## Abstract.

The surface mixed layer (ML) in the Mediterranean Sea is a well stratified domain characterized by low macro-nutrients and low chlorophyll content, for almost 6 months of the year. In this study we characterize the biogeochemical cycling of N in the ML by analysing simultaneous *in situ* measurements of atmospheric deposition, nutrients, hydrological conditions, primary production, heterotrophic prokaryotic production, N<sub>2</sub> fixation and leucine aminopeptidase activity. Dry deposition was continuously measured across the central and western open Mediterranean Sea and two wet deposition events were sampled, one in the Ionian Sea and one in the Algerian basin. Along the transect, N budgets were computed to compare the sources and sinks of N in the mixed layer. *In situ* leucine aminopeptidase activity made up 14 to 66 % of the heterotrophic prokaryotic N demand, and the N<sub>2</sub> fixation rate represented 1 to 4.5 % of the phytoplankton N demand. Dry atmospheric deposition of

inorganic nitrogen, estimated from dry deposition of (nitrate+ammonium) in aerosols, was higher than the N<sub>2</sub> fixation rates in the ML (on average 4.8-fold). The dry atmospheric input of inorganic N represented a highly variable proportion of biological N demand in the ML among the stations, 10-82% for heterotrophic prokaryotes and 1-30% for phytoplankton. As some sites were visited for several days the evolution of biogeochemical properties in the ML and within the nutrient-depleted layers could be followed. At the Algerian Basin site, the biogeochemical consequences of a wet dust deposition event was followed with a high frequency sampling of CTD casts. Notably just after the rain, nitrate was higher in the ML than in the nutrient depleted layer below. Estimates of nutrient transfer from the ML to the nutrient depleted layer could explain up to a 1/3 of the nitrate loss from the ML. Phytoplankton did not benefit directly from the atmospheric inputs into the ML, probably due to high competition with heterotrophic prokaryotes, also limited by N and P availability at the time of this study. Primary producers decreased their production after the rain, recovering to their initial state of activity after a 2 day lag in the vicinity of the deep chlorophyll maximum layer.

### 1. Introduction

The Mediterranean Sea (MS) is a semi-enclosed basin characterized by very short ventilation and residence times due to its own thermohaline circulation (Mermex Group, 2011). In terms of biogeochemistry, the MS is characterized by a long summer stratification period. It is a low nutrient, low chlorophyll (LNLC) system with where there is generally an increasing oligotrophic gradient from west to east and an overall deficit in phosphorus (P) compared to nitrogen (N) (Mermex Group, 2011). This is confirmed by an N/P ratio for inorganic nutrients that is higher than the Redfield ratio, in deep layers, which increases toward the east (Krom et al., 2004).

The relationship between photoautotrophic unicellular organisms and heterotrophic prokaryotes (competition or commensalism) is affected by the balance of light and nutrients as well as possible inputs of organic matter from river runoff or atmospheric deposition.

Phytoplankton generally experience P, N, or NP limitation (Thingstad et al., 2005 ; Tanaka et al., 2011, Richon et al., 2018), whereas heterotrophic prokaryotes are usually P limited, or P and labile carbon co-limited (Sala et al., 2002, Van Wambeke et al., 2002, C ea et al., 2014).

The MS receives anthropogenic aerosols continuously, originating from industrial and domestic activities from around the basin and from other parts of Europe along with pulsed natural inputs from the Sahara. It is thus a natural LNLC study area, well adapted to

135 investigate the role of ocean–atmosphere exchanges of particles and gases on marine  
biogeochemical cycles. Parameterization and representation of the key processes brought into  
play by atmospheric deposition in the MS must take into account the role of pulsed  
atmospheric inputs (Guieu et al., 2014a). Recent studies describe annual records of  
140 atmospheric deposition of trace metals and inorganic macronutrients (N, P) obtained at  
several locations around the MS (Markaki et al., 2010; Guieu and Ridame, in press;  
Desboeufs, in press). All records denote the pulsed and highly variable inputs. Recent models  
and observations show that atmospheric deposition of organic matter (OM) is also highly  
variable and that their annual inputs are of the same order of magnitude as river inputs  
(Djaoudi et al., 2017, Kanakidou et al., 2018; Kanakidou et al., 2020; Galetti et al., 2020).  
145 Moreover, the sum of atmospheric inputs of nitrate, ammonium and soluble organic nitrogen  
has been shown to be equivalent or higher than those of N<sub>2</sub> fixation rates (Sandroni et al.,  
2007), although inorganic atmospheric N inputs alone may also be higher than N<sub>2</sub> fixation  
rates (Bonnet et al., 2011).

Aerosol amendments in bottles, minicosms or mesocosms have been widely used to study  
150 trophic transfer and potential export, as they represent to some extent a ‘simplified’ plankton  
trophic web that can be studied along a vertical dimension (i.e. Guieu et al., 2010; Herut et al.,  
2016; Mescioglu et al., 2019). It has been shown that both diversity and functioning of  
various biological compartments are impacted by aerosol additions in different waters tested  
155 in the MS (Guieu and Ridame, in press, and synthesis Figure 3 therein). Differences in the  
biological responses have been observed, depending on the mode of deposition simulated  
(wet or dry), the type of aerosols used (natural or anthropogenic), and the *in situ*  
biogeochemical conditions at the time of the experiment (Guieu and Ridame, in press).  
Organic carbon from aerosols is partly soluble, and this soluble fraction is partly available to  
marine heterotrophic prokaryotes (Djaoudi et al., 2020). Heterotrophic prokaryotes have the  
160 metabolic capacity to respond quickly to aerosol deposition through growth and changes in  
community composition (Rahav et al., 2016; Pulido-Villena et al., 2008; 2014), while the  
phytoplankton community responds more slowly or not at all (Guieu and Ridame, in press,  
and reference therein).

Owing to the intrinsic experimental limitations, which vary depending on the size and design  
165 of enclosures (i.e. the omission of higher trophic levels, absence of turbulent mixing so  
limiting exchanges by diffusion, and wall effects), such experiments cannot fully simulate *in*  
*situ* conditions (Guieu and Ridame, in press). Thus, it is still necessary to acquire *in situ*

195 observations ~~to understand~~ the consequences of aerosol deposition on biogeochemical cycles.  
 200 ~~Such~~ *in situ* studies are scarce and require ~~dedicated~~ high frequency sampling to follow the effects of deposition on ~~the~~ biogeochemical processes ~~while taking into account the water column dynamics~~. ~~To demonstrate this point~~, the biological response to a Saharan dust event (~~dust flux = 2.6 g m<sup>-2</sup> recorded at a coastal station in Cap Ferrat~~) was detected 4 days after ~~the~~ event by only one ~~offshore~~ water column sampling (at ~~the~~ DYFAMED site). ~~An~~ increase in heterotrophic prokaryotic respiration and abundance, ~~was observed when compared~~ to a sampling ~~that was carried out~~ 16 days before this dust event (Pulido-Villena et al., 2008). ~~Off~~ the Israelian coast, a moderate natural dust storm (1.05 mg L<sup>-1</sup> over 5 m depth) was followed every 12 ~~hours over~~ 5 days (Rahav et al., 2016). ~~Rapid changes were observed, which could~~ have been missed without high frequency sampling. ~~A~~ decrease in picophytoplankton abundance, an increase in heterotrophic prokaryote abundance, as well as ~~a~~ slight increase in primary production (25%) and heterotrophic prokaryotic production (15%) ~~was observed~~. Hence, it is necessary to organize sampling surveys with adaptive strategies to follow aerosol deposition events *in situ* and their impacts on biogeochemical processes, especially in the open waters of the stratified and nutrient limited MS. The objectives of the PEACETIME project were to study fundamental processes and their interactions at the ocean–atmosphere interface ~~following~~ atmospheric deposition (especially of Saharan dust) in the Mediterranean Sea, and how these processes impact the functioning of the pelagic ecosystem (Guieu et al., 2020).  
 215 As atmospheric deposition affects primarily the surface mixed layer (ML), the present study focuses on the upper part of the nutrient depleted layer that extends down to the nutriclines (as defined by Du et al., 2017). During the stratification period, concentrations of nitrate and phosphate ~~inside~~ the ML are often below ~~the~~ quantification limits of standard methods. However, nanomolar concentrations of nitrate (and phosphate) can now be assessed accurately through ~~the~~ Long Waveguide Capillary Cell (LWCC) technique (~~Zhang and Chi, 2002~~), which ~~permits the~~ measurement of fine gradients inside nutrient depleted layers ~~of~~ the MS (Djaoudi et al., 2018).  
 The aims of the present study were to assess the impact of atmospheric nutrient deposition on biogeochemical processes and fluxes in the open sea during ~~the~~ PEACTIME cruise in the MS.  
 225 For this ~~we~~ i) estimated nanomolar variations of nitrate concentrations in the surface mixed layer (ML) facing variable inputs of dry and wet aerosol deposition ~~and~~ ii) we compared the aerosol-derived N inputs to the ML with biological activities: primary production,

265 heterotrophic prokaryotic production, N<sub>2</sub> fixation and ectoenzymatic activity (leucine  
 aminopeptidase). We studied the N budgets along a transect, to include 13 stations crossing  
 the Algerian Basin, Tyrrhenian Sea and the Ionian Sea where dry atmospheric deposition was  
 continuously measured on board together with seawater biogeochemical, biological and  
 270 physical characteristics. We finally focused on a high frequency sampling of a wet deposition  
 event that occurred in the western Algerian Basin, where we investigated the evolution of  
 biogeochemical fluxes of both N and P and microbial activities.

## 2. Materials and Methods

### 2.1 Sampling strategy and measured parameters

275 The PEACETIME cruise (doi.org/10.17600/15000900) was conducted in the Mediterranean  
 Sea, from May to June 2017, along a transect extending from the Western Basin to the center  
 of the Ionian Sea (Fig. 1). For details on the cruise strategy, see Guieu et al. (2020). Short  
 duration stations (< 8 h, 10 stations named ST1 to ST10, Fig. 1) and long duration sites (5  
 days, 3 sites named TYR, ION and FAST) were occupied. Chemical composition of aerosols  
 280 was quantified by continuous sampling along the whole transect. In addition, two rain events  
 were sampled (Desboeufs et al., this issue, in prep.), one on the 29<sup>th</sup> of May at ION site, and a  
 second one, a dust wet deposition event, at FAST site on the 5<sup>th</sup> of June.

