Abstract. Disentangling ecosystem evapotranspiration (ET) into evaporation (E) and transpiration (T) is of high relevance for a wide range of applications, from land surface modelling to policy making. Identifying and analysing the determinants of the ratio of T to ET (T/ET) for various land covers and uses, especially in view of climate change with increased frequency of extreme events (e.g., heatwaves and floods), is prerequisite for forecasting the hydroclimate of the future and tackling present issues, such as agricultural and irrigation practices.

A powerful partitioning method consists in determining the water stable isotopic compositions of ET, E, and T (δ_{ET}, δ_E, and δ_T, respectively) from the water retrieved from the atmosphere, the soil, and the plant vascular tissues. The present work emphasises the challenges this particular method faces (e.g., the spatial and temporal representativeness of the T/ET estimates, the limitations of the models used and the sensitivities to their driving parameters) and the progress that needs to be made in light of the recent methodological developments. As our review is intended for a broader audience beyond the isotopic ecohydrological and micrometeorological communities, it also attempts to provide a thorough review of the ensemble of techniques used for determining δ_{ET}, δ_E, and δ_T, and solving the partitioning equation for T/ET.

From the current state of research, we conclude that the most promising way forward to ET partitioning and capturing the sub-daily dynamics of T/ET is in making use of non-destructive online monitoring techniques of the stable isotopic composition of soil and xylem water. Effort should continue towards the application of the eddy covariance technique for high-frequency determination of δ_{ET} at the field scale as well as the concomitant determination of δ_{ET}, δ_E, and δ_T at high vertical resolution with field-deployable lift systems.

1 Introduction

Only one fifth of the global hydrological flux occurs over the continents (Chahine, 1992; Dirmeyer et al., 2006). The water cycle is therefore, from a purely quantitative point of view, predominantly an oceanic one. Yet it greatly shapes land surfaces and controls their ecological functioning (Marotzke et al., 2017). Small relative changes in local precipitation regimes, as induced by global warming, have tremendous repercussion on, for instance, summer climate variability (Seneviratne et al., 2006) and people's local access to fresh water (Oki and Kanae, 2006; Milly et al., 2005).

Numerous studies also quantify the coupling strength between the land and the atmosphere: soil moisture content as well as the evapotranspiration (ET) flux positively or negatively affect precipitation and surface temperature (Koster et al., 2004; Wei and Dirmeyer, 2019; Zeng et al., 2017). They highlight the decisive role of the critical zone in regulating climate both locally and globally (Grant and Dietrich, 2017).

A pivotal parameter in landscape hydrology and ecology is the transpiration (T) to evapotranspiration (ET) ratio (T/ET) (see the reviews of Kool et al., 2014; Anderson et al., 2017; Stoy et al., 2019). Isolating the T flux in ET is of utmost importance for a wide range of applications, because of its link to plant water uptake, for e.g., optimizing irrigation practices (Skaggs et al., 2010), tackling ecological questions in water-limited ecosystems (Rothfuss and Javaux, 2017), or for a better representation of the relations between the carbon and water cycles in climate models (Humphrey et al., 2018; Ito and Inatomi, 2012). At the global scale, the uncertainty of the T/ET estimate remains high; it has been estimated to range from 13-90 %, depending on the source and type of data (e.g., satellite- or isotopic-based) and method (modelling or data reanalysis) (Lawrence et al., 2007; Alton et al., 2009; Jasechko et al., 2013; Wang et al., 2014; Wei et al., 2017). Ultimately, this conditions the ability of land-surface models to provide sensitivity of the overall ET flux to changes in precipitation and land cover (Wang and Dickinson, 2012).

Spatial and temporal variability add even more uncertainty to our knowledge on T/ET at the local scale, which is a prerequisite for a meaningful use of such estimates for any of the practical and scientific questions mentioned above. Partitioning ET into the raw components E and T at the field and sub-daily spatiotemporal scales is generally performed by an ensemble of partitioning methods, which can be divided into instrumental approaches and correlation-based modelling approaches (Scanlon and Kustas, 2010). The former approach includes, e.g., the eddy covariance (EC) technique (Baldocchi, 2014; Reichstein et al., 2005), soil-flux chamber measurements (Raz-Yaseef et al., 2010; Lu et al., 2017), micro-lysimeter measurements (Kelliher et al., 1992), or atmospheric profile measurements (Ney and Graf, 2018).

