

57 Since the onset of the industrial revolution, human activity has doubled the global cycling of N, with
58 anthropogenic sources contributing 210 Tg of fixed N per year to the global N cycle, surpassing
59 naturally fixed N by 7 Tg N yr⁻¹ [Fowler *et al.*, 2013]. Much of this additional N is deposited on terrestrial
60 ecosystems from atmospheric sources. This magnitude of N deposition results in a range of negative
61 impacts on ecosystems (including grasslands) such as reductions in biodiversity [Bobbink *et al.*, 2010;
62 Southon *et al.*, 2013], acidification of soil, and the mobilisation of potentially toxic metals [Carroll *et*
63 *al.*, 2003; Horswill *et al.*, 2008; Phoenix *et al.*, 2012]

64 Despite large anthropogenic fluxes of N, most terrestrial ecosystems on temperate post-glacial soils
65 are thought to be N-limited (biomass production is most restricted by N availability) [Vitousek and
66 Howarth, 1991; Du *et al.*, 2020], as weatherable sources of phosphorus (P) remain sufficiently large to
67 meet plant P demand [Vitousek and Farrington, 1997; Menge *et al.*, 2012]. Both empirical and
68 modelling studies have shown that pollutant N, when deposited on N-limited ecosystems, can increase
69 productivity [Tipping *et al.*, 2019] and soil organic carbon (SOC) storage [Tipping *et al.*, 2017], largely
70 as a result of stimulated plant growth. This suggests that while there are negative consequences of N
71 deposition, there may also be benefits from enhanced plant productivity and increases in carbon
72 sequestration.

73 Whilst most research focuses on N-limited ecosystems [LeBauer and Treseder, 2008], a number of
74 studies have highlighted that P limitation and N-P co-limitation are just as prevalent, if not more

75 widespread, than N limitation [Fay *et al.*, 2015; Du *et al.*, 2020; Hou *et al.*, 2020]. In a meta-analysis of
76 grassland nutrient addition experiments spanning five continents, Fay *et al.* [2015] found that
77 aboveground annual net primary productivity was limited by nutrients in 31 out of 42 sites, most
78 commonly through co-limitation of N and P [Fay *et al.*, 2015]. Similarly, P additions in 652 field
79 experiments increased aboveground plant productivity by an average of 34.9% [Hou *et al.*, 2020],
80 while it is estimated that P limitation, alone or through co-limitation with N, could constrain up to
81 82% of the natural terrestrial surface's productivity [Du *et al.*, 2020].

82 Furthermore, P limitation may be exacerbated by N deposition [Johnson *et al.*, 1999; Phoenix *et al.*,
83 2004], or become increasingly prevalent as previously N-limited ecosystems transition to N-sufficient
84 states [Goll *et al.*, 2012]. For example, in parts of the Peak District National Park, UK, N deposition has
85 exceeded $3 \text{ g m}^{-2} \text{ yr}^{-1}$, with further experimental additions of $3.5 \text{ g m}^{-2} \text{ yr}^{-1}$ leading to decreases rather
86 than increases in productivity of limestone grasslands [Carroll *et al.*, 2003]. This makes P limitation
87 critical to understand in the context of global carbon and nutrient cycles. By definition, N deposition
88 should impact P-limited ecosystems differently to N-limited ones, yet there is little understanding of
89 how N deposition impacts these systems.

90 While N deposition may worsen P limitation in some instances, plant strategies for P acquisition may
91 require substantial investments of N, suggesting that increased N supply may facilitate enhanced P
92 uptake [Vance *et al.*, 2003; Long *et al.*, 2016; Chen *et al.*, 2020]. Indeed, previous work from long-term
93 experimental grasslands has shown strong effects of N deposition on plant enzyme production
94 [Johnson *et al.* 1999; Phoenix *et al.* 2004], whereby the production of additional extracellular
95 phosphatase enzymes was stimulated. While it is not clear if this response is driven by exacerbated P-
96 limitation resulting from N deposition or extra N availability making elevated enzyme production
97 possible, such changes in plant physiology may promote cleaving of P from organic soil pools. Over
98 time, the accumulation of plant-available P from organic sources may provide a mechanism by which
99 plants exposed to high levels of N deposition may overcome P limitation [Chen *et al.* 2020].

100 By using the integrated C-N-P cycle model N14CP, Janes-Bassett *et al.* [2020] suggest that the role of
101 organic P cycling in models may be poorly represented, as the model failed to simulate empirical yield
102 data in agricultural soils with low P fertiliser input. Organic P access is therefore likely an important
103 means of nutrient acquisition for plants in high N and low P soils [Chen *et al.* 2020], yet our
104 understanding of organic P cycling in semi-natural ecosystems is fairly limited [Janes-Bassett *et al.*
105 2020]. Such interdependencies of the C, N and P cycles make understanding an ecosystem's response
106 to perturbations in any one nutrient cycle challenging, particularly when ecosystems are not solely
107 limited in N. This highlights the need for integrated understanding of plant-soil nutrient cycling across
108 the C, N and P cycles, and in ecosystems that are not solely N-limited.

109 Process-based models have a role to play in addressing this, as they allow us to test our mechanistic
110 understanding and decouple the effects of multiple drivers. There has been increasing interest in
111 linking C with N and P cycles in terrestrial ecosystem models [Wang *et al.*, 2010; Achat *et al.*, 2016;
112 Jiang *et al.*, 2019] as the magnitude of the effects that anthropogenic nutrient change can have on
113 biogeochemical cycling are realised [Yuan *et al.*, 2018]. Yet, few modelling studies have explicitly
114 examined the effects of P limitation, or the role of organic P access in determining nutrient limitation,
115 likely mirroring the relatively fewer empirical studies of these systems.

116 By combining process-based models with empirical data from long-term nutrient-manipulation
117 experiments, we may simultaneously improve our understanding of empirical nutrient limitation, the
118 role(s) of organic P acquisition, and their interactions with anthropogenic nutrient pollution. In
119 particular, this approach offers a valuable opportunity for understanding ecosystem responses to
120 environmental changes that may only manifest after extended periods of time, such as with changes
121 in soil organic C, N and P pools, which typically occur on decadal timescales [Davies *et al.*, 2016a, Janes-
122 Bassett *et al.*, 2020]. Here, we combine new data from a long-term nutrient manipulation experiment
123 on two P-limited upland grasslands (acidic and limestone) occurring on contrasting soils, with the
124 mechanistic C-N-P plant-soil biogeochemical model; N14CP [Davies *et al.*, 2016b].

125 We use these experimental data to explore the role of organic P access in determining ecosystem
126 nutrient limitation and grassland responses to long-term nutrient manipulations. Specifically, we aim
127 to explore how variation in P acquisition parameters, that control access to organic and inorganic
128 sources of P in the model, may help account for differing responses of empirical grassland C, N and P
129 pools to N and P additions. Second, we explore the effects of long-term anthropogenic N deposition
130 and experimental N and P additions on plant and soil variables of the simulated acidic and limestone
131 grasslands. This will help improve our understanding of organic P process attribution within the model
132 and may suggest how similarly nutrient limited grasslands could respond to similar conditions.

133 We hypothesise that 1) access to organic P will be an important determinant of ecosystem nutrient
134 limitation, 2) increased organic P availability may alleviate P limitation resulting from N deposition and
135 3) grasslands capable of accessing sufficient P from organic forms may overcome P limitation resulting
136 from N deposition and nutrient treatments, whereas grasslands lacking such accessibility will not.

137

138

139

140 **2. Methods**

141 **2.1. Field experiment description**

142 The empirical data is from Wardlow Hay Cop (henceforth referred to as Wardlow), a long-term
143 experimental grassland site in the Peak District National Park (UK) [Morecroft *et al.*, 1994]. [Details of](#)
144 [empirical data collection are available in supplementary section 1.](#) There are two distinct grassland
145 communities occurring in close proximity; acidic (National vegetation classification U4e) and
146 limestone (NVC CG2d) semi-natural grasslands (Table S2). Both grasslands share a carboniferous
147 limestone hill but the limestone grassland sits atop a thin humic ranker [Horswill *et al.*, 2008] and
148 occurs predominantly on the hill brow. In contrast, the acidic grassland occurs in the trough of the
149 hill, allowing the accumulation of wind-blown loess and the formation of a deeper soil profile of a
150 palaeo-argillic brown earth [Horswill *et al.*, 2008].

151 Despite contrasting soil types, both the acidic and limestone grasslands are largely P-limited
152 [Morecroft *et al.* 1994; Carroll *et al.* 2003], though occasional N and P co-limitation can occur
153 [Phoenix *et al.* 2003] and more recently, positive growth responses in solely N-treated plots have
154 been observed, in line with the latest understanding that long-term N loading may increase P supply
155 by increasing phosphatase enzyme activity [Johnson *et al.* 1999; Phoenix *et al.* 2004; Chen *et al.*
156 2020].

157 Nutrients (N and P) have been experimentally added to investigate the effects of elevated N
158 deposition and the influence of P limitation [Morecroft *et al.*, 1994]. Nitrogen treatments simulate
159 additional N deposition to the background level and the P treatment acts to alleviate P limitation.
160 Nutrients are added as solutions of distilled water and applied as fine spray by backpack sprayer, and
161 have been applied monthly since 1995, and since 2017 bi-monthly. Nutrient additions are in the
162 form of NH_4NO_3 for nitrogen and $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ for phosphorus. Nitrogen is applied at rates of 0
163 (distilled water control – 0N), 3.5 (low nitrogen – LN) and 14 $\text{g N m}^{-2} \text{yr}^{-1}$ (high nitrogen – HN). The P
164 treatment is applied at a rate of 3.5 $\text{g P m}^{-2} \text{yr}^{-1}$ (phosphorus – P).

165 Data collected from the Wardlow grasslands for the purpose of this work are; aboveground biomass
166 C, SOC, and total N, which is assumed to be equivalent to modelled SON. This new data is combined
167 with total P data that was collected by Horswill *et al.* at the site [Horswill *et al.*, 2008]. Summaries of
168 these data are available within the supplementary material (Table S4) and details of their collection
169 and conversion to model-compatible units in supplementary section S1.

170

171 **2.2. Summary of model processes**

172 2.2.1. N14CP model summary

173 The N14CP ecosystem model is an integrated C-N-P biogeochemical cycle model that simulates net
174 primary productivity (NPP), C, N and P flows and stocks between and within plant biomass and soils,
175 and their associated fluxes to the atmosphere and leachates [Davies *et al.*, 2016b]. N14CP was
176 originally developed and tested on 88 northern Europe plot-scale studies, including grasslands,
177 where C, N and P data were available. All but one of the tested ecosystems exhibited N limitation
178 [Davies *et al.*, 2016b]. It has also been extensively and successfully blind-tested against SOC [Tipping
179 *et al.*, 2017] and NPP data from unimproved grassland sites across the UK [Tipping *et al.*, 2019].