- Supprimé: 15

- Supprimé: b
- Supprimé: station

At least 3 CTD casts were conducted at each short station. One cast focused on the epipelagic  
 layer (0-250 m), another on the whole water column. Both of these were sampled with a  
 285 standard, classical-CTD rosette equipped with a sampling system of 24 Niskin bottles (12 L),  
 and a Sea-Bird SBE9 underwater unit equipped with pressure, temperature (SBE3),  
 conductivity (SBE4), chlorophyll fluorescence (Chelsea Acquatracka) and oxygen (SBE43)  
 sensors. A third cast, from surface to bottom was performed under 'trace metal clean  
 conditions' using a second instrumental package including a titanium rosette (called TMC-  
 290 rosette) mounted on a Kevlar cable and equipped with Go-Flo bottles that were sampled in a  
 dedicated clean lab container. The long duration sites were abbreviated as TYR (situated in  
 the center of the Tyrrhenian Basin), ION (in the center of the Ionian Basin), FAST (in the  
 western Algerian Basin). These 3 sites were selected using satellite imagery, altimetry and  
 Lagrangian diagnostics and forecasted rain events (Guieu et al., 2020). At these sites, repeated  
 295 casts were performed over a minimum of 4 days, alternating CTD- and TMC- rosettes (Table  
1). The succession of CTD casts at the FAST site is numbered in days relative to a rain event  
 collected on board the ship. The first cast of the series was sampled 2.3 days before the rain

event, and the last 2 days after. The FAST site was revisited following the study of ST10 (3.8 days after the rain event).

325 Primary production (PP), prokaryotic heterotrophic production (BP), heterotrophic prokaryotic abundances (hprok), ectoenzymatic activities (leucine aminopeptidase (LAP) and alkaline phosphatase (AP)), were determined on water samples collected with the classical CTD-rosette. Dissolved inorganic nutrients, dissolved organic nitrogen (DON) and phosphorus (DOP) were measured on water samples collected using the TMC-rosette. LAP and AP were determined from two layers in the epipelagic waters (5 m depth and deep chlorophyll maximum (DCM)) at the short stations and at the ION and TYR sites. In addition, LAP and AP were determined at 4 depths between 0 and 20 m for 4 profiles at FAST site, to get insight on the variability within the ML.

335 **2.2 Analytical methods and fluxes calculations**  
**2.2.1 Nutrients in the atmosphere**

For dry deposition estimations, the total suspended aerosol particles (TSP inlet) were collected continuously throughout the campaign. Aerosol sampling was accomplished by using filtration units on adapted membranes for off-line chemical analysis (Tovar-Sanchez et al., 2020). In parallel to the total aerosol filter sampling, water soluble fractions of the aerosols was sampled continuously, using a Particle-into-Liquid-Sampler (PILS, Orsini et al., 2003). Moreover, two wet deposition events were sampled on board the ship during the cruise, one at the ION site, one at the FAST site using rain collectors with on-line filtration (porosity 0.2 µm) (details in Desboeufs et al., this issue, in prep).

345 The nitrate and ammonium concentrations in the aerosols, abbreviated in the text to NO<sub>3</sub> and NH<sub>4</sub> respectively, (nitrite concentrations were under analytical detection limits) were analyzed continuously on board from May 13<sup>th</sup>, using PILS sampling coupled on-line with double way ion chromatography (PILS-IC, Metrohm, model 850 Professional IC with Metrosep A Supp 7 column for anion measurements and Metrosep C4 column for cation measurements). The time resolution for PILS-IC analysis was 70 min. for anions and 32 min for cations. Dissolved Inorganic Nitrogen (DIN) fluxes released from the dry deposition were estimated by multiplying the NO<sub>3</sub> and NH<sub>4</sub> obtained by PILS-IC measurements by the dry settling velocities of N-bearing aerosols, i.e. 0.21 and 1 cm s<sup>-1</sup> for NH<sub>4</sub> and NO<sub>3</sub>, respectively (Kouvarakis et al., 2001). Mean concentrations were used from the PILS-IC data which were measured (1) during the occupation at each short station lasting between 0.13 and 0.66 days,

Supprimé: Inorganic phosphate (DIP) concentrations were estimated from total phosphorus concentrations in particulate aerosols on filters since it was generally under detection limits using the PILS-IC technique. NO<sub>3</sub>, NH<sub>4</sub> and DIP were also determined by ion chromatography in the dissolved fraction of the 2 rain samples.

Mis en forme : Couleur de police : Automatique

Supprimé: aerosol concentrations of ...

445 (i.e. enabling on average 5 measurements for NO<sub>3</sub> and 11 measurements for NH<sub>4</sub>), and (2)  
 between two successive casts at the sites with a time lag in between of 0.4 to 1.21 days (i.e.  
 enabling on average 15 measurements for NO<sub>3</sub> and about 30 for NH<sub>4</sub>). At ST1, NH<sub>4</sub> and  
 NO<sub>3</sub> concentrations were obtained using IC analyses following water extraction from aerosol  
 filter sampling as the PILS-IC was not operational.

450 Total dissolved phosphate (TDP) concentrations were estimated from soluble P  
 concentrations extracted from particulate aerosols collected on filters after ultrapure water  
 extraction HR-ICP-MS analysis (Neptune Plus, Thermo Scientific™) (Fu et al., this issue, in  
 prep) since it was generally under detection limits using the PILS-IC technique. The  
 frequency of TDP analysis was therefore less than for DIN: the filters sampled over the  
 duration of the short station (0.28 - 1.15 days depending on the stations). At the 3 sites, filters  
 455 collected aerosols during periods including each CTD casts sampling date, when possible.

Atmospheric deposition flux of soluble P was estimated by multiplying the TDP  
 concentration by a dry settling velocity of 1 cm s<sup>-1</sup>. At the FAST site a 3 cm s<sup>-1</sup> velocity was  
 used as this value is better adapted for lithogenic particles (Izquierdo et al., 2012).

460 In the rain samples, collected onboard the ship, NO<sub>3</sub>, NH<sub>4</sub> and dissolved inorganic  
 phosphorus (DIP) were also determined using ion chromatography following recovery of the  
 dissolved fraction in the samples. The wet deposition fluxes of these nutrients were then  
 estimated from the measured concentrations in the dissolved fractions from the rain samples,  
 multiplied by total precipitation. Total precipitation was taken from the total hourly  
 precipitation accumulated during the rain event over the region from the ERA5 hourly data  
 465 reanalysis (Hersbach et al., 2018). Total precipitation was obtained by adding the hourly  
 rainfall onto the grid-points (0.25° x 0.25°) spanning the ship location, more or less 1° around  
 this central grid-point for integrating the regional variability (Table 3). In the rain samples,  
 total particulate P (TPP) and dissolved organic P (DOP) were also available. The dissolved  
 fraction and solution from digestion (Heimbürger et al., 2012) of particulate fractions in the  
 470 filters were analysed by ICP-AES (Inductively Coupled Plasma Atomic Emission  
 Spectrometry, Spectro ARCOS Ametek®) for total particulate TPP. The speciation  
 organic/inorganic of TDP was determined from ICP-MS and IC analysis. DOP was estimated  
 from the difference between TDP, obtained by ICP-MS, and DIP, obtained by ion  
 chromatography.

Seawater samples for standard nutrient analysis were filtered online (< 0.2 µm, Sartorius Sartrobran-P-capsule with a 0.45 µm prefilter and a 0.2 µm final filter) directly from the GoFLo bottles (TMC-rosette). Samples collected in acid-washed polyethylene bottles were immediately analyzed on board. Micromolar nitrate + nitrite (NO<sub>x</sub>) and DIP were determined using a segmented flow analyzer (AAIII HR SealAnalytical©) following Aminot and K rouel (2007) with a limit of quantification of 0.050 µM for NO<sub>x</sub> and 0.020 µM for DIP. Samples for the determination of nanomolar concentrations of dissolved nutrients were collected in HDPE bottles previously cleaned with supra-pure HCl. For NO<sub>x</sub> (considered as NO<sub>3</sub> as nitrite fraction was mostly negligible), samples were acidified to pH 1 inside the clean van and analyzed back in the laboratory using a spectrometric method in the visible (540 nm), with a 1 m LWCC (Louis et al., 2015). The limit of detection was 6 nM, the limit of quantification was 9 nM and the reproducibility was 8.5%. DIP was analyzed immediately after sampling using the LWCC method after Pulido-Villena et al. (2010), with a limit of detection of 1 nM (Pulido-Villena et al., 2021). Total dissolved phosphorus (TDP) and nitrogen (TDN) were measured using the segmented flow analyzer technique after high-temperature (120  C) persulfate wet oxidation mineralization (Pujo-Pay and Raimbault, 1994). DOP (DON) was obtained as the difference between TDP (TDN) and DIP (NO<sub>x</sub>). Labile DOP (L-DOP) was determined as 31% DOP (Pulido-Villena et al., this issue, in prep.). Total hydrolysable amino acids (TAAs) were determined as described in detail in Van Wambeke et al. (2021). Briefly 1 ml of sample was hydrolyzed at 100 C for 20 h with 1 ml of 30% HCl and then neutralized by acid evaporation. Samples were analyzed by high performance liquid chromatography in duplicate according to Dittmar et al. (2009) protocols.

### 545 2.2.3 Biological stocks and fluxes in the epipelagic waters

Flow cytometry was used for the enumeration of autotrophic prokaryotic and eukaryotic cells, heterotrophic prokaryotes (hprok) and heterotrophic nanoflagellates (HNF). Subsamples (4.5 mL) were fixed with glutaraldehyde grade I 25% (1% final concentration), flash frozen and stored at -80  C until analysis. Counts were performed on a FACSCanto II flow cytometer (Becton Dickinson). The separation of different autotrophic populations was based on their scattering and fluorescence signals according to Marie et al. (2000). For the enumeration of hprok (Gasol and Del Giorgio, 2000), cells were stained with SYBR Green I (Invitrogen – Molecular Probes). HNF staining was performed with SYBR Green I as described in

Christaki et al. (2011). All cell abundances were determined from the flow rate, which was calculated with TruCount beads (BD biosciences).