Another powerful instrumental method to partition ET is based on the analysis of its hydrogen or oxygen isotopic composition, i.e., the water vapour atom ratio in rare (^{2}H or ^{18}O) and abundant (^{1}H or ^{16}O) stable isotopes and expressed on the international "delta" (δ) scale (Dubbert and Werner, 2019). The method utilizes the natural discrepancies in isotopic composition of the ecosystem evaporation (δ_E) and transpiration (δ_T) fluxes. The difference $\delta_T - \delta_E$ originates primarily from thermodynamic and kinetic fractionation during phase change and transport processes undergone by water evaporating from soil on the one hand, and water extracted by a root system and transpired by the canopy on the other hand. The observed discrimination against

Preprint. Discussion started: 19 November 2020

Biogeosciences Discussions Open Access EGU

stable isotopologues along the soil-plant-atmosphere water path can be conceptualized two-fold, i.e., phase change- and diffusion-driven, and quantified by the so-called equilibrium and kinetic fractionations, respectively, for which we will later review the physically-based expressions. The term ($\delta_T - \delta_E$) is also determined by

(i) the difference in lower boundary conditions acting on E and T, i.e., the δ-value of soil water at the evaporating front (EF) and leaf water at the transpiration site, respectively, and

(ii) the prevalence (or non-prevalence) of isotopic steady state (ISS) for transpiration, i.e. whether δ_T is independent of time (Farquhar and Cernusak, 2005; Dubbert et al., 2014a). Note that the ISS assumption is generally not made for evaporation flux (but see for an exception: Rothfuss et al., 2010).

The T/ET fraction is obtained by inverting the isotopic mass balance equation $\delta_{ET} = (1 - T/ET)\delta_E + (T/ET)\delta_T$ (Yakir and Sternberg, 2000):

$$T/ET = \frac{\delta_{ET} - \delta_E}{\delta_T - \delta_E} \tag{1}$$

Equation (1) highlights how the isotopic partitioning methodology differs from other instrumental approaches, such as based on a combination of different techniques (e.g., lysimeter and EC measurements): it solely relies on measurements and/or analytical modelling of the stable isotopic compositions of the components ET, E, and T. Behind this apparent simplicity, the isotopic partitioning methodology is limited in its application in different ways, such as the inability – until recently – to provide continuous (i.e., non-destructive) δ_E, δ_T, and δ_{ET} assessments. Part of these limitations were overcome with the availability of field-deployable laser-based spectrometers. These instruments allow for long-term monitoring of soil water vapour and plant transpiration isotopic compositions when combined with gas-permeable membrane or tubing technology (Beyer et al., 2020).

A variety of different methods exists to measure or estimate δ_E, δ_T and δ_{ET}. The central aim of this study is to identify the challenges the ensemble of isotopic methods currently face and how they should progress in the future (section 3). Particularly, the abovementioned emerging monitoring methods are reviewed for the specific purpose of ET partitioning. As such, our work differs from those of Wang and Yakir (2000), Yakir and Sternberg (2000), Xiao et al. (2018), and Sun et al. (2019). In addition and for non-specialists readers, we thoroughly review the underlying concepts and techniques involved in the determination of δ_E, δ_T and δ_{ET}. In order to highlight the important progresses made over the past 30 years, we also give a literature overview (section 2). Finally, section 5 presents a summary as well as the possible ways forward for the isotopic partitioning community.

2 Literature overview

A total of 39 studies were found by entering the search terms "(("evapotranspiration" or "transpiration" or "evaporation") and partition* and isotop*)" into the ISI Web of Science search engine (http://www.webofknowledge.com/). The reader will find a graphical summary in Fig. 1 as well as a detailed description for each of the entries in Table A2 of Appendix A. On average, approximately 1.3 (2.4) partitioning studies were published each year over the period 1989-2007 (2008-2020) with an average annual citation rate of 12 (143) (Fig. 1a).