180 However, N14CP has not been extensively tested against sites known to exhibit P limitation,
181 especially where these are explicitly manipulated by long term experimental treatments. While the
182 importance of modelled weatherable P (P_{Weath0}) and historic N deposition on N-limited C, N and P
183 have been investigated [Davies *et al.* 2016b], the potential influence of organic P on ecosystem
184 nutrient limitation and responses to nutrient perturbations have yet to be explored.

185 Here, we modify N14CP to add experimental N and P additions to simulate a long-term nutrient
186 manipulation experiment similar to that at the limestone and acidic grasslands at Wardlow, and we
187 use empirical data from Wardlow to explore the role of organic P cleaving in determining ecosystem
188 state. A full model description can be found in Davies *et al.*, [2016b], however, a summary of the
189 most relevant features is given here for convenience.

190 2.2.2. Net primary productivity and nutrient limitations

191 Plant biomass is simulated in the model as two sets of pools of coarse and fine tissues representing
192 both above and belowground plant C, N and P, with belowground biomass for each plant functional
193 type ~~(PFT)~~ represented by a root fraction. NPP adds to these on a quarterly basis with growth
194 occurring in quarters 2 and 3 (spring and summer). In N14CP, NPP depends on a single limiting
195 factor, in accordance with Liebig's law of the minimum. The factors that can limit growth in the
196 model include available N and P, temperature or precipitation, the latter two being provided as
197 input driver data (see section 2.3.2).

198 First, the potential maximum NPP limited by climate is calculated using regression techniques, as in
199 Tipping *et al.* [2014]. The corresponding plant demand for N and P to achieve this potential NPP is
200 then calculated [Davies *et al.*, 2016b; Tipping *et al.*, 2017]. This demand is defined by PFT plant
201 functional type stoichiometry, which changes through time in accordance with ecosystem succession
202 (see section 2.3.2). Stoichiometry of coarse tissue is constant but the fine tissue of each plant
203 functional type ~~each PFT's fine tissue~~ has two stoichiometric end members. This allows ~~ing~~ the
204 model to represent transitions from N-poor to N-rich plant communities ~~species~~ or an enrichment of
205 the fine tissues within ~~a single species~~ plants (or a combination of both) [Davies *et al.*, 2016b],
206 dependent on available N. This allows a degree of flexibility in plant C:N ratios in response to
207 environmental changes such as N deposition. If the available nutrients cannot meet the calculated
208 plant nutrient demand, the minimum calculated NPP based on either N or P availability is used,
209 giving an estimation of the most limiting nutrient to plant growth.

210 Nutrient co-limiting behaviour can occur in the model through increased access to organic P sources
211 in the presence of sufficient N (see 2.2.3), and by having the rate of N fixation dependent on plant
212 and microbial available P [Davies *et al.*, 2016b]. The initial rate of N fixation is based on literature
213 values for a given plant functional type and is downregulated by anthropogenic N deposition, but
214 not soil N content more generally, as it is assumed that atmospherically deposited N is readily

215 available to N-fixers. Nitrogen fixation in the model is also related to P availability. The degree to
216 which P availability limits this maximum rate of fixation is determined by a constant; K_{Nfix} [Davies et
217 al. 2016b]. ~~The initial rate of N fixation is based on literature values for a given PFT but is~~
218 ~~downregulated by anthropogenic N deposition and related to P availability. The degree to which P~~
219 ~~availability limits this maximum rate of fixation is determined by a constant; K_{Nfix} [Davies et al.~~
220 ~~2016b].~~ This means that while modelled NPP is limited by availability of a single nutrient, co-
221 limitation may occur through P limitation of N fixation [Danger *et al.* 2008].

222

223 2.2.3. Plant and soil N and P cycling

224 A simplified summary of key pools and processes regarding plant-soil nutrient cycling are detailed in
225 Figure 1. Details such as initial base cation pools, their effects on soil pH, and most parameter names
226 have been omitted for clarity but are available from the original model development study [Davies *et*
227 *al.* 2016b]. Key changes for the purpose of this work are highlighted in red.

228 Plant available N is derived from biological fixation, the decomposition of coarse litter and SOM,
229 atmospheric deposition and direct N application. Fine plant litter enters the SOM pool directly due
230 to its rapid rate of turnover whereas coarse litter contributes N and P through decomposition and
231 does not join the SOM pool. Plant available P also comes from SOM and coarse litter decomposition,
232 direct treatment, desorption of inorganic P from soil surfaces, and sometimes cleaving of organic P
233 [Davies *et al.*, 2016b]. The sorbed inorganic P pool builds over time with inputs of weathered P and
234 sorption of any excess plant available inorganic P, and desorption occurs as a first order process.

235 Phosphorus enters the plant-soil system by weathering of parent material, the initial value of which
236 (P_{Weath0} within the model) can be set to a default value, or made site-specific by calibrating this initial
237 condition to soil observational data (as in methods section 2.3.3). From this initial pool, annual
238 releases of weathered P are determined by first-order rate constants that are temperature

239 dependent, with the assumption that no weathering occurs below 0 degrees Celsius. This weathered
240 P can then contribute toward plant-available P in soil water or be sorbed to soil surfaces. ~~In principle,~~
241 ~~P can be added in small quantities by atmospheric deposition [Ridame and Guieu, 2002] or by local~~
242 ~~redistribution [Tipping et al., 2014].~~ In principle, P can be added in small quantities by atmospheric
243 deposition [Ridame and Guieu, 2002] but for the purpose of this work, P deposition is set to zero in
244 the model. While the contribution of P through atmospheric deposition is increasingly realised
245 [Aciego et al. 2017], we cannot account for the losses of P that may also occur through landscape
246 redistribution [Tipping et al. 2014]. ~~For the purpose of this study, P deposition is set to zero as its net~~
247 ~~contribution to the total P pool in comparison to weathering is assumed to be minimal.~~

248 The size of the available P pool is determined by summing: P retained within plant biomass prior to
249 litterfall, inorganic P from decomposition, dissolved organic P and P cleaved from SOP by plants.
250 Accessibility of each P form is determined by a hierarchal relationship in the order mentioned above,
251 whereby plants and microbes access the most readily available P sources first and only move onto
252 the next once it has been exhausted.

253 When N is in sufficient supply and more bioavailable P forms have been exhausted from the total
254 available pool, simulated plants can access P from SOM via an implicit representation of extracellular
255 P-cleaving enzymes with a parameter termed P_{Cleave} . While empirical data quantifying this parameter
256 is scarce, N14CP constrains P_{Cleave} by utilising a maximum SOM C:P ratio; $[C:P]_{fixlim}$, that ensures SOM
257 stoichiometry is not unrealistically disrupted by excessive removal of organic P (Equation 1).

258

$$259 \quad P_{Cleave} = SOP - \frac{SOC}{[C:P]_{fixlim}} \quad \text{Equation 1}$$

260

261 The functioning of the P_{Cleave} parameter, including its stoichiometric constraint, remains the same in
262 this work but we have introduced a modifier to adjust the rate at which plants can access this P

263 source. This parameter; $P_{\text{CleaveMax}}$, represents the maximum amount ($\text{g m}^{-2} \text{ season}^{-1}$) of cleaved P that
264 plants can acquire from the available P pool to satiate P demand.

265 A fraction of plant biomass is converted to litter in each quarterly time step and contributes a
266 proportion of its C, N and P content to SOM, which is sectioned into three pools (fast, slow and
267 passive) depending on turnover rate [Davies *et al.*, 2016b]. Soil organic P (SOP) is simulated
268 alongside SOC and SON using C:N:P stoichiometries of coarse and fine plant biomass. Decomposition
269 of SOP, and its contribution to the available P pool, is subject to the same turnover rate constants as
270 for SOC and SON.

271 Carbon is lost as CO_2 following temperature-dependent decomposition and as dissolved organic
272 carbon. Likewise, N and P are lost via dissolved organic N and P in a proportion consistent with the
273 stoichiometry of each SOM pool. Inorganic N is lost via denitrification and inorganic P can be sorbed
274 by soil surfaces. Both inorganic N and P can be leached in dissolved forms if they are in excess of
275 plant demand.