565 Particulate primary production (PP) was determined ~~at~~ 6 layers from the shallow ~~CTD casts~~ (0-250 m) ~~sampled before sun rise~~. Samples were inoculated with <sup>14</sup>C-bicarbonate and incubated in on-deck incubators refrigerated ~~using~~ running surface seawater and equipped with various blue screens to simulate different irradiance levels. After ~~24 h~~-incubations, samples were filtered through 0.2 polycarbonate filters and treated for liquid scintillation measurement as described in detail in Marañón et al. (2021). A temperature correction was applied as explained in Marañón et al. (2021). N<sub>2</sub> fixation rates (N<sub>2</sub>fix) were determined as described in Ridame et al. (2011) using 2.3 L of unfiltered seawater (acid-washed polycarbonate bottles) enriched with <sup>15</sup>N<sub>2</sub> gas (99 atom% <sup>15</sup>N) to obtain a final enrichment of about 10 atom% excess. ~~24 h~~-incubations for N<sub>2</sub>fix were conducted under the same temperature and irradiance as the corresponding PP incubations.

570

575

To calculate heterotrophic prokaryotic production (BP) epipelagic layers (0-250 m) were incubated with tritiated leucine using the microcentrifuge technique as detailed in Van Wambeke et al. (2021). We used the empirical conversion factor of 1.5 ng C per pmol of incorporated leucine according to Kirchman (1993). Indeed, isotope dilution was negligible under these saturating concentrations as ~~periodically~~ checked with concentration kinetics. As we ~~only~~ used ~~2~~ ~~on board~~ temperature controlled dark-incubators, a temperature correction was applied as explained in Van Wambeke et al. (2021). Ectoenzymatic activities were measured fluorometrically, using ~~the~~ fluorogenic model substrates that were L-leucine-7-amido-4-methyl-coumarin (Leu-MCA) and 4-methylumbelliferyl-phosphate (MUF-P) to track aminopeptidase (LAP) activity and alkaline phosphatase (AP) activity respectively, ~~as~~ described in Van Wambeke et al. (2021). Briefly the release of MCA from Leu-MCA and MUF from MUF-P were followed by measuring ~~the~~ increase of fluorescence in the dark (exc/em 380/440 nm for MCA and 365/450 nm for MUF, wavelength width 5 nm) in a VARIOSCAN LUX microplate reader. Fluorogenic substrates were added at varying concentrations in 2 ml wells (0.025, 0.05, 0.1, 0.25, 0.5 and 1 μM) in duplicate. From ~~the~~ varying velocities obtained, we determined the parameters ~~V<sub>m</sub>~~ (maximum hydrolysis velocity) and K<sub>m</sub> (Michaelis-Menten constant that reflects enzyme affinity for the substrate) ~~as well as their corresponding errors~~ by fitting the data using a non-linear regression ~~using~~ the following equation:

$$V = V_m \times S / (K_m + S)$$

where V is the hydrolysis rate and S the fluorogenic substrate concentration added. TAA and

L-DOP were then used as substrates to determine LAP and AP *in situ* activities using Michaelis-Menten equations (Van Wambeke et al., 2021, Pulido-Villena et al., 2021).

### 2.3. Vertical partition of the epipelagic layer

The ML can be in a state of stirring and the density and seawater properties are homogeneous, or in a state of rest with homogeneous density but it is the vertical variations in the non-conservative components (such as nutrients); dependent on momentum and heat fluxes at the interface with the atmosphere, that determine the strength and vertical extent of the mixing (Brainerd and Gregg, 1995). In this study, with the absence of concomitant turbulence measurements, the mixed layer depth (MLD) was estimated indirectly using the shape of CTD profiles. Classical methods to evaluate MLD from CTD profiles are based on thresholds of the vertical density gap (de Boyer Montegut et al., 2004; D'Ortenzio et al., 2005) or on the vertical extension of fixed buoyancy content (Moutin and Prieur, 2012). As discussed in Gardner et al. (1995), the choice of criterion is sensitive to the subtle changes from active mixing to rest, with consequences for the representative time scales of the MLD estimates. In this study, the ML was shallow (10 - 20 m), rapidly activated by the mechanical effects of the wind, and sampled at high frequency (some hours at long duration stations). An approach based on buoyancy criterion has been preferred to resolve short term fluctuations in the mixing state, and MLD was determined as the depth where the residual mass content is equal to  $1 \text{ kg m}^{-2}$ , with an error of estimation of 0.5 m relative to the vertical resolution of the profile (1 m).

In the current case of a shallow ML in such a LNLC system, the nutrient depleted layer comprises the ML and the layer below, referred to hereafter as 'NDLb' (b for bottom or base) when examining the NO<sub>3</sub> distribution and as PDLb when considering the DIP distributions.

This layer vertically extends between the MLD and the nitracline (phosphacline) depth (Fig. 2). The latter interface is estimated by the depth of the NO<sub>3</sub> (DIP) depletion density, which is the deepest isopycnal at which micromolar NO<sub>3</sub> (DIP) is zero (Kamykowski and Zentara, 1985; Omand and Mahadevan, 2015). The NO<sub>3</sub> (DIP) depletion density is estimated at every discrete profile of micromolar NO<sub>3</sub> (DIP) concentration, by the intercept of the regression line reported in a nutrient-density diagram.

Supprimé: 2.3 Enrichment experiments¶

At the three long duration sites, enrichment experiments were performed using seawater from 5 m depth to assess factors limiting BP in the surface mixed layer. The date of sampling for these experiments [FAST (June 2, 22:00), TYR (May 16, 20:00) and ION (May 25, 20:00)] was before the rain event occurring at FAST and at ION. Eight series of triplicate 60 mL polycarbonate bottles were filled with unfiltered seawater and amended as follows: C : no enrichment, N: +1 μM NO<sub>3</sub> + 1 μM NH<sub>4</sub>; P: + 0.2 μM DIP; G: + 10 μM C-glucose; NP: N + P; NG: N + G; PG: P + G; NPG: N + P + G. After 48 h incubation in the dark at *in situ* temperature, BP was determined in the 24 bottles (as described in previous section).¶

There are various mechanisms, dynamical or biological, that can trigger exchanges of nutrients between the ML and NDlb (PDLb). Using the hypothesis of vertical (one-dimensional) regimes, there are two processes of exchange, by diffusion or advection (Du et al., 2017). The flux of nutrient can be expressed as:

$$F_{NO_3} = F_{DIF} + F_{ADV}$$

The diffusive flux  $F_{DIF}$  is expressed by the gradient of nutrient concentration times a vertical diffusivity coefficient  $K_z$  as:

$$F_{DIF} = K_z \times \nabla_z (NO_{3ML} - NO_{3NDLb}) / MLD$$

The typical magnitude of  $K_z$  in the surface layers of the PEACETIME stations is assessed to be  $10^{-5} \text{ m}^2 \text{ s}^{-1}$ , as discussed in Taillandier et al. (2020).

The advective flux  $F_{ADV}$  corresponds either to the entrainment of deeper water in the mixed layer due to erosion of the near-surface pycnocline, or to the detrainment of waters below the mixed layer by restratification, depending on the variations in wind stresses and solar heating (Cullen et al., 2002). It is expressed as the variation in the nutrient concentration across the

ML times the temporal variation of the MLD, as:

$$F_{ADV} = (NO_{3ML} - NO_{3NDLb}) \times dMLD / dt$$

A shallow ML (10 - 20 m) is primarily influenced by wind bursts that lead to intermittent variations of several meters per day ( $10^{-5} \text{ m s}^{-1}$ ) in the MLD. These advective fluxes provide transient exchanges that are one order of magnitude greater than well-established diffusive fluxes. As a consequence, over the time scale of a significant atmospheric deposition, and the associated rapid variations of the MLD, the input of atmospheric nutrients would preferentially be exported below the ML by advection rather than by diffusion. In other terms, using the hypothesis of non-stationary regimes due to rapid changes in atmospheric conditions (that control both the mixing state of the interface and atmospheric nutrient inputs), we assume that vertical advection is the main process of exchange.

At the short stations and sites, the term  $NO_{3ML} - NO_{3NDLb}$  can be inferred by the difference between mean nanomolar (LWCC) concentrations inside the NDlb and the mean inside the ML. Since advective flux estimates require knowledge of the evolution of the MLD over time, such fluxes are only accessible at the sites. At short stations, as advective fluxes could not be characterized, only a qualitative assessment of nutrient fluxes across ML is given. When  $NO_{3ML} - NO_{3NDLb} < 0$ , the NDlb is supplied with nutrients across the nutricline, and could be then possibly transferred into the ML. This means that nutrients within the ML are impacted by inputs from below. When  $NO_{3ML} - NO_{3NDLb} > 0$ , the ML is supplied in nutrients

#### 2.4 Budget from the metabolic fluxes

775 Trapezoidal integration was used to integrate BP, PP and N2fix within the ML. The biological activity at ~~the~~ surface was considered ~~to be~~ equal to that of the first layer sampled (around 5 m depth at the short stations, 1 m depth at the FAST site). When the MLD was not sampled, the volumetric activity at this depth was linearly interpolated between ~~the 2~~ closest data ~~points~~ above and below the MLD.

780 We used an approach similar to Hoppe et al. (1993) to compute ~~the~~ *in situ* hydrolysis rates for LAP and AP. We assumed that total amino acids (TAA) could be representative of dissolved proteins. *In situ* hydrolysis rates of LAP and AP were determined using molar concentrations of TAA and L-DOP, respectively ~~and~~ used as ~~the~~ substrate concentration in the Michaelis-Menten kinetics. For LAP, the transformation of *in situ* rates expressed in nmol TAA hydrolyzed L<sup>-1</sup> h<sup>-1</sup> were then transformed ~~into~~ nitrogen units using N per mole TAA, as the molar distributions of TAA were available. Integrated *in situ* LAP hydrolysis rates were

Supprimé: s

785 calculated assuming the Michaelis-Menten parameters Vm and Km obtained at ~~a~~ 5 m depth to be representative of the whole ML. ~~Thus~~ an average *in situ* volumetric LAP flux in ~~the~~ ML was obtained by combining ~~the~~ average TAA concentrations in the ML with these kinetic parameters, and ~~multiplying~~ this volumetric rate ~~by~~ the MLD. Daily BP, AP and LAP integrated activities were calculated from hourly rates x 24. Assuming no direct excretion of

790 either nitrogen or phosphorus, the quota C/N and C/P of cell demand is equivalent to ~~the~~ cell biomass quotas. We used ~~molar~~ C/N ratios derived from Moreno and Martiny (2018) (range 6-8, mean 7) for phytoplankton and from Nagata et al. (1986) for heterotrophic prokaryotes (range 6.2-8.4, mean 7.3). C/P of sorted cells (cyanobacteria, picophytoeukaryotes) in P depleted conditions ranged ~~from~~ 107 to 161 (Martiny et al., 2013), and we considered a mean of 130 for phytoplankton. A value of 100 was used for heterotrophic prokaryotes (Godwin and Cotner, 2015).