276

277

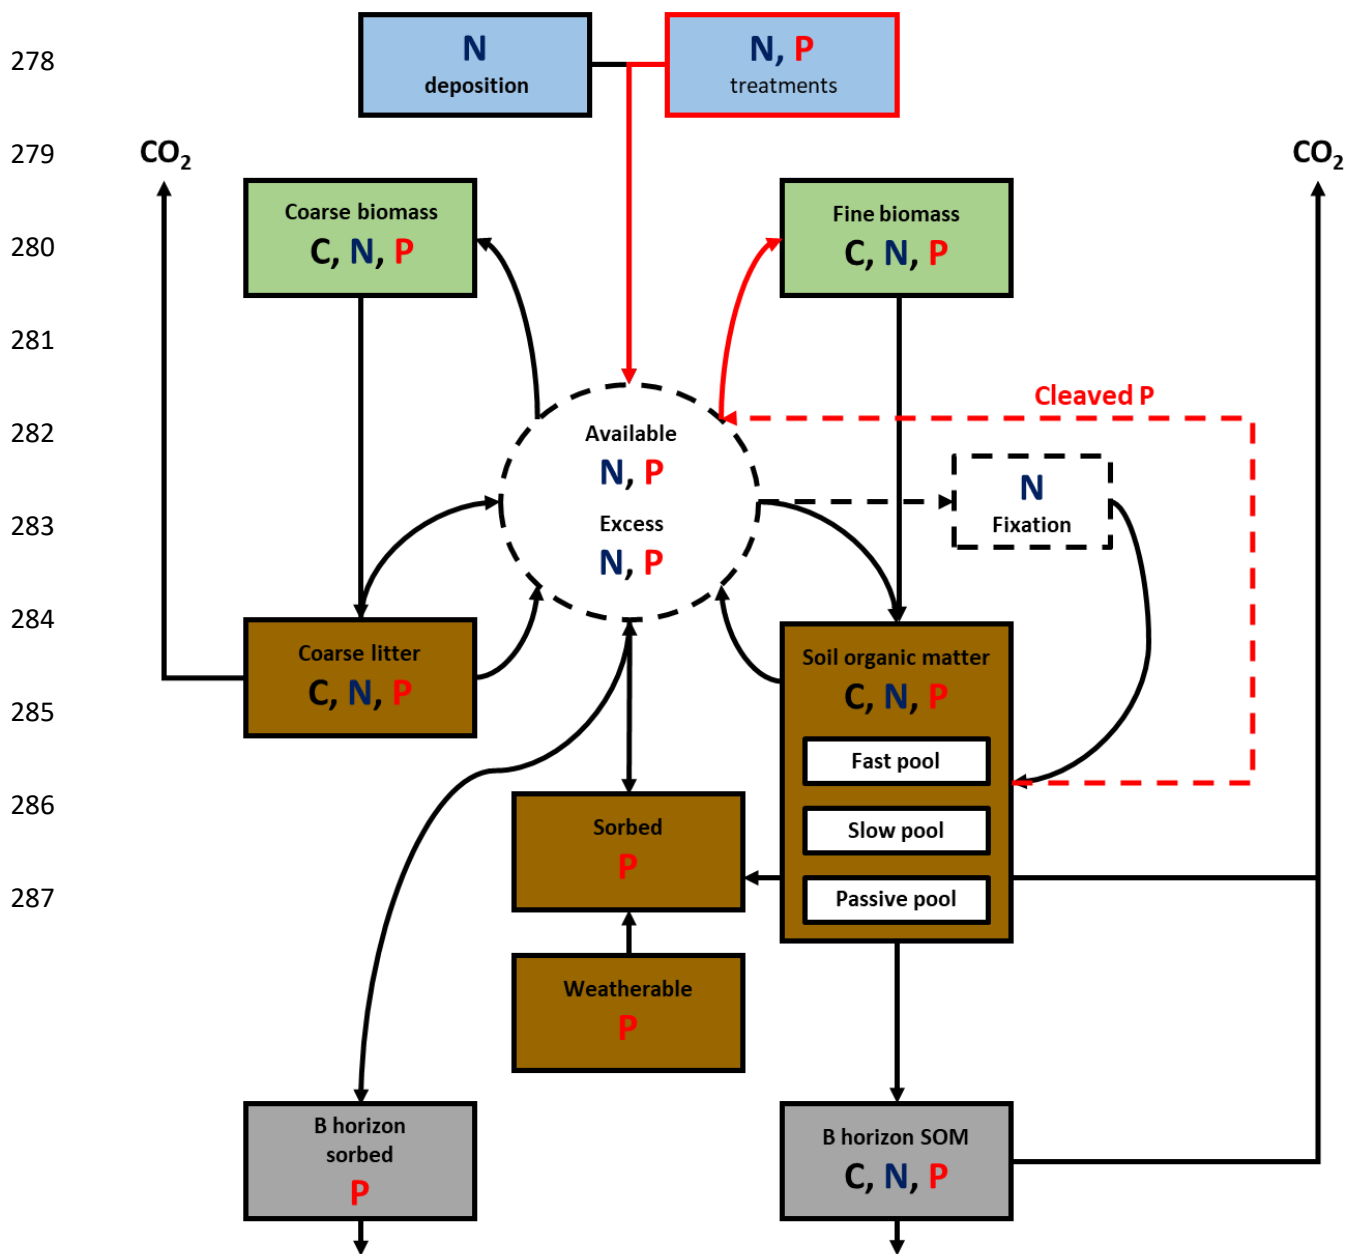

Figure 1: A simplified schematic of the key flows and pools of C, N and P within N14CP, adapted from the full schematic available in Davies *et al.* (2016a). Red lines highlight modifications to N14CP for the purpose of this work, including adding experimental nutrients and allowing uptake of cleaved P to be more flexible. Solid lines indicate input to another pool and a dashed line indicates either a feedback or interaction with another pool. In the model, N can enter the available pool via atmospheric deposition, nutrient treatments, biological fixation, and decomposition of coarse litter and SOM. For P, the two main sources are the inorganic sorbed pool and from the turnover of SOM. The former is derived initially from the weatherable supply of P, defined by its initial condition ($P_{\text{Weath}0}$). P can also be added to this pool experimentally as with N. The dashed line going from available N and P to N fixation represents the downregulation of N fixation by N deposition and the dependency of N fixation on P availability. The cleaving of organic P from SOM and its incorporation into the plant-available nutrient pool, is represented by the dashed red line and its uptake by plants, determined by $P_{\text{CleaveMax}}$, shown with a solid red line.

288 **2.3. Simulating the field manipulation experiment with the model**

289 We use data from the Wardlow limestone and acidic grasslands to explore the potential role organic
290 P access may have in determining grassland nutrient limitation when exposed to long-term N
291 deposition and more recently, experimental nutrient manipulation. We use environmental input
292 data collated from Wardlow to drive model processes. Empirical data regarding contemporary soil C,
293 N and P for the contrasting grasslands is used to calibrate the initial size of the weatherable P pool
294 within the model, and to allow access to organic cleaved P to vary to account for patterns in the
295 data. We do not aim to perfectly replicate the Wardlow grasslands but rather use the unique
296 opportunity that Wardlow provides to test our understanding of such P-limited ecosystems and how
297 our conceptualisation of P access mechanisms within the model may affect them. In addition, we
298 can use the model-simulated grasslands to investigate the potential effects of long-term N
299 deposition and nutrient manipulation on ecosystems which may differ in their relative availability of
300 different P forms.

301

302 **2.3.1. Nutrient applications**

303 Nutrient treatments are treated in N14CP as individual plots in the simulations with differing
304 amounts of inorganic N and P applied in line with the field experimental treatments (section 2.1).
305 The N and P treatments are added to the bioavailable N and P pools of the model on a quarterly
306 basis in line with the model's time-step. While Wardlow nutrient treatments are applied monthly
307 and N14CP quarterly, the annual sum of applied N or P is equivalent, and nutrients are applied
308 during all quarters.

309

310 2.3.2. Input drivers

311 N14CP simulations run on a quarterly time step and are spun up from the onset of the Holocene
312 (10,000 BP in the model). This is to capture the length of time required for soil formation following
313 deglaciation in north west Europe and is not an attempt to truly model this long term period.
314 Instead, it allows us to form initial conditions for modern day simulations that takes in what we
315 know about the site's history and forcings.

316 To use this spin up phase and simulate contemporary soil C, N and P stocks, we use a variety of input
317 driver data. Inputs nearer the present are more accurately defined based on site-scale
318 measurements and assumptions are made regarding past conditions. This approach of spinning up
319 to present-day observations avoids the assumption that ecosystems are in a state of equilibrium,
320 which is likely inaccurate for ecosystems exposed to long-term anthropogenic changes in C, N and P
321 availability. Input driver data include [PFT-plant functional type](#) history, climatic data and N
322 deposition data. A summary of the data used for model input is provided in supplementary Table S3.

323 To simulate the sites' [PFT-plant functional type](#) history, we used data on Holocene pollen
324 stratigraphy of the White Peak region of Derbyshire [Taylor *et al.* 1994], which captures important
325 information regarding Wardlow's land-use history for the entire duration of the model spin up
326 phase.

327 Input drivers are provided as annual time series to drive the model and as the acidic and limestone
328 sites are co-located, these input timeseries are shared for both grasslands. It is assumed in the
329 model that anthropogenic N deposition was negligible prior to 1800 and the onset of the industrial
330 revolution. After 1800, N deposition is assumed to have increased similarly across Europe [Schopp *et*
331 *al.*, 2003]. In N14CP, this trend is linearly extrapolated from the first year of data (1880) back to 1800
332 [Tipping *et al.*, 2012]. Data regarding N deposition that is specific to Wardlow was incorporated
333 between the years 2004 and 2014 and the Schöpp *et al.* [2003] anomaly scaled to represent the high
334 N deposition of the site.

335 To provide climate forcing data, daily minimum, mean and maximum temperature and mean
336 precipitation records beginning in 1960 were extracted from the UKPC09 Met office CEDA database
337 (Table S3). The data nearest to Wardlow was calculated by triangulating latitude and longitude data
338 and using Pythagoras' theorem to determine the shortest distance. These data were converted into
339 mean quarterly temperature and precipitation. Prior to this, temperature was assumed to follow
340 trends described in Davies *et al.* [2016b] and mean quarterly precipitation was derived from Met
341 Office rainfall data between 1960 to 2016 and held constant.

342

343 2.3.3. Model parameters for the acidic and limestone grasslands

344 The N14CP model has been previously calibrated and tested against a wide range of site data to
345 provide a general parameter set that is applicable to temperate semi-natural ecosystems, without
346 extensive site-specific calibration [Davies *et al.*, 2016b]. The majority of those parameters are used
347 here for both grasslands. However, two parameters relating to P sources and processes were
348 allowed to vary between the sites: the initial condition for the weatherable P pool, P_{Weath0} ; and the
349 rate of plant access to organic P sources, $P_{\text{CleaveMax}}$ (Figure 1). We allowed P_{Weath0} to vary for each
350 grassland as variation in a number of factors including lithology and topography mean that we
351 should expect the flux of weathered P entering the plant-soil system to vary on a site-by-site basis
352 [Davies *et al.* 2016b]. Indeed, we should expect that P_{Weath0} differs between the acid and limestone
353 grasslands, as despite their proximity, they have differing lithology. Davies *et al.* [2016b], show that
354 variation in this initial condition considerably helps explain variance in contemporary SOC, SON and
355 SOP stocks between sites. However, it is difficult to set this parameter directly using empirical data,
356 as information on lithology and P release is limited at the site scale.

357 As this is the first time that N14CP has been knowingly applied to ecosystems of a largely P-limited
358 nature, we also allowed the maximum rate at which plants could access cleaved P ($P_{\text{CleaveMax}}$) to vary,
359 to investigate how plant P acquisition might change when more readily accessible P forms become

360 scarcer. Empirical quantification of organic P access is poor [Janes-Bassett *et al.* 2020], hence we use
361 a similar data-driven calibration for $P_{\text{CleaveMax}}$ as we do for P_{Weath0} .

362 We ran a series of simulations systematically varying P_{Weath0} and $P_{\text{CleaveMax}}$ and comparing the results
363 to observations. We simulated the two grasslands and their treatment blocks with a set of 200
364 parameter combinations. This captured all combinations of 20 values of P_{Weath0} between 50 and 1000
365 g m^{-2} and 10 values of $P_{\text{CleaveMax}}$ between 0 to 1 g m^{-2} per growing season using a \log_{10} spacing to focus
366 on the lower range of $P_{\text{CleaveMax}}$ values. The P_{Weath0} range was set to capture the lower end of P_{Weath0}
367 estimates described in Davies *et al.* [2016b], which were more likely to be appropriate for these P-
368 poor sites. We explored a range of values for $P_{\text{CleaveMax}}$, from zero where no access to organic sources
369 is allowed, to 1 g m^{-2} per growing season – a rate in the order of magnitude of a fertilizer application.
370 The model outputs were compared to measured, SOC, SON and total P (Table S4) for each grassland.
371 We tested how these parameter sets performed by calculating the error between the observations
372 and model outputs of the same variables for each combination of $P_{\text{CleaveMax}}$ and P_{Weath0} . The sum of
373 the absolute errors between modelled and observed soil C, N and P data were scaled (to account for
374 differing numbers of observations) and summed to provide an F value (Equation 2) as an overall
375 measure of error across multiple observation variables. ~~The parameter combination with the lowest~~
376 ~~F value that still maintained the grassland's empirical response to nutrient additions for both the~~
377 ~~acidic and limestone grasslands (Supplementary section S1.1.), was used within the analysis.~~

378

$$F = \left(\frac{SAE[C_{SOM}]}{\bar{C}_{SOM,Obs}} \right) / C_n + \left(\frac{SAE[N_{SOM}]}{\bar{N}_{SOM,Obs}} \right) / N_n + \left(\frac{SAE[P_{Total}]}{\bar{P}_{Total,Obs}} \right) / P_n \quad (\text{Equation 2})$$

379

380

381

382 Plant biomass C data were excluded from the cost function to allow for blind testing of the model's
383 performance against empirical observations. As the variable most responsive to nutrient additions,
384 both in terms of rapidity and magnitude of the response, we deemed these the most rigorous data
385 to use for separate testing. We included soil C, N and P data from all nutrient treatments rather than
386 just the control to ensure that the selected parameter combination could better account for
387 patterns in empirical data. For instance, we know that empirical N treatments can increase plant and
388 soil enzyme activity in both Wardlow grasslands, [Johnson *et al.* 1999; Phoenix *et al.* 2004; Keane *et*
389 *al.* 2020] which a calibration to control-only data may not have captured.

390 While the cost function is a useful tool in allowing the model to simulate the magnitude of
391 contemporary C, N and P pools, it does not allow us to capture all necessary information to
392 accurately simulate grassland responses to long-term nutrient manipulations ~~of contrasting nutrient~~
393 ~~limitation~~. The pattern of grassland response, i.e. how a variable responds to nutrient treatment, is
394 an important consideration and is determined in the model by the most limiting nutrient.
395 Consequently, the parameter combination with the lowest F value, that still maintained a grassland's
396 empirical response to nutrient additions, ~~(Supplementary section S1.1.)~~, was used within the
397 analysis.

398

399

400 3. Results

401

402 Below, we first present data regarding the results of the calibration of P_{Weath0} and $P_{\text{CleaveMax}}$ for each
403 grassland, and how simulated grassland C, N and P using these parameter combinations compares to
404 the empirical data (section 3.1, Figure 2). [Raw empirical data is available in table S1 in section 2 of](#)
405 [the supplementary material](#). Second, we explore how the limiting nutrient of the modelled
406 grasslands has changed through time in response to N deposition and experimental treatment
407 (section 3.2, Figure 3). Third, we explore how C, N and P pools in the simulated grasslands have
408 responded to N deposition and nutrient treatment within the model, and include empirical data to
409 contextualise changes (section 3.3, Figure 4). Finally, we present the C, N and P budgets for both
410 modelled grasslands to examine changes in C, N and P pools more closely, in order to better our
411 mechanistic understanding of changes in nutrient flows within the model (section 3.3, Figure 5).

412

413 3.1. Varying phosphorus source parameters

414

415 The model calibration selected parameter values for P_{Weath0} and $P_{\text{CleaveMax}}$ that indicate contrasting
416 use of P sources by the two simulated grasslands, with the acidic grassland capable of acquiring
417 more P from organic sources, having a $P_{\text{CleaveMax}}$ value of $0.32_{162} \text{ g m}^{-2} \text{ season}^{-1}$ compared to the
418 limestone, with a value 10 times smaller at $0.03_{16} \text{ g m}^{-2} \text{ season}^{-1}$. Conversely, inorganic P availability
419 was greater in the limestone grassland due to the larger weatherable pool of P, P_{Weath0} , at 300 g m^{-2}
420 compared to 150 g m^{-2} in the acidic.

421 The selected parameter combinations resulted in the model simulating the acidic grassland as N-

422 limited and the limestone as P-limited, with reasonable congruence between observed and

423 modelled data. The outputs for the calibrated model are shown in Figure 2 against the observations

424 for above-ground biomass C, soil organic C, and N for both the acidic and limestone grasslands (Fig

425 2). Raw data used for Figure 2 are provided in supplementary tables S5 and S6.

426 Overall, N14CP more accurately simulated the magnitude of limestone grassland C, N and P pools
427 than the acidic, and it generally captured the pattern of responses to nutrient treatment, albeit this
428 is not always supported by high r^2 values. The model estimates of above ground biomass C are
429 broadly aligned with the observations: capturing variation between the grasslands and treatments
430 ($r^2 = 0.58$), and on average overestimating the magnitude by 12.9% (SE \pm 11.9) and 12.1% (SE \pm 9.4)
431 for the acidic and limestone grasslands respectively (Fig 2a).

432 Soil organic C on average was slightly overestimated (7.1% with SE \pm 3.3) for the limestone grassland
433 (Fig 2b), with a larger average overestimate for the acidic grassland (39.9% with SE \pm 6.8). However,
434 in this latter case the variation between treatments was better captured. Despite a low r^2 value for
435 SOC (0.01), the model broadly captured the patterns we observe in the empirical data, with N
436 addition increasing SOC in the acidic and P addition increasing SOC in the limestone. However, the
437 intermediate increase in SOC with P in the acidic grassland is not captured by the model, nor is the
438 magnitude of the negative effect of LN treatment on limestone SOC.

439 Simulated magnitudes of SON are well-aligned with observations for the acidic grassland, with an
440 average error of 2.3% (SE \pm 3.2), whilst SON for the limestone grassland was on average
441 underestimated by 17.8% (SE \pm 3.6) (Fig 2c). The variation between treatments was better captured
442 for acidic than limestone SON but was overall reasonable ($r^2 = 0.39$).

443 Finally, the model overestimated total soil P (defined in the model as organic P plus sorbed P) by an
444 average of 6.0% (SE \pm 4.3) for the limestone but underestimated by 54.7% (SE \pm 8.0) in the acidic
445 grassland, which was the least accurately predicted variable out of those investigated (Fig 2d). With
446 only two empirical data points for TP across only two nutrient treatments, it is difficult to discern the
447 relationship between treatments and TP so an r^2 value is of little relevance here.