Supprimé: 1

### 3. Results

### 3.1 Nutrient patterns and biological fluxes along the PEACETIME transect

815 The ML ranged between 7 m at ST9 and 21 m at ST1 (Table S1, Fig. 3). The nitracline was shallow in the Provençal Basin (50 – 60 m), dropping to 70 m in the Eastern Algerian and Tyrrhenian Seas; becoming deeper in the Western Algerian and Ionian Seas (80 - 90 m, Table S1). Mean NO<sub>3</sub> concentrations in the NDLb ranged from the quantification limit (9 nM) to 116 nM (Table S1, Fig. 4). In the ML, mean NO<sub>3</sub> concentrations ranged from 9 to 135 nM.

820 For the 'group 1' stations (see Table S1), the NO<sub>3</sub> concentrations were low (below 50 nM) within both the ML and the NDLb, with weak differences precluding any gradient between the two layers. For the 'group 2' stations, NO<sub>3</sub> concentrations were moderate (50 - 80 nM) both within the ML and the NDLb but still exhibiting a small difference between the two layers, indicating again no significant instantaneous exchanges. For 'group 3', higher NO<sub>3</sub> concentrations were measured in both the ML and the NDLb (> 80 nM) but the small positive differences (< 20 nM) between the two layers still indicate weak or negligible exchanges between the two layers. For 'group 4', high and moderate NO<sub>3</sub> concentrations were measured within the ML and NDLb, respectively, with a large positive difference (> 20 nM) between the layers. This indicates the presence of a gradient from the ML to the NDLb.

825 At 5 m depth, VmLAP ranged from 0.21 to 0.56 nmol MCA-leu hydrolyzed l<sup>-1</sup> h<sup>-1</sup>, and Km LAP ranged from 0.12 to 1.29 μM. The mean TAA within the ML ranged from 0.17 to 0.28 μM. From these 3 series of parameters, we derived the mean *in situ* LAP hydrolysis rate within the ML, which ranged from 0.07 to 0.29 nmol N l<sup>-1</sup> h<sup>-1</sup> (results not shown but detailed in Van Wambeke et al., 2021).

830 The vertical distribution of PP and BP for the short stations are described in Marañon et al. (2021). Briefly, PP exhibited a deep maximum close to the DCM depth or slightly above whereas vertical distribution of BP generally showed 2 maxima, one within the mixed layer, and a second close to the DCM. Integrated PP (Table 1, Table S2) ranged from 138 (TYR17 May) to 284 (SD1) mg C m<sup>-2</sup> d<sup>-1</sup>. Integrated BP (0-200 m) ranged from 44 (ION27may) to 113 (FAST+0.53) mg C m<sup>-2</sup> d<sup>-1</sup>. Overall, in absence of a rain event the Mediterranean Sea, at the time of the PEACETIME cruise, the transect exhibited the classical west-east gradient of increasing oligotrophy detected by ocean colour (see Fig. 8 in Guieu et al., 2020).

### 3.2 N budgets and fluxes at short stations

845 Biological rates (all expressed in N units) within the ML at the short stations were compared (Table 2). Phytoplankton N demand (phytoN demand) was the greatest rate, followed by

heterotrophic prokaryotic N demand (hprokN demand). On average, phytoN demand was 2.9 times greater than that of hprokN, but with a large variability (min x1.5, max x8.1). LAP hydrolysis rates represented between 14 and 66 % of the hprokN demand (mean ± sd : 37% ± 19%), N<sub>2</sub> fixation rates represented between 1 to 4.5% of the phytoN demand (2.6% ± 1.3%) and 3 to 11% of the hprok N demand (6.4% ± 2.4%). N<sub>2</sub> fixation rates integrated over the ML correlated slightly better with hprokN demand (r = 0.75) than with phytoN demand (r = 0.66). Dissolved inorganic N (DIN=NO<sub>3</sub>+NH<sub>4</sub>) solubilized from dry atmospheric deposition ranged from 17 to 40 μmol N m<sup>-2</sup> d<sup>-1</sup>, with on average 79% of this being NO<sub>3</sub> (Table 2). This new DIN input was similar or higher than N<sub>2</sub> fixation rates within the ML (from x1.3 to x11, mean x 4.8-fold). On average within the ML, the new DIN from dry deposition represented 27% of the hprokN demand (range 10-82%) and 11% of the phytoN demand (range 1-30%).

**3.3 Biogeochemical evolution at the ION site**

The ION site was occupied from the 25<sup>th</sup> to the 29<sup>th</sup> of May. Rain events in the vicinity of the ship were observed on May 26<sup>th</sup> and May 29<sup>th</sup> (Desboeufs et al., this issue, in prep). On the 29<sup>th</sup> of May the rain event was associated with a rain front covering more than 5 000 km<sup>2</sup>. A rain sample could be taken on board between 5:08 and 6:00 (local time), i.e. just 3 hours before the last CTD cast. The chemical composition of the rain indicated an anthropogenic background influence (Desboeufs et al., this issue, in prep.). TDP solubilized from dry atmospheric deposition decreased from 268 nmol P m<sup>-2</sup> d<sup>-1</sup> May 25<sup>th</sup>-26<sup>th</sup> to 124 nmol P m<sup>-2</sup> d<sup>-1</sup> May 27<sup>th</sup>-28<sup>th</sup>). DIN fluxes from dry atmospheric deposition were on average 29 ± 4 μmol N m<sup>-2</sup> d<sup>-1</sup> with no significant difference during the occupation of the site (Table S2). In the rain, the molar ratio DIN/DIP was 208. DOP in the collected rain was also an important source (60%) of the total dissolved P from that wet deposition (Table 3). CTD casts, dedicated to biogeochemical studies, were taken each 24 h for biological fluxes or 48 h for DIP and NO<sub>3</sub>. Thus the time sequence for nutrients in the water column at ION is given for only by three profiles. The first profile (25<sup>th</sup> of May before rain events in the area) is 'flat', corresponding to fair weather conditions and a shallow ML with low and homogeneous concentrations of NO<sub>3</sub> in the ML and the NDLb (Fig. 4). Shortly after, there was an atmospheric depression some events of rain were observed in the area on May 26<sup>th</sup> but not on board, and the ML started to deepen 13 h before the second cast sampling nutrients (on the

1120 ~~27<sup>th</sup> of May~~. This cast was marked by high nitrate in the ML (Fig. 3). The mixing should have set up a homogeneous ML, but wind conditions rose ~~to~~ 20 kt just at the time of the cast (Fig. 3). The interval ~~between the second and~~ the third cast ~~sampling nutrients~~ (29<sup>th</sup> of May, ~~cast done~~ 3 hours after the rain ~~sampled on board~~) is marked by a slight relaxation of weather depression, and a deepening of the ML down to 20 m. ~~This cast was marked by a~~ NO<sub>3</sub> decrease in both the ML and ND**L**, but values were higher in ML. Given the remaining signature at 15 m and the deepening of the ML, the two layers might have stayed isolated.

1125 However, the calculation of vertical advective fluxes between the layers showed a downward flux in the first interval 25-27 May (Fig. 4, Table S1) and an upward flux in the second interval (27-29 May).

1130 Due to the lack of high frequency sampling, it was also particularly difficult to assess the direct time evolution effects of dry atmospheric deposition at the ION site. Nevertheless, it was clear from the casts sampled on the 27<sup>th</sup> and 29<sup>th</sup> of May that this site was characteristic of group 4 (i.e. higher NO<sub>3</sub> concentrations in the ML than in the ND**L**), indicating recent inputs from the atmosphere. ~~E~~ctoenzymatic activities were only sampled on the 25<sup>th</sup> of May. V<sub>m</sub> of LAP at 5 m (0.22 nmol N l<sup>-1</sup> h<sup>-1</sup>) was one of the lowest values recorded during the cruise ~~whilst~~ V<sub>m</sub> of AP showed the highest value (5.6 nmol P l<sup>-1</sup> h<sup>-1</sup>). PP integrated over the euphotic zone increased slightly from ~~188~~ to ~~226~~ mg C m<sup>-2</sup> d<sup>-1</sup> (Table S2), but due to changes in the MLD ~~at~~ the ION site (range 11-21 m) this trend was not visible when integrating PP over the ML. Integrated over the ML, BP increased slightly, from 7.5 to 10.3 mg C m<sup>-2</sup> d<sup>-1</sup> between the 25<sup>th</sup> and the 29<sup>th</sup> of May, ~~and indicated that hprok benefited more from the atmospheric inputs than the autotrophs as PP decreased at 5m depth (Fig. S1, Table S2)~~. The profiles of hprok and *Synechococcus* abundances showed no particular trend with time, with higher variations within the DCM (Fig. S1).

### 3.4 N budgets and fluxes at the FAST site

1145 During the ~~time at the FAST site~~, two periods of rains occurred: the evening of June 2nd-3rd and the early morning of the 5th (Tovar-Sanchez et al., 2020). On a spatial scale, the rain radar data indicated the presence of a rain front with patchy, numerous and intense rain events occurring over a large area surrounding the ship's location. These two episodes were concomitant with a dust plume transported in altitude (between 1 and 4 km) and resulted in wet deposition of dust (Desboeufs et al., this issue, in prep.). The second rain event was

1150 ~~sampled on board on June 5th (between 02:36 and 03:04, local time) and was associated with~~

a dust wet deposition flux  $\sim 40 \text{ mg m}^{-2}$ . The DIN/DIP ratio in the rain reached 480 (Table 3). After the rain, daily fluxes of DIN solubilized from dry aerosol deposition strongly decreased from  $45$  to  $9.8 \text{ } \mu\text{mol N m}^{-2} \text{ d}^{-1}$  between June 4th and 5th.

1250

The beginning of the sampling at FAST site (-2.3; -1.5; -0.25) was marked by moderate and similar decreases in  $\text{NO}_3$  concentration within the ML and NDLe. Integrated stocks of  $\text{NO}_3$  within the ML (Table S2) reflected slight changes with MLD (from 14 to 10 m during this time interval).