448

449

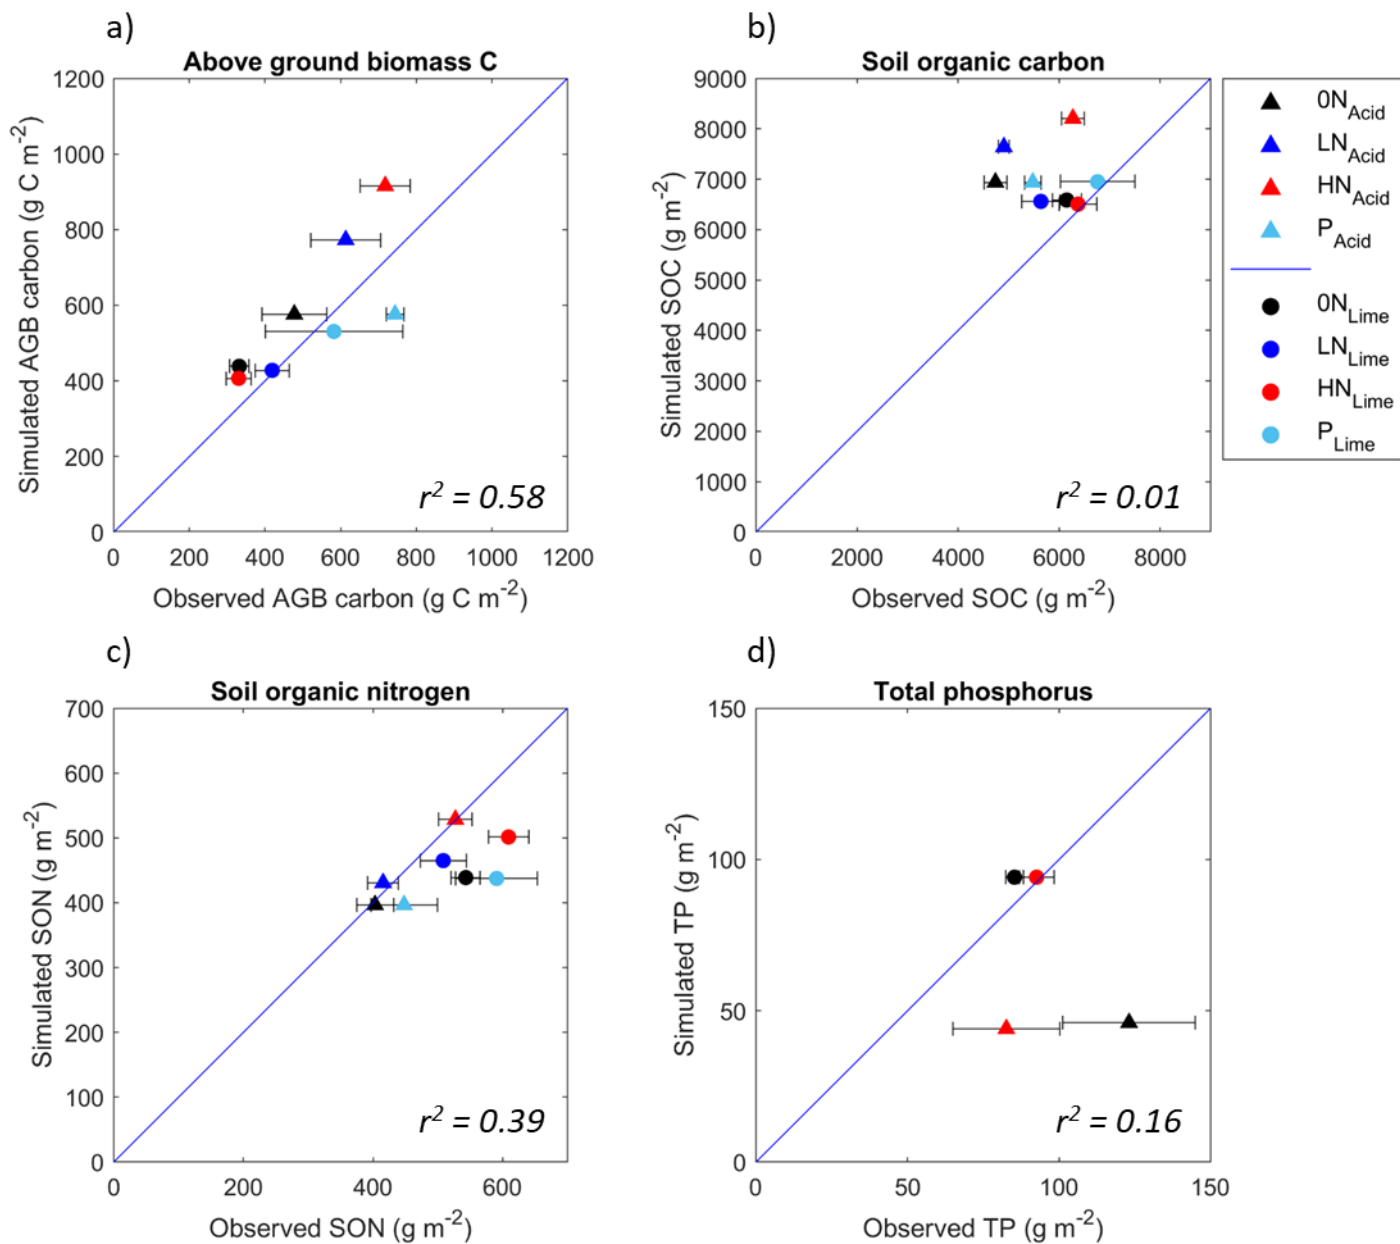

Figure 2: A comparison of the observed values of a) aboveground biomass carbon, b) soil organic carbon, c) soil organic nitrogen and d) total soil phosphorus from both grasslands, with simulated values from the model. The blue line represents a 1 to 1 relationship and the closer the data points are to the line, the smaller the discrepancy between observed and modelled data. All data are in grams per metre squared and all treatments for which data were collected are presented. The horizontal error bars represent the standard error of the empirical data means. The r^2 value of regression models fitted to the data give an overall indication of the direction of response of each variable to nutrient addition, hence a low value is not necessarily indicative of poor model fit

452 **3.2. The limiting nutrient through time**

453 Modelled acid grassland NPP remained N-limited from 1800 through to 2020 under most nutrient
454 treatments (Fig 3). Nitrogen deposition increased the potential NPP through time and the grassland
455 moved toward co-limitation in the LN treatment (i.e. the N and P lines were closer) but remained N-
456 limited (Fig 3b). In the HN treatment, the acidic grassland shifted to P limitation as N-limited NPP
457 surpasses P-limited NPP (Fig 3c).

458 The simulated limestone grassland was also initially N-limited, but was driven through a prolonged
459 (c. 100 year) state of apparent co-limitation until clearly reaching P-limitation in 1950, solely as a
460 result of N deposition (Fig 3). In the ON treatment, the grassland remained P-limited but the
461 potential NPP values for N and P are similar, suggesting the grassland is close to co-limitation (Fig
462 3e). The LN and HN treatment amplified pre-existing P-limitation, lowering the potential NPP of the
463 grasslands (Fig 3f, g). With the addition of P in 1995, P limitation is alleviated, and the ecosystem
464 transitions to a more productive N-limited grassland (Figure 3h).

465 Another way to interpret the extent of nutrient limitation within N14CP with specific reference to P-
466 demand, is to assess the rate of P cleaving through time. These data corroborate the N and P-limited
467 NPP data, showing that in the limestone grassland, the maximum amount of cleavable P is accessed
468 by plants in the ON, LN and HN treatments from approximately 1900 through to the end of the
469 experimental period in 2020 (Fig S1, Table S14), highlighting its consistent state of P limitation.

470 Conversely, while cleaved P is used in the ON treatment in the acidic grassland, it occurs at
471 approximately one third of the total rate, hence the grassland is not entirely P-limited (Fig S1, Table
472 S10). The LN treatment increases the rate of access to cleaved P and HN causes it to reach its
473 maximum value, confirming the shift to P limitation suggested by the NPP data (Fig S1, Table S10).
474 Soil organic P cleaving does not occur in the P-treated plots of either grassland.

475

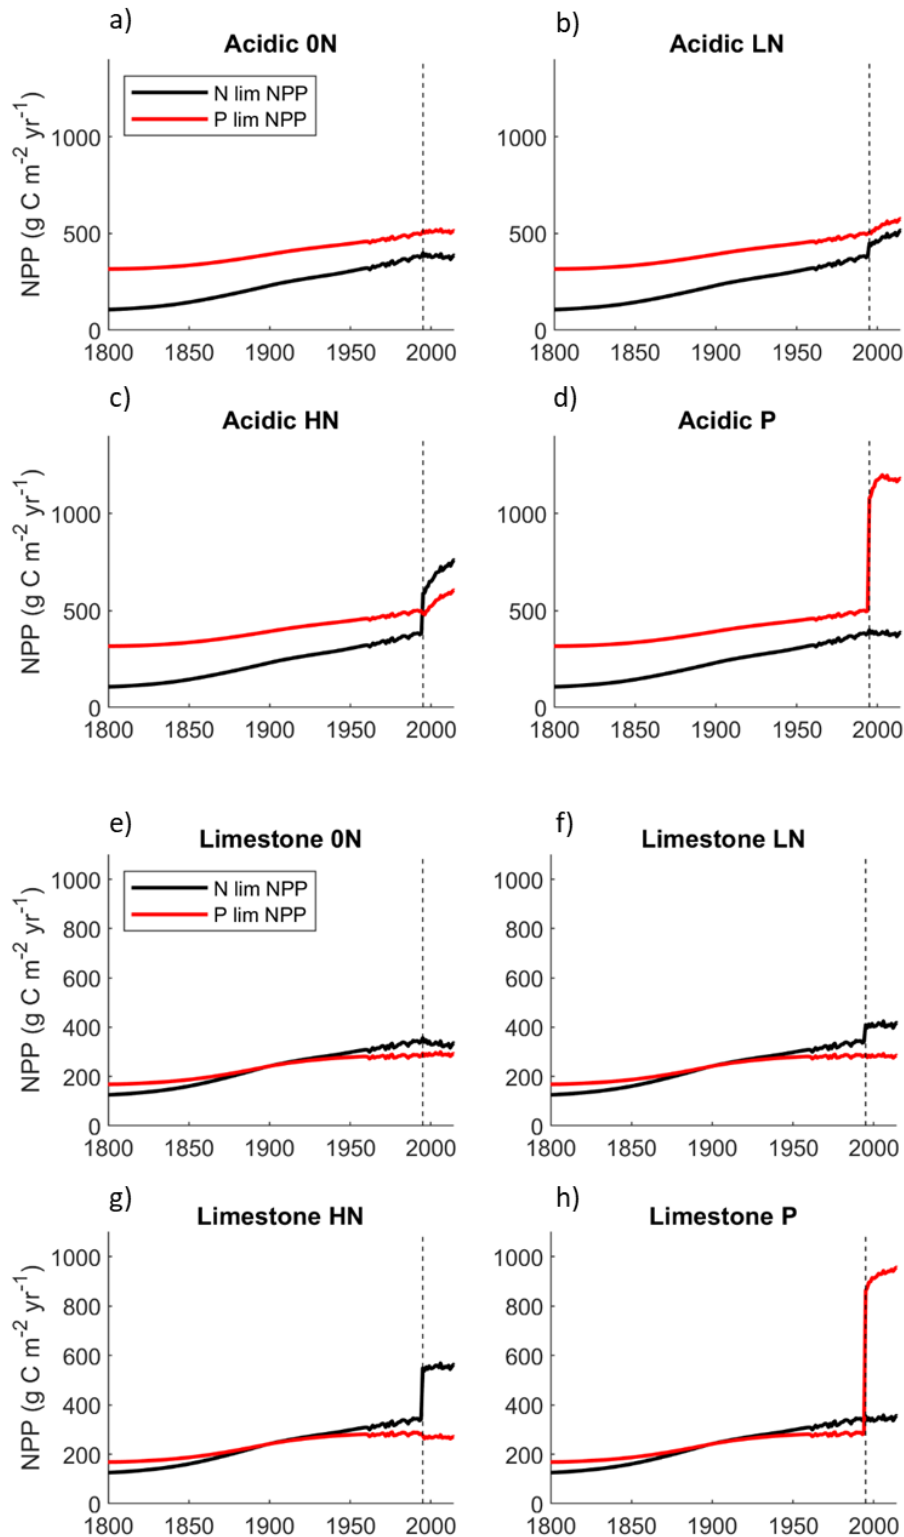

Figure 3: Plots showing the nutrient most limiting productivity for all nutrient treatments in both simulated grasslands. The vertical dashed line is the year of first nutrient addition within the model (1995). The value of the lines represents the maximum amount of productivity attainable given the availability of N and P separately. Due to a Liebig's law of the minimum approach to plant growth, it is the lowest of the two lines that dictates the limiting nutrient of the grassland and represents actual modelled productivity. Where lines share a value, it can be considered in a state of N-P co-limitation.

477 **3.3. Modelled trends and responses to nutrient additions**

478

479 The model allows the temporal trends and responses to nutrient additions to be further explored.

480 Figure 4 provides the temporal responses for the treatments, and Figure 5 a full nutrient budget for

481 the year 2020. Full data for changes in soil C, N and P and plant biomass C pools since the onset of

482 large-scale N deposition (1800 within the model) for both grasslands are included in supplementary

483 Table S15. All data used for determining responses of biomass C and soil organic C, N and P pools to

484 experimental nutrient additions are in supplementary Tables S16 (acidic) and S17 (limestone).

485

486 3.3.1. Acidic grassland

487 The modelled time series suggest that in the ON (control) treatment for the acidic grassland,

488 background levels of atmospheric N deposition between the period 1800-2020 resulted in an almost

489 four-fold increase in biomass C, a near-twofold increase in SOC and SON and increased the size of

490 the SOP pool by almost a fifth (Fig 4).

491 Since initiated in 1995, all C and N pools responded positively to N but not P treatments (Fig 5a, c,

492 Tables S7, S8). The LN and HN treatments further increased aboveground biomass C by 36.2% and

493 61.7% (Fig 4a) and increased the size of the total SOC pool by 11.5% and 20.6% respectively (Fig 4c).

494 Similarly, the total SON pool in the acidic grassland increased by 9.7% in the LN treatment and 36.6%

495 in the HN (Fig 4e).

496 Responses of the SOP pool are in contrast to those of the SOC and SON pools, with LN and HN

497 decreasing SOP by 4.4% and 9.1% respectively, while P addition substantially increased the size of

498 the SOP pool by 76.7% (Fig 4g). Nitrogen treatments facilitated access to SOP from both subsoil and

499 topsoil, increasing plant available P and facilitating its uptake into biomass material (Fig 5e, Table

500 S9).

501

502 3.3.2. Limestone grassland

503 Model simulations for the limestone grassland also suggest N deposition between 1800 and 2020
504 considerably increased aboveground biomass C, SOC and SON pools (Fig. 4), but to a lesser extent
505 than in the acidic grassland. Soil organic C and SON increased by almost half and biomass C more
506 than doubled. Soil organic P accumulated at a faster rate than in the acidic grassland, increasing by
507 about a third (Fig 4, Table S15).