1255

On June 5th, the rain event (Table 3) was associated with a strong wind burst and an abrupt mixing. The comparison between  $\text{NO}_3$  concentrations from two casts, sampled 6 h before and 6 h after the rain (FAST-0.25 and FAST+0.24), showed a clear N enrichment of the ML as mean  $\text{NO}_3$  increased from 56 to 93 nM and  $\text{NO}_3$  integrated stocks increased by  $888 \text{ } \mu\text{mol N m}^{-2}$  (Fig. 3, Table S2). There was also clear difference in the mean  $\text{NO}_3$  concentrations

1260

between ML and NDLe ( $93 \pm 15$  vs  $51 \pm 7$  nM, respectively). This is the highest  $\text{NO}_3$  difference observed during the cruise between these 2 layers (Fig. 4), confirming that this ML enrichment could not be attributed to inputs from below. The relaxation of this wind burst was progressive, with a continuous deepening of the ML (Table S1). The export of the atmospheric  $\text{NO}_3$  into the NDLe was maximal after the rain event (FAST+0.24). At the end of the site occupation period (FAST+3.8) high  $\text{NO}_3$  concentrations (mean 135 nM) were measured again within the ML.

1265

DIP concentration dynamics were different from  $\text{NO}_3$  with the DIP integrated fluxes within the ML, similar 6 h before and 6 h after the rain ( $136 \text{ } \mu\text{mol m}^{-2}$ ). It is only from then on, that DIP flux progressively increased reaching a maximum ( $281 \text{ } \mu\text{mol P m}^{-2}$ ) one day after the rain (FAST+1).

1270

Immediately after the rain, integrated PP (euphotic zone) decreased from  $274 \text{ mg C m}^{-2} \text{ d}^{-1}$  (FAST-0.9) to  $164 \text{ mg C m}^{-2} \text{ d}^{-1}$  (FAST+0.07) and continued to decrease the following day. It is only 3.8 days after the rain that the initial values (before the rain) of integrated PP could be observed again (Table S2). Such variations were mostly due to changes in volumetric rates

1275

within the DCM depth (Fig. S2), as the activity did not change significantly within the ML ( $28\text{-}33 \text{ mg C m}^{-2} \text{ d}^{-1}$ , Fig. S2, Fig. 5). Integrated BP over 0-200 m showed the opposite trend to that of PP, and tended to increase after the rain (from  $86 \pm 3 \text{ mg C m}^{-2} \text{ d}^{-1}$  ( $n = 4$ ) before, and up to  $113 \text{ mg C m}^{-2} \text{ d}^{-1}$  (FAST+0.5) after (Table S2)). Although modest, this increasing trend was also visible when integrating BP only over the ML (12-15 before; 15-19  $\text{mg C m}^{-2} \text{ d}^{-1}$

**Supprimé:**  $\text{NO}_3$  concentration in the ML showed a progressive enrichment with a maximum few hours after the rain event and a smooth decline until the initial conditions were restored 2.3 days after the rain (Fig. 3). Afterwards, the nutrient dynamics was not consistent with this evolution as shown by the high concentrations measured at FAST+3.8. The same analysis can be drawn with respect to exchanges across the ML (Fig. 4, Table S1):  $\text{NO}_3$  flux remained low until the rain event, and then a large advective flux is estimated relative to the enrichment of ML and the quick deepening of the ML, this flux declined during the relaxation to initial conditions.¶

Concerning atmospheric wet deposition, the rain event collected on board at FAST lasted 28 min (Table 3). Like for the rain sampled at ION site, DIN flux was much higher than DIP flux, with molar N/P inorganic ratio of 1439, and the percentage of DOP represented 44% of total dissolved P deposition. The chemical composition indicates that the rain sample collected at FAST site was characteristic of a wet dust deposition (Fu et al., this issue, in prep. b) corresponding to a dust deposition of  $12 \text{ mg m}^{-2}$ . This is among the least intense dust deposition fluxes recorded in this area from a long time-series of deposition (Vincent et al., 2016). During FAST site occupation, two periods of rains occurred related to rain fronts (affecting a domain of  $\sim 5000 \text{ km}^2$ ) moving eastward from Spain and North Africa regions: between the evening of June 3 until 5 in the early morning (Desboeufs et al., this issue, in prep.). These two episodes were concomitant with a dust plume transported in altitude (between 1 and 4 km), covering the half of western Mediterranean basin during June 4, and allowed below-cloud deposition of dust (as confirmed by LIDAR records, Desboeufs et al., this issue, in prep.). The rain event collected at FAST site occurred on board after a first night of wet deposition over the whole area and toward the end of the transport of the dust plume. The particulate flux of this collected rain sample was thus likely in the lower range of the wet dust deposition fluxes that had affected the whole area between 3 and 5 June. Indeed, the *in situ* measurements of a dust tracer in the water column (particulate aluminum) show that the total export of particulate matter was rather of the order of  $\sim 55 \text{ mg m}^{-2}$  during the period instead of  $12 \text{ mg m}^{-2}$  as seen in a single collected rain event, and even this value is probably underestimated due to the lack of sampling big dust particles sinking (Bressac et al., this issue, in prep.). After the rain, average daily dry DIN deposition decreased from  $45 \text{ } \mu\text{mol}$  (...)

1565 after). The abundances of picophytoplankton groups were mostly varying in the vicinity of the  
DCM depth with peaks occurring 1-2 days after the rain (grey profiles, Fig S3), in particular  
for prokaryotes (*Prochlorococcus*, *Synechococcus*). Heterotrophic prokaryotes and  
nanoflagellate abundances slightly increased within the DCM depth after the rain.

#### 1570 4. Discussion

The specific context of the oceanographic survey constrained the data analysis:  
biogeochemical responses to a rain event have been scaled in time over a few days (3 - 5), and  
in space spanning tens of km (40 - 50). Their evolution was restricted to the vertical  
1575 dimension, integrating lateral exchanges by horizontal diffusion or local advection that  
occurred over the prescribed space and time scales. In the vertical dimension, exchanges of  
nutrients across the ML were controlled by advection due to rapidly changing conditions  
(MLD fluctuations along with nutrient inputs from the atmosphere) rather than to diffusion  
between stationary pools. Four groups of stations, corresponding to different stages of ML  
enrichment and relaxation, due to the nutrient inputs from single rain events, have been  
1580 characterized based on the differences in NO3 concentration between ML and NDlb (see  
section 2.4). As shown in Fig. 4, this succession of stages is in agreement with the NO3 fluxes  
from above and below the ML. Moreover, they provide a temporal scaling of the oceanic  
response to atmospheric deposition, with a quasi-instantaneous change at the time of the rain  
event and a 2-day relaxation period to recover to pre-event conditions

1585 In this context, we will i) discuss the nitrogen budget within the ML at the short stations  
considered as a 'snapshot', and ii) analyze in detail, using a time series of CTD casts, the  
biogeochemical changes within the ML and the NDlb following the atmospheric wet  
deposition event at the FAST site, discussing the possible modes of transfer of nutrients  
1590 between these 2 layers.

#### 4.1 A snapshot of biological fluxes in the ML and their link to new DIN from atmospheric dry deposition

1595 The dependence of hprok on nutrients rather than on labile organic carbon during  
stratification conditions is not uncommon in the MS (Van Wambeke et al., 2002, C ea et al,  
2017; Sala et al., 2002) and has also been shown during PEACETIME cruise (P, or N,P  
colimitation, Fig. S4). Hprok have an advantage due to their small cell size, and their kinetic

3.5 Enrichment experiments at long stations¶  
At TYR site, BP was significantly stimulated only after addition of 2 major elements, with a greater response with PN and NPG combinations (Fig. 6). At ION site, BP was primarily limited by P availability, as only combinations with P, single or in combination with other elements, stimulated BP whereas all other combinations of enrichment did not stimulate BP significantly compared to the control. At FAST site, BP was primarily limited by N availability, as all combinations with N, single or in combination with other elements, stimulated BP. However at this site it is likely that BP was also co-limited by 2 elements, as G addition alone also stimulated BP. Note that the PN combination has induced a higher stimulation of BP than other double combinations (NG or PG).¶

Supprim : In this study, *in-situ* characterization of the biogeochemical response to atmospheric deposition was studied for the surface mixed layer (ML) at the interface with the atmosphere.

1805 We considered hprokN demand together with phytoN demand and compared it to autochthonous (DON breakdown by ectoenzymatic activity) and allochthonous (~~atmospheric deposition~~) sources. ~~To the best of~~ our knowledge this is the first time that these fluxes ~~are~~ compared based on their simultaneous measurements ~~at sea~~. A high variability was observed ~~between~~ the 10 short stations (Table 2). The regeneration of nitrogen through aminopeptidase activity was clearly the ~~primary~~ provider of N to hprok ~~as~~ 14 to 66% ~~(mean ± sd : 37% ± 19%)~~ of the hprokN demand could be satisfied by *in situ* LAP activity. Such percentages may be largely biased by the conversion factors from C to N and propagation of errors for the LAP hydrolysis rates and BP rates. However, the C/N ratio of hprok is relatively narrow under large variations of P or N limitation (6.2 to 8.4; Nagata, 1986).

1815 Other regeneration sources exist ~~such as~~ direct excretion of NH<sub>4</sub> or low molecular weight DON sources with no necessity ~~for~~ hydrolysis prior to uptake (Jumars et al., 1989). For instance, Feliú et al. (2020) calculated that NH<sub>4</sub> and DIP excretion by zooplankton would satisfy 25-43% ~~of the~~ phytoN demand and ~~22-37% of the~~ phytoP demand ~~over the whole euphotic zone~~. Such percentages suggest that direct excretion by zooplankton ~~along with~~ ectoenzymatic activity, ~~provide~~ ~~substantial~~ N for biological activity.

1820 N<sub>2</sub> fixation ~~is also a source of new N that can~~ ~~directly~~ fuel hprok ~~as~~ some ~~diazotrophs~~ are heterotrophic (Delmont et al. 2018, and references therein), or indirectly, as part of the fixed N<sub>2</sub> ~~that~~ rapidly cycles through hprok (Caffin et al., 2018). Furthermore, ~~it has been observed~~ ~~that there is~~ a better coupling of N<sub>2</sub>fix rates with BP rather than with PP ~~in~~ the eastern MS (Rahav et al., 2013b). ~~This was also observed within the ML in this study. Our data sho that~~ ~~the~~ hypothetical contribution of N<sub>2</sub>fix rates to hprokN demand ~~within the ML~~ was low ~~(6.4 ± 2.4%)~~ ~~and~~ consistent with the low N<sub>2</sub>fix rates observed in the MS (i.e. Rahav et al., 2013a;

1865 Ibello et al., 2010; Ridame et al., 2011; Bonnet et al., 2011). This differs from other parts of the ocean, primarily limited by N but not P, such as the south eastern Pacific where N<sub>2</sub> fixation rates are high (Bonnet et al., 2017) and can represent up to 81 % of the hprokN demand (Van Wambeke et al., 2018).