508 Responses of the aboveground biomass C and SOC pools in the limestone grassland differ greatly to
509 those of the acidic, declining with N addition and increasing with P addition (Fig 4). This response
510 was ubiquitous to all C pools, with declines in subsoil, topsoil and biomass C (Fig 5b, Table S11).
511 Biomass C declined by 2.4% and 7.3% with LN and HN addition (Fig 4b) and SOC declined by 0.5%
512 and 1.4% with the same treatments (Fig 4d). Phosphorus addition increased biomass C and SOC by
513 22.0% and 6.1% respectively (Fig 4b, d).

514 Nitrogen treatments increased the size of subsoil, topsoil and available N pools, but led to small
515 declines in biomass N (Fig 5d, Table S12). The P treatment slightly reduced subsoil and topsoil SON
516 compared to the control yet increased available N and biomass N, to the extent where biomass N is
517 greater in the P than HN treatment (Fig 5d, Table S12). Total SON increased by 6.4% and 15.0% with
518 LN and HN respectively and declined by 0.2% with P treatment (Fig 4f).

519 The response of the limestone P pools mirrors that of carbon, with declines in subsoil SOP, topsoil
520 SOP, available P and biomass P with LN and HN addition (Fig 5f, Table S13). The limestone grassland
521 SOP pool declined by 0.2% with LN and 0.5% with HN addition, with an increase of 20.0% upon
522 addition of P (Fig 4h). The P treatment substantially increased total ecosystem P in the limestone
523 grassland, particularly in the topsoil sorbed pool (Fig 5f, Table S13).

524

525

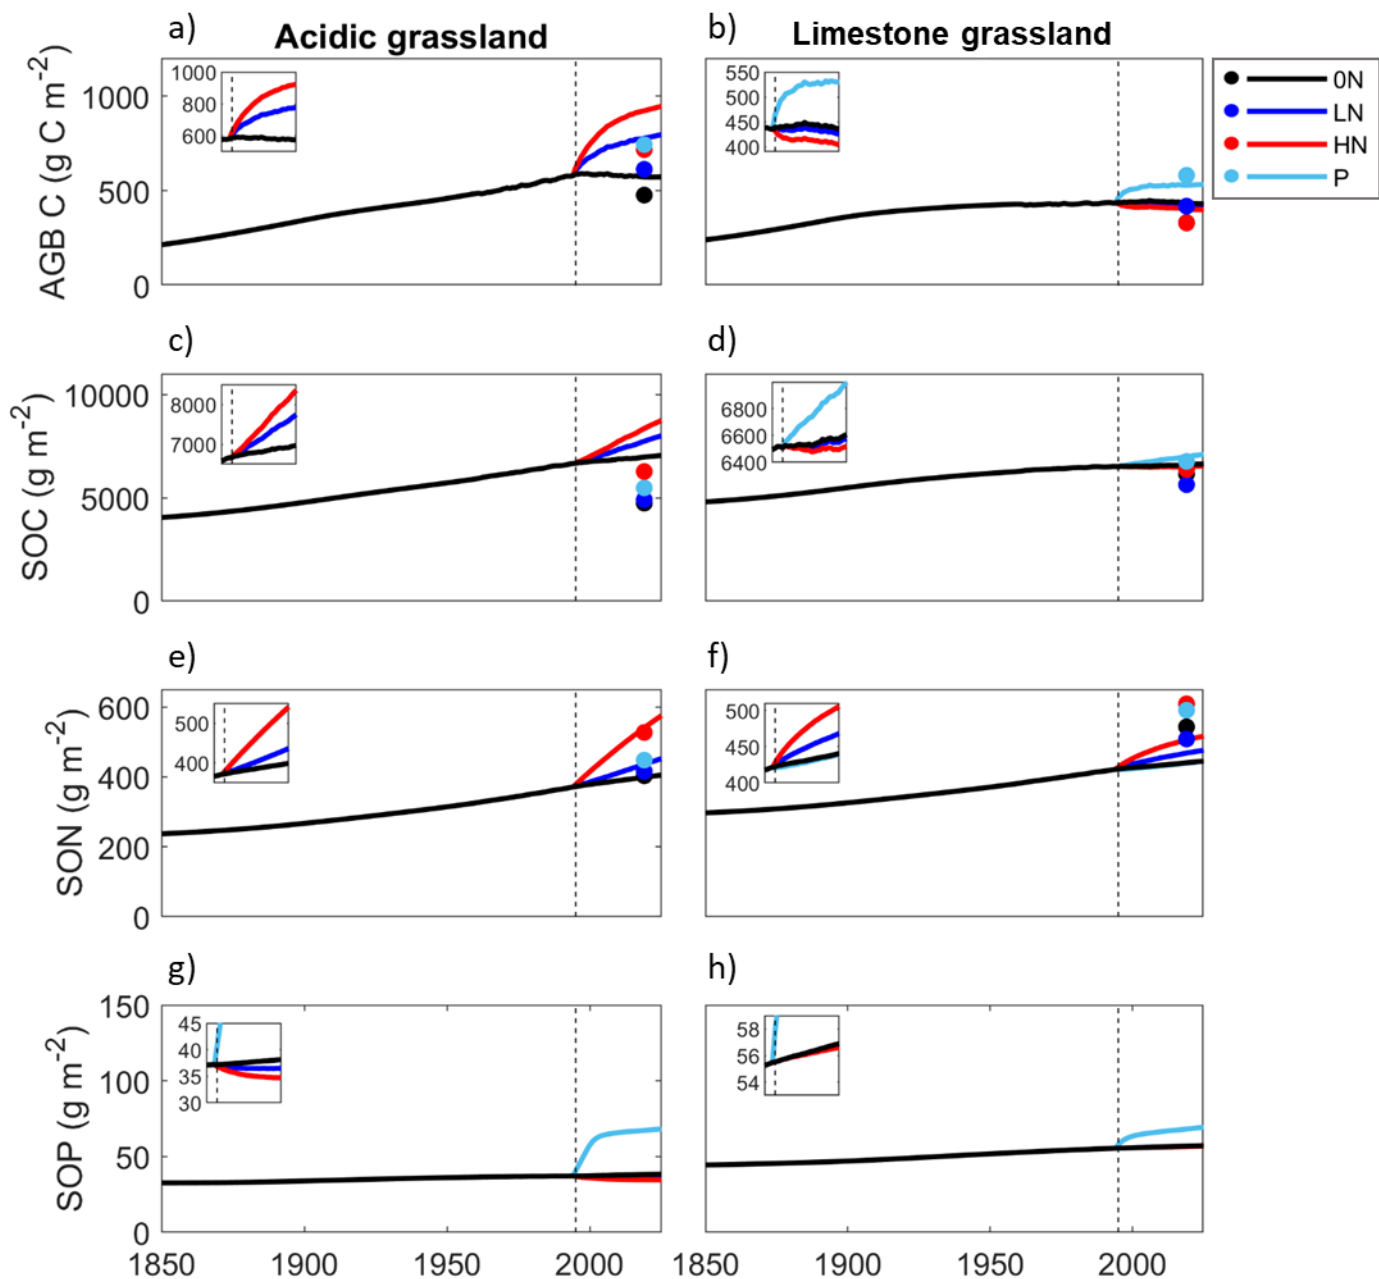

Figure 4: Time series plots of aboveground biomass C, soil organic C, N and P for the acidic (panels a, c, e and g respectively) and limestone modelled grasslands (panels b, d, f and h respectively). The vertical dashed line represents the first year of nutrient addition (1995) and marks the beginning of the experimental period. The inset subplots focus on this experimental period (1995-2020) and highlight changes occurring as a result of nutrient additions rather than background N deposition. All nutrient treatments at Wardlow are represented in all panels though not all lines are visible if they do not differ from ON. Both grassland share a y axis. Empirical data from figure 2 are plotted on the respective panels, with the exception of panels g and h, where empirical data is incompatible with modelled data (total P versus organic P).