1870 Considering LAP as the most relevant regeneration source of N, it is clear that even the sum of LAP activity and N<sub>2</sub> fixation were not sufficient to meet hprokN demand (cumulated, these fluxes contributed 19 to 73% of HbactN demand). The last source of new N we examined was DIN released by dry atmospheric deposition. Such DIN fluxes presented a low variability along the transect (29 ± 7 μmol N m<sup>-2</sup> d<sup>-1</sup> at the short stations) and were among the lowest measured in the Mediterranean environment, which normally ranges from 38 to 240 μmol N m<sup>-2</sup> d<sup>-1</sup> (Desboeufs et al., in press). It has to be noted that the fluxes measured during the PEACETIME cruise are representative of the open sea atmosphere while published fluxes

1875 were measured at coastal sites where local/regional contamination contributes significantly to the flux (Desboeufs, in press). Atmospheric deposition also delivers organic matter (Djaoudi et al., 2017, Kanakidou et al., 2018), which is bioavailable for marine hprok (Djaoudi et al., 2020). Dissolved organic nitrogen (DON) released from aerosols, not determined here, can be estimated from previous studies. DON solubilized from aerosols contributes 19 to 42% of the total dissolved N released from dry deposition in the MS (Desboeufs, in press), with an average of 32%. Considering this mean, DON released from dry deposition was estimated to range from 8 to 19 μmol N m<sup>-2</sup> d<sup>-1</sup> at the short duration stations. The total dissolved N solubilized from dry deposition (inorganic measured + organic estimated) would thus represent 14 to 121% of the hprokN demand. Because of the low variability in DIN (and

1885 estimated DON) fluxes derived from dry deposition, the atmospheric contribution was mainly driven by biogeochemical conditions and not by the variability of atmospheric fluxes during the cruise (CV of Nprok Ndemand and phyto N demand at the short stations were 45% and 89%, respectively, and that of DIN flux 25%). However, the calculated contribution can also be biased by the deposition velocity used to calculate DIN solubilized from the dry deposition. Deposition velocity was set at 1 cm sec<sup>-1</sup> for NO<sub>3</sub> and 0.21 cm sec<sup>-1</sup> for NH<sub>4</sub>. As NO<sub>3</sub> was the dominant inorganic form released by dry deposition, it is clear that the choice of 1 cm sec<sup>-1</sup> for NO<sub>3</sub> influenced its contribution. This choice was conditioned by the

1895 predominance of NO<sub>3</sub> in the large mode of Mediterranean aerosols such as dust or sea salt particles (e.g., Bardouki et al., 2003). However, the deposition velocity of NO<sub>3</sub> between fine and large particles could range from 0.6 to 2 cm sec<sup>-1</sup> in the Mediterranean aerosols (e.g.

1955 Sandroni et al., 2007). Even considering the lower value of  $0.6 \text{ cm sec}^{-1}$  from the literature, the contribution of DIN from atmospheric dry deposition to hprokN demand within the ML would still be significant (up to 72%).

#### 4.2 Biogeochemical response after a wet event – N and P budgets at FAST site

1960 Rain events are more erratic than dry atmospheric deposition but represent on average much higher new nutrient fluxes to the MS surface waters on an annual basis, e.g. 84% of annual atmospheric DIN fluxes in Corsica Island (Desboeufs et al., 2018). On the scale of the Mediterranean basin, the annual wet deposition of DIN was found to be 2-8 times higher than DIN from dry deposition (Markaki et al., 2010). Wet deposition also contributes significantly to DON atmospheric fluxes in the MS: For example at Frioul Island (Bay of Marseille, NW MS), total (wet + dry) DON atmospheric fluxes ranged between 7 and 367  $\mu\text{mol DON m}^{-2} \text{ day}^{-1}$  and represented  $41 \pm 14\%$  of the total atmospheric nitrogen flux (Djaoudi et al., 2018). In the Eastern MS (Lampedusa Island) DON atmospheric fluxes ranged between 1.5 and 250  $\mu\text{mol DON m}^{-2} \text{ day}^{-1}$  contributing to 25% of the total atmospheric nitrogen flux, respectively (Galletti et al., 2020). In both studies, bulk atmospheric fluxes of DON were positively correlated with precipitation rates, indicating the preponderance of wet deposition over dry deposition.

1975 At the FAST site, the maximum net variations of NO<sub>3</sub> and DIP concentrations within the ML before/after the rainy period reached  $1520-665 = +855 \mu\text{mol N m}^{-2}$  for NO<sub>3</sub> and  $281-137 = +144 \mu\text{mol P m}^{-2}$  for DIP (Table S2). In other terms, based on a mean MLD of 16 m, the net observed increases in the ML were  $+9 \text{ nM DIP}$  and  $+54 \text{ nM NO}_3$ . As the rain event in the area would have increase by  $0.07 \text{ nM DIP}$  and  $21 \text{ nM NO}_3$  concentrations over the whole mixed layer, the net variations observed in the ML are thus higher than the calculated variation in stocks deduced from the N and P concentrations of this rain event (Table 3). This is still true when including all P or N chemical forms (particulate and soluble inorganic + organic fractions). For example the P concentration in the ML would increase by  $\sim 0.68 \text{ nM}$ . As described in the results section 3.4, the rains affecting the FAST site were spatially patchy over a large area ( $\sim 40-50 \text{ km}$  radius around the R/V). Thus, we could consider that the biogeochemical impacts observed at FAST site were probably due to a suite of atmospheric events rather than due to the single event collected on board. It is possible that meso- and sub-

Supprimé: , and

Supprimé: We examined if the four groups of stations described in results section 3.1 and based on NO<sub>3</sub> distribution were also characterized by particular biological fluxes. Although a large variability of biological activities were observed in the ML among those 4 groups, some trends were depicted. LAP activity in ML was higher at the stations of group 1 (with lowest NO<sub>3</sub> concentration in ML and NDLb), in comparison to the group 4 (which exhibited the larger difference of concentrations between ML and NDLb) ( $121 \pm 54$  compared to  $46 \pm 23 \mu\text{mol N L}^{-1} \text{ d}^{-1}$ , respectively). The stations from group 1 also presented the lowest DIN dry deposition flux ( $26 \pm 6 \mu\text{mol N m}^{-2} \text{ d}^{-1}$ ). Finally, it was always in a station from group 4 that the higher phytoN demand, HbactN demand and N<sub>2</sub>fix rates were detected. Part of the variability obtained among the different groups was also related to the instantaneous character of comparison. Indeed, it is clear that a succession of biogeochemical changes occurs at different time scales during an atmospheric deposition event. Such comparison as a function of time was ...

mesoscale dynamics encountered at FAST site (Figs 5 and 12 in Guieu et al., 2020) can explain such cumulative impact.

2185 Interestingly, a delay of about 19 h was observed in the maximum net accumulation within the ML between DIP (FAST+1.05) and NO<sub>3</sub> (FAST+0.24). The DIN/DIP ratio in the rain (1438) was much higher than the Redfield ratio. As the biological turnover of DIP in the MS is rapid (from min to few h, Talarmin et al., 2015), new DIP from rain might have behaved differently than DIN. Two different mechanisms can explain this delay: (i) processes linked to

2190 bypasses and luxury DIP uptake (storage of surplus P in hprok before a rapid development of grazers (Flaten et al, 2005; Herut et al 2005, Thingstad et al., 2005) that are later responsible for DIP regeneration), so that DIP net accumulation is delayed and/or (ii) abiotic processes such as rapid desorption from large sinking particles followed by adsorption of DIP onto submicronic iron oxides still in suspension as observed experimentally in Louis et al. (2015).

2195 The first proposed mechanism may be supported by the observed increase of BP, along with a stable PP which suggests an immediate benefit of the new nutrients from rain by hprok rather than phytoplankton. The so-called luxury DIP uptake by the competing organisms like hprok is efficient (small cells with high surface/volume ratio and DIP kinetic uptake adapted to low concentrations). It is of course difficult to quantify such in situ variations in comparison to

2200 mesocosms/minicosms dust addition experiments, in which clearly heterotrophy is favoured first (Marañón et al., 2010; Guieu et al., 2014b; Gazeau et al., 2021). Few attempts in the field have confirmed these trends (Herut et al., 2005, Pulido-Villena et al., 2008) but, as stated in the introduction, these studies lacked high frequency sampling.

The second proposed mechanism, the abiotic desorption/adsorption, is compatible with the

2205 observed 19 h delay (Louis et al., 2015). Note that most of the estimates of such abiotic processes are from dust addition experiments with contrasting results, some showing this abiotic process of absorption/desorption while the particles are sinking (Louis et al., 2015), and other not (Carbo et al., 2005) or showing it as negligible in batch experiments (Ridame et al., 2003). It is possible that DIP adsorbed onto large particles rapidly sinks out of the ML,

2210 and desorbs partly during its transit in the PDLb, where it could stay longer thanks to the pycnoclines barriers.