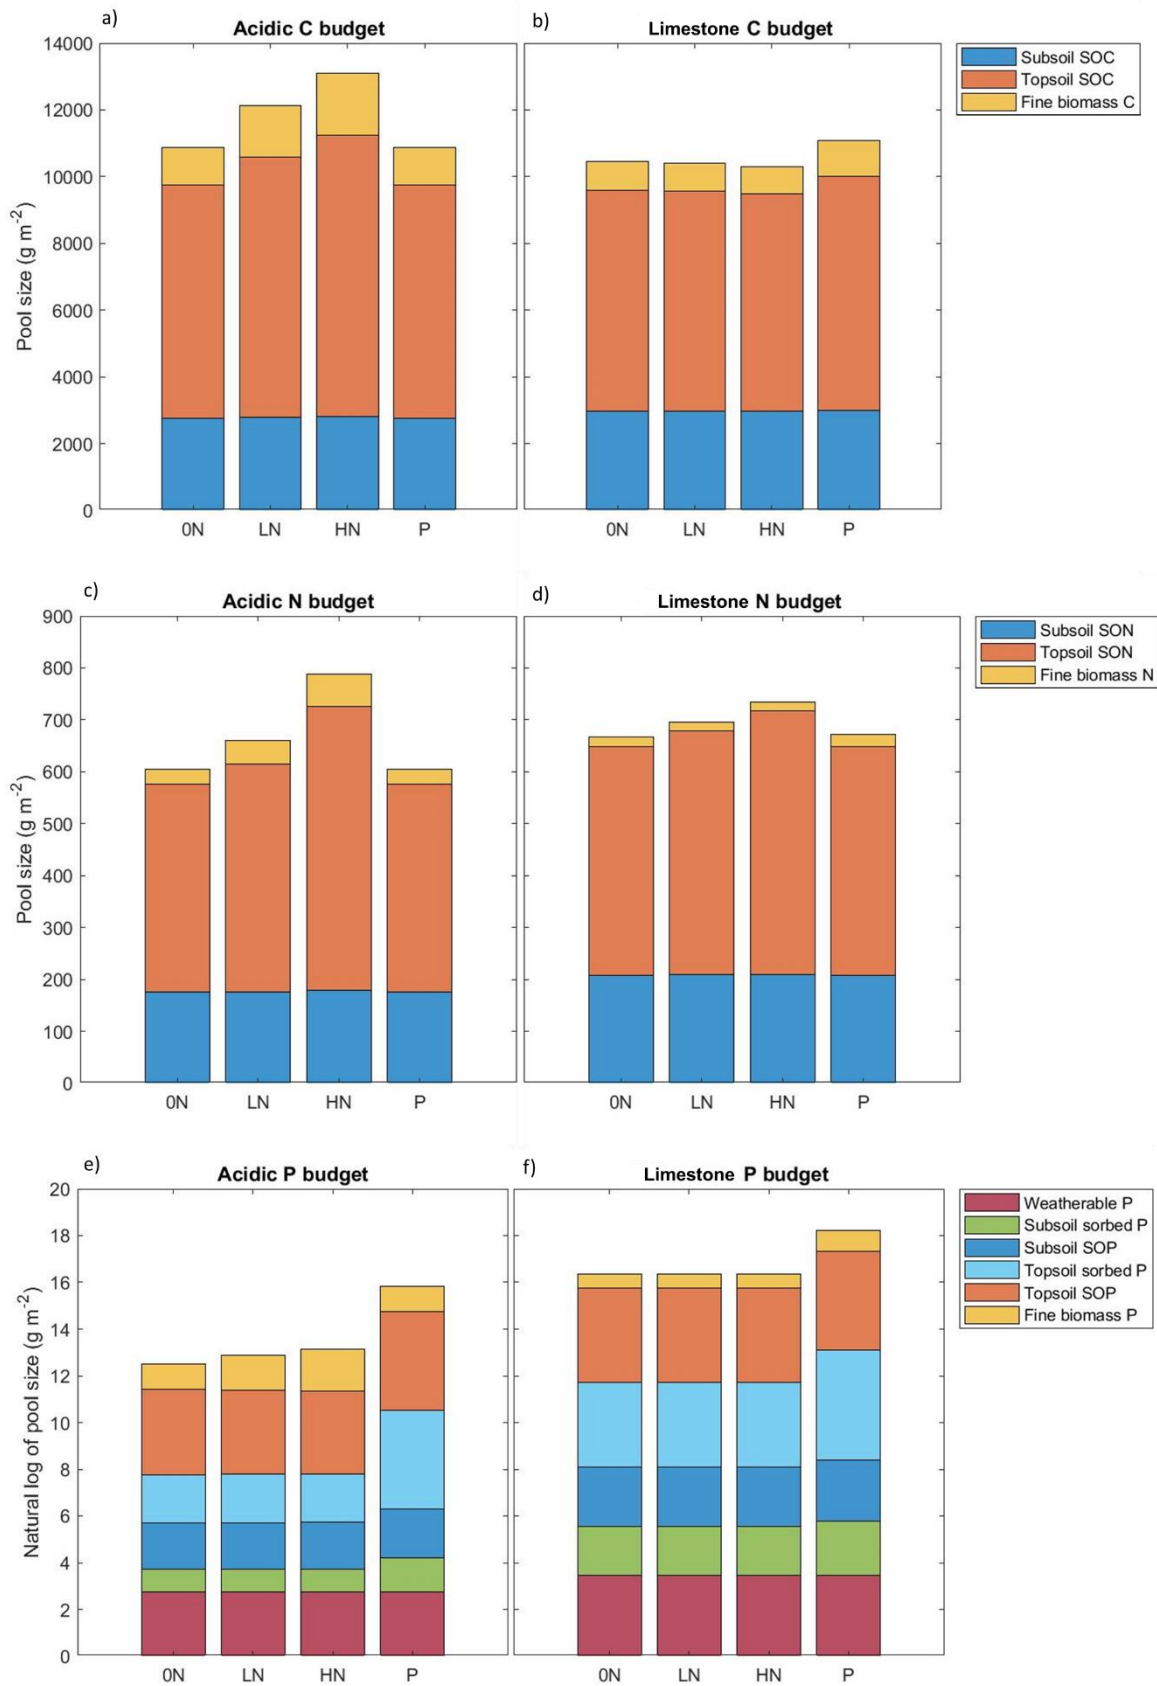

Figure 5: Modelled C, N and P budgets for the acidic (panels a, c and e) and limestone (panels b, d, f) grasslands for the year 2020. Modelled sizes of C and N pools are in grams per metre squared, and P pools are presented as \log_n grams per metre squared. Temporary pools such as available N and P and fixed N are not presented here to avoid ‘double counting’ in other pools and wood litter C, N and P are not presented due to their negligible sizes.

529 **4. Discussion**

530 **4.1. Simulating contrasting grasslands by varying plant access to P sources**

531 This is the first instance in which N14CP, and to the best of our knowledge, any other integrated C-N-
532 P cycle model, has explicitly modelled P-limited ecosystems and investigated their responses to N
533 deposition and additional nutrient treatments. By using empirical data from long-term experimental
534 grasslands to drive and calibrate N14CP, we could test the model's ability to simulate two
535 contrasting P-limited grasslands, and how organic P access may affect this ability. While the purpose
536 of this work was not to explicitly reproduce the Wardlow grasslands within N14CP, by comparing
537 data from Wardlow to the simulated grasslands, we can simultaneously develop our understanding
538 of the model's representation of under-studied P cycling processes and contextualise what this may
539 mean for empirical systems such as Wardlow.

540 The model suggests that the acidic grassland was characterised by high access to organic P, with
541 comparatively low inorganic P availability, whereas the limestone grassland was the opposite, with
542 low organic and high inorganic P availability. These simulated differences could reflect the relative
543 availability of different P sources at Wardlow. As the acidic grassland formed in a hillside depression,
544 loess has accumulated, thickening the soil profile and distancing the plant community from the
545 limestone bedrock. The plant rooting zone of the acidic grassland is therefore not in contact with the
546 bedrock, and roots almost exclusively occur in the presence of organic P sources which can be
547 cleaved and utilised by plants [Caldwell, 2005; Margalef *et al.*, 2017]. Conversely, the limestone
548 grassland soil rarely exceeds 10 cm depth, and the rooting zone extends to the limestone beneath,
549 providing plants with greater access to weatherable calcium phosphate [Smits *et al.*, 2012].

550 Such parameter combinations allowed for reasonable congruence between empirical and simulated
551 data, with an average discrepancy of only 6.6% (SE \pm 9.1) and 1.2% (SE \pm 4.4) for the acidic and
552 limestone grasslands respectively across all variables (Table S5). However, model performance
553 differed greatly between the two grasslands. For instance, the model accurately captured the

554 magnitude of limestone C, N and P data and their expected P-limited responses to nutrient
555 treatment, but was less effective at simulating the acidic grassland. N14CP did not simulate an
556 increase in biomass C or SOC with P addition in the acidic grassland, instead simulating a solely N-
557 limited grassland. While this may be expected of a model that employs a law-of-the-minimum
558 approach, N14CP has a number of mechanisms to account for N and P interdependence, meaning
559 that in principle, it is capable of simulating positive responses to LN, HN and P treatment, as
560 observed in the empirical data from 2017 (section 2.2.2).

561 The overestimation of acidic C pools and underestimation of total P suggests that the model is
562 simulating that too much organic P is being accessed by plants in response to N addition and
563 transferred into plant biomass pools (Fig 2d). Few parameter sets were simultaneously able to
564 simulate the magnitude of the empirical TP pool and the positive response of biomass to N addition
565 in the acidic grassland. This may also be due to limitations in the empirical P data, as P data used for
566 calibrating P cycling were available for only two nutrient treatments and represented total soil P, not
567 organic P. While we acknowledge the technical and theoretical issues associated with distinguishing
568 between organic and inorganic P pools [Lajtha *et al.* 1999; Barrow *et al.* 2020], such distinctions
569 would help in understanding this discrepancy and likely improve the model's ability to simulate P-
570 limited systems, particularly when organic P availability may be important.

571 Additionally, N14CP's representation of organic P cleaving likely underestimates the ability of soil to
572 rapidly occlude and protect organic P that enters solution. For example, inositol phosphate, a major
573 constituent of organic P, has been found to be used extensively by plants grown in sand but is hardly
574 accessed by plants grown in soil [Adams and Pate 1992]. Such organic phosphates become strongly
575 bound to oxides in the soil, protecting them from attack by phosphatase enzymes [Barrow 2020].
576 This may be particularly prevalent in the acidic grassland at Wardlow where N deposition has
577 resulted in acidification and base cation depletion [Horswill *et al.* 2008], potentially enhancing the
578 formation of iron and aluminium complexes and immobilising P [Kooijman *et al.*, 1998].

579 In addition to physico-chemical processes reducing P availability, in P-limited grassland soils,
580 microbial processes may be dominant drivers of ecosystem P fluxes [Bünemann et al. 2012]. For
581 instance, while mineralisation of organic P may increase inorganic P in solution [Schneider et al.
582 2017], this can be rapidly and almost completely immobilised by microbes, particularly when soil P
583 availability is low [Bünemann et al. 2012]. As the model lacks a mechanism for increasing access to
584 secondary mineral P forms comparable to organic P-cleaving, and microbial P immobilisation is
585 incompletely represented for P-limited conditions, it is possible that the uptake of organic P by the
586 acidic grassland in the model is exaggerated.

587 ~~As the model lacks a mechanism for increasing access to secondary mineral P forms comparable to~~
588 ~~organic P-cleaving, the uptake of organic P by the acidic grassland is very likely exaggerated.~~

589 The model's inability to simulate a positive response to both N and P addition in the acidic grassland
590 may be an unintended consequence of the downregulation of N fixation by N deposition included
591 within N14CP [Davies *et al.* 2016b]. While this representation is appropriate [Gundale *et al.* 2013],
592 when N deposition exceeds fixation (as at Wardlow), fixation is essentially nullified (as in Tables S8,
593 S12), meaning deposition becomes the sole source of N to the grassland. This in effect, removes the
594 dependence of N acquisition on P availability, and could make modelling behaviour akin to N-P co-
595 limitation [Harpole *et al.*, 2011] under high levels of N deposition challenging. This suggests that
596 current C-N-P cycle models that employ a Liebig's law of the minimum can provide a broad
597 representation of multiple variables by calibrating access to both organic and inorganic P sources
598 [Davies *et al.* 2016b], provided the ecosystem in question's limiting nutrient leans towards N or P
599 limitation. Furthermore, where access to organic P forms is likely to be lower, as in the limestone
600 grassland, model performance may improve. This could be further explored by allowing N fixation
601 limits in the model to adapt to P nutrient conditions or by attenuating the suppression of N
602 deposition on N fixation, to represent acclimatisation of N-fixers to greater N availability [Zheng *et*
603 *al.* 2018].

604 Ultimately, differences in modelled accessibility to organic forms of P enabled N14CP to distinguish
605 between the two empirical grasslands, and simulate the magnitude and pattern of data with
606 reasonable accuracy, albeit with the previously mentioned caveats.