We tentatively made a P budget between FAST+1.05 and FAST+2.11 where a net decrease of DIP (-87 μmol P m<sup>-2</sup>) was observed in the ML. During this time, advective flux of DIP toward the PDLb was not detectable as DIP concentrations within the ML were always lower than

2215 within the PDLb (Pulido-Villena et al., 2021). This indicated that the DIP was assimilated

- Supprimé:
- Supprimé:
- Supprimé: )
- Supprimé: One reason for this discrepancy might be, as developed in section 3.4, that the collected rain sampled on board represented only a fraction of the whole rain episode that affected a large area around the ship. Based on aluminum inventory in the water column (Bressac et al., this issue, in prep.), the total dust deposition having affected the FAST site was 4.6 times higher on the same order (55 mg m<sup>-2</sup>) than than the dust flux measured deducted from our single rain event (12 40 mg m<sup>-2</sup>). It is likely that the deduced new N and P increases within the ML due to the collected rain are well still underestimated. If we consider the above cited factor of 4.655 mg m<sup>-2</sup>, the atmospheric flux could have provided an addition of about 33 29 nM for NO<sub>3</sub> and 0.037 09 nM for DIP (0.35 94 nM total P) in the ML, more in agreement with the marine volumetric variation, at least for NO<sub>3</sub>, and suggesting even that atmospheric nitrate input could alone explain the increase of NO<sub>3</sub> in the ML.¶

2280 and/or transformed to DOP via biological processes, and/or adsorbed onto particles and then  
 exported to PDLb by sedimentation. By integration of PP and BP over this period (34.5 and  
 19.7 mg C m<sup>-2</sup>, respectively) and, by assuming that all the disappearing 87 μmol DIP m<sup>-2</sup>  
 2285 would be consumed by hprok and phytoplankton, we could estimate a C/P ratio reached in  
 their biomass of  $((34.5+19.7)/12 \times 1000)/87=52$ . Such C/P suggests that DIP was not limiting  
 these organisms anymore. Indeed a decrease of C/P quotas may highlight a switch from P to  
 2290 C limitation for heterotrophic bacteria (Godwin and Cotner, 2015) and from P to N limitation  
 or increased growth rates for phytoplankton (Moreno and Martiny, 2018). Furthermore, as  
 DIP is also recycled via alkaline phosphatase within the ML, we also consider another source  
 of DIP via alkaline phosphatase activity, from which *in situ* activity (see Van Wambeke et al.,  
 2295 2021 for *in situ* estimates) could release 139 μmol DIP m<sup>-2</sup> during this period. Assuming also  
 that DIP resulting from of AP hydrolysis was fully assimilated for P biological needs, then  
 2300 C/P ratio would be  $((34.5+19.7)/12 \times 1000)/(87+139)=19$ . This low ratio seems unrealistic  
 for phytoplankton (Moreno and Martigny, 2018) as well as hprok, even growing in surplus C  
 conditions (Makino et al., 2003; Lovdal et al., 2008; Godwin and Cotner, 2015).

2295 Some of the P recycled or brought into the ML from atmospheric deposition has consequently  
been exported below the ML. DIP is abiotically adsorbed on mineral dust particles (Louis et  
 al., 2015), most of them sinking, and thus constitute a source of export out of the ML. It is  
 also possible that such sorbing process on dust particles enables the export of other P-  
 2300 containing organic molecules, for instance DOP or viruses produced following luxury DIP  
 assimilation. Free viruses, richer in P than N relative to Hprok, could adsorb, like DOM, onto  
 dust particles and constitute a P export source. Indeed, free viruses sorb onto black carbon  
 particles, possibly reducing viral infection (Mari et al., 2019; Malits et al., 2015). However,  
 particle quality is a determining factor for DOM or microbial attachment, and what has been  
 shown for black carbon particles is not necessarily true for dust particles. For instance the  
 2305 addition of Saharan dust to marine coastal waters led to a negligible sorption of viruses to  
 particles and increased abundance of free viruses (Pulido-Villena et al., 2014), possibly linked  
 to an enhancement of lytic cycles in the ML after relieving limitation (Pradeep Ram and  
 Sime-Ngando, 2010).

2310 We are aware of all the assumptions made here (i) conversion factors, (ii) *in situ* estimates of  
 alkaline phosphatase, (iii) some missing DIP sources in the budget, such as the excretion of  
 zooplankton estimated to amount to 22-37% of the phytoP demand at FAST site (Feliú et al.,  
 2020), (iv) lack of knowledge on the different mechanisms linking P to dust particles, and (iv)

the hypothesis which considers the station as a 1D system. Nevertheless, all these results together suggest that both luxury consumption by Hprok and export via scavenging on mineral particles probably occurred simultaneously and could explain the observed variations of DIP in the ML.

Supprimé: ing

Supprimé: .

Supprimé: likely

Supprimé: to

Supprimé: opposition

For NO<sub>3</sub>, and in contrast to the observations for DIP, we observed physical exchanges by advection between the ML and NDLb. A N budget within the ML during the period of net NO<sub>3</sub> decrease (between FAST+0.24, and FAST+2.11, Table S2), indicates a net loss of 1343

Supprimé: Indeed, NO<sub>3</sub> was higher within the ML than within the NDLb at FAST+0.24 and FAST+0.53 and then NO<sub>3</sub> was lower within the ML than within NDLb at FAST+1.05 and FAST+2.11, suggesting a rapid transfer of NO<sub>3</sub> in the NDLb.

Supprimé: s for DIP, we made an

μmol N m<sup>-2</sup> within the ML. For this period lasting 1.8 days, the time-integrated phytoN and hprokN demands were 682 μmol N m<sup>-2</sup> and 378 μmol N m<sup>-2</sup>, respectively, so that total

possible source of N amounted to 1443 μmol N m<sup>-2</sup>. Keeping in mind that the same potential caveats pointed to DIP (see above) also apply for the calculation of N budget, the biological N demand appeared lower than the sources (difference ~380 μmol N m<sup>-2</sup>). On the other hand, at FAST site, vertical advective fluxes of NO<sub>3</sub> from ML to NDLb were up to 337 μmol N m<sup>-2</sup> d<sup>-1</sup> (Fig. 4), i.e ~600 μmol N m<sup>-2</sup> was lost from the ML over 1.8 days. From these two different approaches, exported NO<sub>3</sub> should range between 380 and 600 μmol N m<sup>-2</sup> over this period.

Thus, about 40% of the NO<sub>3</sub> accumulated in the ML after the rain was likely exported by vertical advection to the NDLb. Organisms present in the DCM could benefit of this input of new nutrients. Indeed, PP and abundances of all 4 phytoplankton groups (*Synechococcus*, *Prochlorococcus*, nano and picoeukaryotes) increased at the DCM after 24h and remained high for 2 days after the rain event (Fig. S3). The increase in abundances were higher for prokaryotic phytoplankton abundances, as such organisms would likely benefit from their small size and their ability to use DON/DOP organic molecules (Yelton et al., 2016).

## 5. Conclusions

Mis en forme : Police :Italique

This study reports for the first time, in the context of an oceanographic cruise, simultaneous sampling of atmospheric and ocean biogeochemical parameters to characterize in situ the biogeochemical responses to atmospheric deposition within the ML. High-frequency sampling, in particular at the FAST site, confirmed the transitory state of exchanges between

Supprimé: -

Supprimé: .

Supprimé: in the context of an oceanographic cruise,

Supprimé: dust

Supprimé: long duration

Supprimé: transient status

2410 the ML and the NDLe. Even if dry deposition measured along the transect was homogeneous and amongst in the lowest observed in the MS, that input could represent up to 121% of the hprokN demand. Furthermore, the signature of the dust wet deposition event on DIP and DIN concentrations was clearly emphasized, considering both the local rain fluxes and the horizontal oceanic mixing of water masses affected by the rain front. Finally, a comparison

2415 with the mesocosms results (where the fertilization is more important due to high dust concentrations) is hard to extrapolate with the data presented here.

Our results have shown the important role played by the ML in the biogeochemical and physical processes responsible for transfers of matter and nutrients between the atmosphere and the nutrient depleted layer below. Thanks to the use of the LWCC technique and access to nanomolar variations of NO<sub>3</sub> and DIP in repeated CTD casts, it was possible to demonstrate the role of the ML and exchanges of NO<sub>3</sub> from the ML to the NDLe by vertical advection

2420 when variations of ML D occurred simultaneously to transitory accumulation of NO<sub>3</sub> after a deposition event. The time sequence occurring after a wet dust deposition event was summarized Fig. 6: accumulation of NO<sub>3</sub> in the ML, advection to NDLe, luxury consumption of DIP by hprok and delayed peaks of DIP, decrease of primary production and its recovery after 2 days mainly visible in the nutrient depleted layer. The effect of dust deposition is a complex and time-controlled trophic cascade within the microbial food web.

Our study shows the important role of intermittent, but strong abiotic effects such as downwelling advective fluxes from the ML to the nutrient depleted layers. It will be

2430 important to consider these aspects on budgets and non-stoichiometric models, especially when climate and anthropogenic changes are predicted to increase aerosol deposition in the Mediterranean Sea.

Supprimé: the dust wet deposition event, as usual, was intermittent and patchy in space and time and we caught only one part of the deposition. We hypothesized a fully non-stationary and purely vertical evolution of the oceanic response, lasting for a few days (48 h occupation of the FAST site) and spanning over 40 - 50 km. Under these assumptions, we assume our sampling representative of a wider-ranging water mass than the one crossed by the vessel, integrating every local patch of rain event (rather than only the one received onboard) thanks to horizontal oceanic stirring

**Table 2.** N budget at the short stations within the surface mixed layer (ML). Integrated stocks (NO<sub>3</sub>, μmol N m<sup>-2</sup>) and fluxes (heterotrophic prokaryotic N demand (hprokN demand), phytoplankton N demand (phytoN demand), in situ leucine aminopeptidase hydrolysis fluxes (LAP), dry atmospheric deposition of NO<sub>3</sub> and NH<sub>4</sub> (all fluxes in μmol N m<sup>-2</sup> d<sup>-1</sup>). Values presented as mean ± sd. SD was calculated using propagation of errors; For hprokN demand triplicate measurements at each depth and a C/N ratio of 7.3 ± 1.6; for phytoN demand triplicate measurements of PP at each depth and a C/N ratio of 7 ± 1.4; for LAP the analytical TAA error and the Vm and Km errors; for N<sub>2</sub>fix the coefficient of variation was 10% for volumetric fluxes > 0.1 nmole N l<sup>-1</sup> d<sup>-1</sup> and 20% for lower values. For dry deposition, sd is based on the variability of the NO<sub>3</sub> and NH<sub>4</sub> concentrations solubilized from aerosols during the occupation of the station (see methods section 2.2.1). MLD: mixed layer depth. na: not available because under LWCC detection limits.

Figures legends¶

Figure S1: Vertical distribution of heterotrophic prokaryotic production (BP), particulate primary production (PP), and abundances of heterotrophic prokaryotes (hprok), *Synechococcus*-like cells (syn), eukaryotic picophytoplankton (pico euk) and nanophytoplankton (nano euk) at the ION site. Casts numbered the date of their sampling before (blue profiles) and after (grey profiles) the rain sampled onboard.

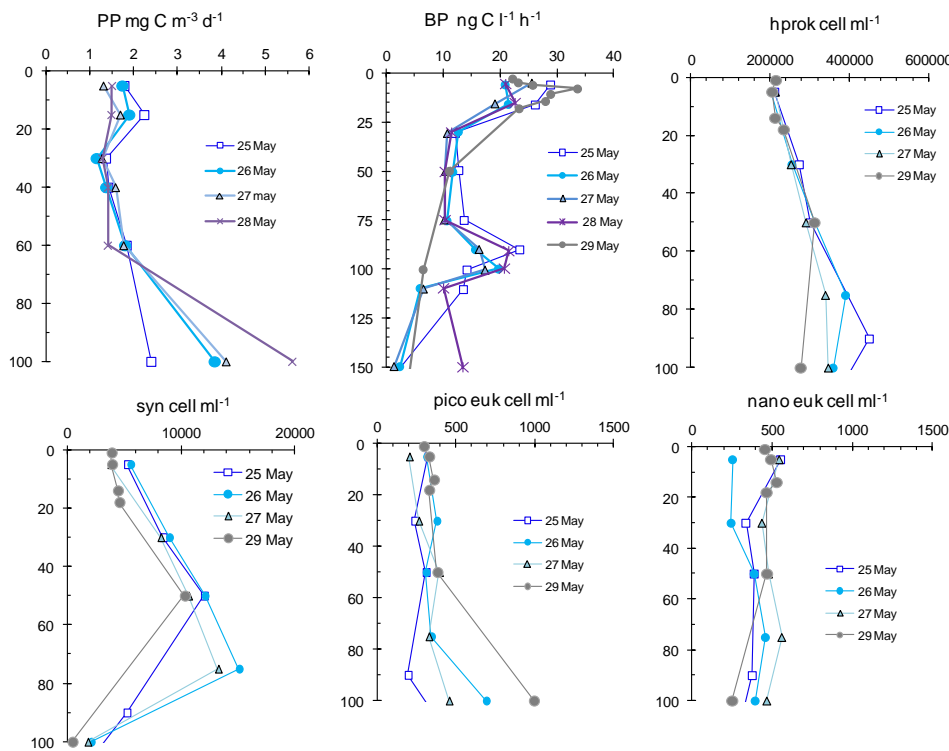

Figure S2: Vertical distribution of heterotrophic prokaryotic production (BP), particulate primary production (PP), and in vivo fluorescence profiles at the FAST site. Stations numbered in days before (blue profiles) and after (grey profiles) the rain event.

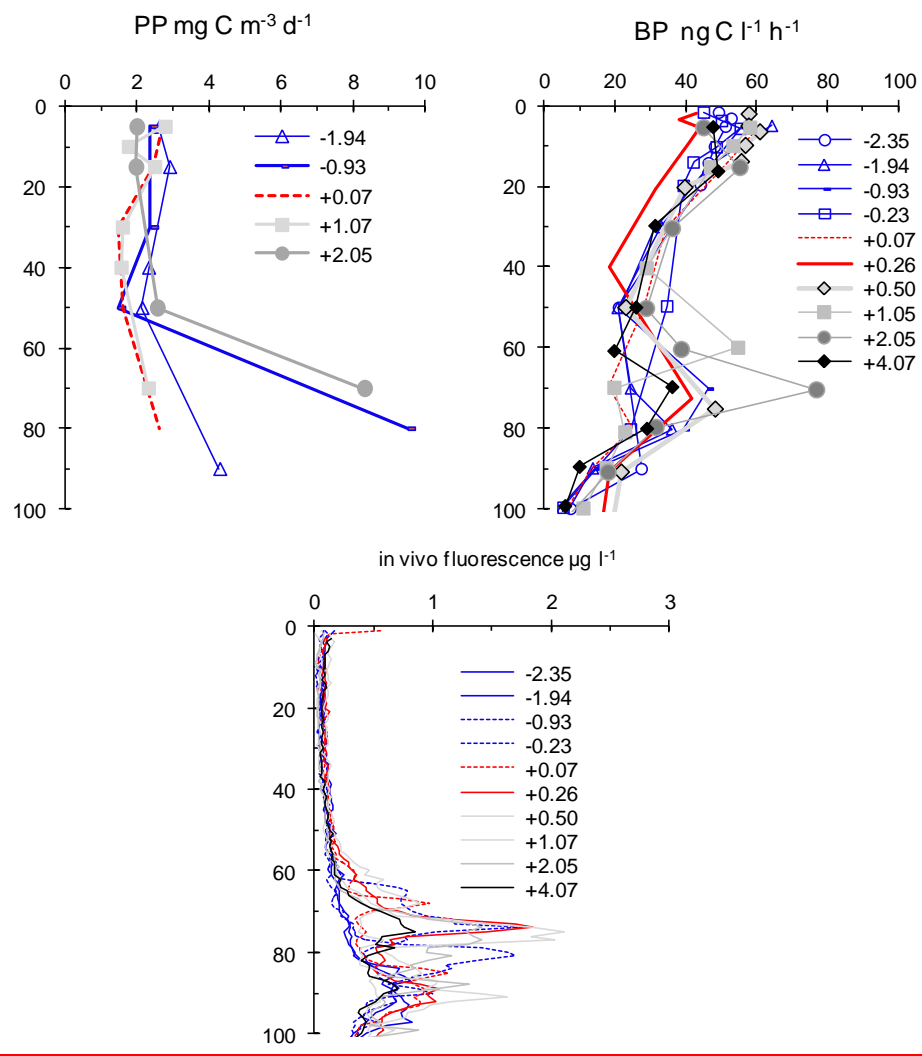

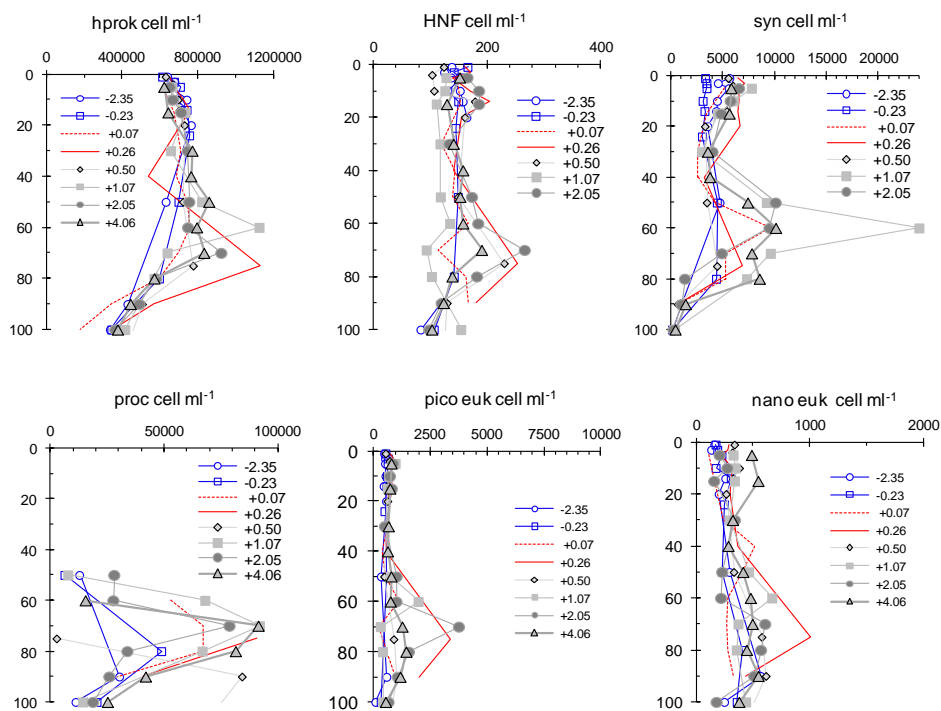

Figure S3. Vertical distribution of abundances for heterotrophic prokaryotes (hprok), heterotrophic nanoflagellates (HNF), *Synechococcus*-like cells (syn), *Prochlorococcus* (proc), eukaryotic picophytoplankton (pico euk) and nanophytoplankton (nano euk) at the FAST site. Stations numbered in days before (blue profiles) and after (grey profiles) the rain event sampled on board.

### Enrichment experiments

At the three sites, enrichment experiments were performed using seawater from 5 m depth to assess factors limiting BP in the surface mixed layer. The sampling of seawater for these experiments [FAST (June 2, 22:00), TYR (May 16, 20:00) and ION (May 25, 20:00)] was done before the rain events occurring at the FAST and ION sites. Eight series of triplicate 60 mL polycarbonate bottles were filled with unfiltered seawater and amended as follows: C : no enrichment, N: +1  $\mu\text{M}$   $\text{NO}_3$  + 1  $\mu\text{M}$   $\text{NH}_4$ ; P: + 0.2  $\mu\text{M}$  DIP; G: + 10  $\mu\text{M}$  C-glucose; NP: N + P; NG : N + G; PG : P + G; NPG: N + P + G. After 48 h incubation in the dark at *in situ* temperature, BP was determined in the 24 bottles (as described in M&M section).

At the TYR site, BP was significantly stimulated only after addition of 2 major elements, with a greater response with PN and NPG combinations (Fig. S4). At the ION site, BP was primarily limited by P availability, as only combinations with P (single or in combination with other elements), stimulated BP whereas all other combinations of enrichment did not stimulate BP significantly compared to the control. At the FAST site, BP was primarily limited by N availability, as all combinations with N, single or in combination with other elements, stimulated BP. However at this site it is likely that BP was also co-limited by 2 elements, as G addition alone also stimulated BP. Note that the PN combination has induced a higher stimulation of BP than other double combinations (NG or PG).

Figure S4. Results of the enrichment experiment. BP reached after 36 h of enrichment in the dark. C: control unamended, P: +DIP, N:+ $\text{NO}_3$ + $\text{NH}_4$ , G: +glucose, and combinations of these elements in PN, NG, PG and NPG. Stars show significantly different BP compared to the unamended control.

**Table S1:** NO<sub>3</sub> ranges within the surface mixed layer (ML) and the base of the nitrate depleted layer below (NDLb) and advective fluxes when measurable. FAST stations are chronologically indexed in days before (negative index) and after (positive index) the occurrence of the rain event. no lwcc: no data because at these stations concentrations were determined only by classical analysis and were under its detection limits (50 nM), na : not available. From comparison of concentrations, we identified four groups of stations: group 1: poor nitrates in ML and NDLb (< 15 nM); group 2: moderate nitrates in ML and NDLb (50 nM < NO<sub>3</sub> < 80 nM); group 3: high nitrate in ML and NDLb (NO<sub>3</sub> > 80 nM); group 4: weak positive differences (< 20 nM) and group 4-high nitrate in ML and moderate to high in NDLb, large positive differences (> 20 nM). MLD: mixed layer depth. sd of fluxes were estimated using propagation of errors on NO<sub>3</sub>ML, NO<sub>3</sub>NDLb and dMLD/dt.