607

608 **4.2. Consequences of differential P access on ecosystem C, N and P**

609 While the model's estimation of $P_{\text{CleaveMax}}$ for the acidic grassland is likely overestimated, the model
610 experiment has highlighted that differences in organic versus inorganic P availability are a key
611 determinant of an ecosystem's nutrient limitation, and consequently, how they respond to changes
612 in anthropogenic N and P availability. For instance, while being exposed to the same background
613 level of N deposition and the same magnitude of experimental treatment, the modelled acidic
614 grassland was able to stimulate growth in response to LN and HN treatment whereas the modelled
615 limestone grassland was negatively affected by it.

616 Nitrogen addition increases plant demand for P and can shift ecosystems toward a state of P
617 limitation or increase the severity of limitation where it already exists [Menge and Field, 2007; An *et*
618 *al.*, 2011; Goll *et al.*, 2012]. Consistent with this, both simulated grasslands saw SOP decline with LN
619 and HN treatment, worsening P limitation in the limestone grassland, and depleting the SOP pool in
620 the acidic. As P cleaved from organic pools is the least bioavailable within the model hierarchy
621 (methods 2.2.3), this is indicative of increasing P stress in both grasslands. While SOP declined in
622 both grasslands, the responses of available and biomass P to nutrient treatments differed markedly
623 between the grasslands. Due to the higher rate of $P_{\text{CleaveMax}}$ in the acidic grassland, more P
624 ~~accumulated in the~~ was in plant-available forms ~~pool~~ and hence P does not become the limiting
625 factor under N treatments (Table S9). Conversely, available and biomass P decline under LN and HN
626 addition in the limestone grassland (Table S13), highlighting how the grassland's $P_{\text{CleaveMax}}$ capability is
627 insufficient to meet increased P demand.

628 Such high access to organic P sources in the modelled acidic grassland likely led it to respond to
629 nutrient enrichment in an N-limited manner, increasing productivity in response to N deposition and
630 LN and HN treatments as the model's limiting nutrient stimulated plant growth. Detrital C inputs
631 from plant biomass are the primary source of SOC accumulation within N14CP [Davies *et al.*, 2016b]
632 and as such, changes in SOC integrate long term trends in net primary productivity in systems where
633 external nutrients are supplied. The provision of additional N in the modelled LN and HN treatments
634 therefore led to large increases in biomass accumulation and consequently, almost linearly increased
635 SOC (Fig 4c).

636 Similar increases in N-limited grassland SOC under N addition have been shown, resulting from
637 significant increases in below-ground carbon input from litter, roots [He *et al.*, 2013] and detrital
638 inputs [Fornara *et al.*, 2013], mechanisms similar to those reported by the model. Similarly, Tipping
639 *et al.* [2017] used N14CP to show that N deposition onto N-limited UK ecosystems ubiquitously
640 increased SOC storage by an average of 1.2 kgCm⁻² (c. 10%) between 1750 and 2010 [Tipping *et al.*,
641 2017].

642 Despite its P-limited condition under the HN treatment (Fig 3c), the acidic grassland continued to
643 accumulate biomass with N addition as the grassland's greater access to topsoil SOP (Table S9)
644 allowed it to acquire sufficient P to stimulate additional growth but not necessarily to alleviate P
645 limitation. This is consistent with the acidic grassland at Wardlow, where N treatment stimulated
646 root surface phosphatases, likely supplying more SOP to plants [Johnson *et al.*, 1999]. Our simulated
647 acidic grassland therefore supports the hypothesis that prolonged N deposition may increase SOP
648 access to such an extent that P limitation is alleviated and growth can be stimulated [Chen *et al.*
649 2020]. Organic P release from SOM and its potential immobilisation, is poorly represented in models
650 and we encourage further study aimed at quantifying these processes [Chen *et al.* 2020; Janes-
651 Bassett *et al.*, 2020; Phoenix *et al.*, 2020]. However, such high rates of SOP access only occurred

652 under experimental LN and HN treatments, and in reality, such rapid degradation of SOP may
653 eventually degrade the pool to such an extent that P limitation soon returns.

654 Conversely, biomass C and SOC in the modelled limestone grassland responded positively to P
655 addition, via similar mechanisms to the N-response in the modelled acidic grassland. However, in
656 contrast to the acidic grassland, N addition caused declines in limestone biomass and SOC, the
657 former of which has been observed at the limestone grassland at Wardlow [Carroll *et al.*, 2003].
658 Reductions in limestone biomass C (and consequently SOC) in the model are a combined result of
659 reductions in bioavailable P (Table S13), occurring via N-driven increases in stoichiometric P demand,
660 in addition to an inability to access sufficient P from the SOP pool (Table S14). Plants therefore
661 cannot meet P demand and new biomass is insufficient to replace senesced plant material,
662 decreasing net biomass C input to the SOC pool. This suggests that in P-limited limestone grasslands
663 such as at Wardlow, where access to organic P forms may be comparatively limited, N deposition
664 may worsen pre-existing P limitation and reduce ecosystem C stocks [Goll *et al.* 2012, Li *et al.*
665 2018].~~This implies that in ecosystems where plants are not well adapted to acquiring organic forms~~
666 ~~of P [Phoenix *et al.* 2020], or where organic P is scarce, N deposition may worsen pre-existing P~~
667 ~~limitation and reduce ecosystem C stocks [Goll *et al.* 2012; Li *et al.* 2018].~~

668

669 **4.3. Model limitations**

670

671 While N14CP is a fairly simple ecosystem model by design, it is one of few models to integrate the C,
672 N and P cycles for semi-natural ecosystems and has been extensively tested against empirical NPP
673 and soil C, N and P data ~~it is one of the first process-based biogeochemical models to explicitly~~
674 ~~incorporate P with the C and N cycles for semi-natural ecosystems, and to simulate NPP and soil C, N~~
675 ~~and P dynamics, for which it has been extensively tested~~ [Davies *et al.* 2016a; Davies *et al.* 2016b;
676 Tipping *et al.* 2017; Tipping *et al.* 2019; Janes-Bassett *et al.* 2020]. Previous work with N14CP has

677 identified the need to enhance its ability to simulate organic P cycling [Janes-Bassett *et al.* 2020],
678 which we aimed to do in this study by using long-term experimental data from contrasting P-limited
679 grasslands.

680 N14CP's simplified representation of plant nutrient pools and plant control over nutrient uptake, is
681 largely controlled by stoichiometric demand [Davies *et al.* 2016a], and does not incorporate many
682 plant strategies for P acquisition [Vance *et al.* 2003]. Indeed, by allowing $P_{\text{CleaveMax}}$ to vary to account
683 for empirical data, we attempt to somewhat increase plant control over organic P uptake. We
684 acknowledge earlier that such an approach likely underestimates the ability of soil surfaces and
685 microbes to protect newly-cleaved P from plant uptake. As such, where we may expect access to
686 organic P to be high, such as the acidic grassland at Wardlow, such modelled representation of
687 plant-mediated P access may lead to unrealistic depletions in soil P and increases in biomass and soil
688 C, and we would encourage further work aimed at improving model-representation of plant controls
689 on organic P cycling [Fleischer *et al.* 2019].

690 While we feel incorporating a suite of plant strategies for acquiring P would represent over-
691 parameterisation, we acknowledge that a modelled equivalent to $P_{\text{CleaveMax}}$ for accessing inorganic P
692 forms is lacking, such as carbon-based acid exudation to increase mineral P weathering [Achat *et al.*
693 2016; Phoenix *et al.* 2020], which likely contributes toward the poor representation of the acidic
694 total P pool. Biota-enhanced P weathering and nutrient redistribution by mycorrhizal hyphae are
695 important for nutrient cycling [Quirk *et al.* 2012], and fungal community structure and function is
696 strongly influenced by perturbations in the C and N cycles [Moore *et al.* 2020]. Such processes are
697 not included within N14CP as the extent to which weathering can be controlled by such mechanisms
698 and the manner in which these can be represented in C-N-P cycle models is debated [Davies *et al.*
699 2016b].

700 Currently, N14CP assumes C to be in unlimited supply, with its uptake by plants and consequent
701 input into soil pools controlled by C:N:P stoichiometry, hence C availability has little effect on N and

702 P dynamics within the model. Increasing atmospheric CO₂ may increase nutrient availability, as
703 plants may reallocate additional carbon resources toward nutrient acquisition [Keane *et al.* 2020] or
704 elevated CO₂ (eCO₂) may increase limitation of other nutrients such as N [Luo *et al.* 2004]. The
705 inclusion of eCO₂ into N14CP poses a particularly enticing research opportunity, and we aim to use
706 this study as a foundation for future work to include this process.

707

708 5. Conclusions

709 We have shown that by varying two P-acquisition parameters within N14CP, we can account for
710 contrasting responses of two P-limited grasslands ~~of differing soil P chemistry,~~ and with reasonable
711 accuracy. However, such coarse representation of organic P cycling in the model likely overestimates
712 the ability of plants to use newly-cleaved P and limits our ability to simulate grasslands where N and
713 P interact to control plant productivity, including the potential for N inputs to alleviate P limitation.

714 Differences in organic P access was a key factor distinguishing the contrasting responses of the
715 modelled grasslands to nutrient manipulation, with high plant access allowing the acidic grassland to
716 acquire sufficient P to match available N from chronic deposition and prevent ‘anthropogenic P
717 limitation’. In the acidic grassland, N treatment stimulated plant access of organic P, promoting
718 growth and C sequestration. However, the model suggests that this is an unsustainable strategy, as
719 the SOP pool rapidly degrades, and if N additions are sustained, P limitation may return. Conversely
720 in the limestone grassland, which was less able to access organic P, additional N provision
721 exacerbated pre-existing P limitation by simultaneously increasing plant P demand and reducing P
722 bioavailability. This reduced productivity and consequently C input to soil pools declined, resulting in
723 SOC degradation exceeding its replacement.

724 We further show that anthropogenic N deposition since the onset of the industrial revolution has
725 had a substantial impact on the C, N and P pools of both the modelled acidic and limestone
726 grasslands, to the extent where almost half of contemporary soil C and N in the model could be
727 from, or caused by, N deposition.

728 Our work therefore suggests that with sufficient access to organic P, long-term N addition may
729 alleviate P limitation. Where organic P access is limited, N deposition could shift more ecosystems
730 toward a state of P limitation or strengthen it where it already occurs [Goll *et al.*, 2012], reducing
731 productivity to the point where declines in grassland SOC stocks - one of our largest and most labile
732 carbon pools – may occur.

733 *Data availability:* Data archiving is underway with the NERC's Environmental Information Data
734 Centre (EIDC) and a DOI will be available once this process is complete. All data to be archived is
735 present in the supplementary information for review purposes.