To the authors' knowledge, the first scientific article reporting on the possibility to partition ET on basis of the differences in isotopic composition of ecosystem ET, soil evaporation, and plant transpiration was that of Bariac et al. (1987). An attempt to use this possibility was made in the study of Walker and Brunel (1990) (Table A2) –, of which ET partitioning was the not the major focus – but remained, according to the authors, not conclusive. Ten years later, Jean-Pierre Brunel and his colleagues could provide the first water stable isotope-derived estimation of the relative importance to ET of the transpiration of the tropical and water-stress resistant plant *Guiera senegalensis* (Brunel et al., 1997), which was noticeably low (approx. 20%). In the meantime, Moreira et al. (1997) applied the so-called 'Keeling plot' technique (Keeling, 1958) (see section 3.1) for determination of the isotopic composition of ET for the specific purpose of partitioning. The isotopic compositions of soil E and plant T at two sites (one pasture, one forest) in the Amazon basin were inferred by using the atmospheric part of the Craig and Gordon (1965) model (see section 3.2) and by assuming steady state transpiration flux (see section 3.3), respectively. The authors could provide evidence of the strong prevalence of T in the ET budget. In a hybrid work coupling a review of the state of the art with field measurements, Wang and Yakir (2000) computed an exceptionally high T/ET ratio value (96.5-98.5%). Hsieh et al. (1998) and Ferretti et al. (2003) opted for a common water isotope mass-balance equation applied at the plot scale, which they solved by making a series of simplifying hypotheses: atmospheric water vapour is in thermodynamic equilibrium with soil water, and the isotopic composition of T is the amount-weighted average of the isotopic compositions of precipitation and soil water. Ferretti et al. (2003) obtained T/ET values ranging between 10 and 60%, depending on the growing season, in a semi-arid grass steppe, while Hsieh et al. (1998) estimated T/ET to span from 14 to 71% as annual rainfall increased along two sampling transects in Hawaii.

Yepez et al. (2003) applied the Keeling plot technique specifically to two distinct ecosystem layers of a savanna woodland in southern Arizona, USA, i.e., the understorey dominated by the *Sporobolus wrightii* C_4-grass and the canopy populated by the mesquite tree *Prosopis velutina*. By doing this, they could capture the isotopic composition of ET representative of each of the two ecosystem layers. In order to partition ET, the authors computed the isotopic composition of the whole ecosystem T as a composite function of the isotopic compositions of grass and tree T fluxes. Finally, it was determined that grass and tree T amounted to 15 and 75 % of total ET. In a follow up study, Yepez et al. (2005) used large gas exchange chambers positioned either on bare soil plots or sparsely vegetated areas of a semi-arid grassland in Arizona, USA. They determined – again with the Keeling plot technique – the isotopic composition of E and ET following an irrigation pulse. This is, to the authors' knowledge, the first use of a closed chamber system in the context of ET partitioning, where T is the single source of the change in air moisture concentration. In contrast to the previous partitioning studies, Yepez et al. (2005) determined the isotopic composition of the non-steady state (NSS) T flux on the basis of plant physiological and micro-meteorological measurements using the formulation of Farquhar and Cernusak (2005) (see also for later examples: Sun et al., 2014; Hu et al., 2014). Yepez et al. (2005) finally calculated T/ET values ranging between 35 and 43% the first three days after irrigation, and decreased to 22 % after one week. This showed the relative prevalence of E at the grassland site. In another study in semi-arid environmental setting (Marrakech, Morocco), Williams et al. (2004) observed that irrigation enhanced soil E of an olive orchard (*Olea europaea* L.). Mid-day T/ET average decreased from approx. 100% (determined prior irrigation) to 69-86% (computed over the 5-day period after irrigation). Xu et al. (2008) investigated the discrepancies between T/ET assessments from either δ^2H of δ^{18}O data collected in a subalpine shrubland (Balang Mountain, China). As for Yepez et al. (2005), they calculated the uncertainties linked with determination of T/ET with the Isoerror software (Phillips and Gregg, 2001). Furthermore, they could differentiate between canopy (*Quercus aquifolioides*) and understory (e.g., *Cystopteris montana*) contributions to ET by using the multi-source mixing model Isosource (Phillips and Gregg, 2003).

Wenninger et al. (2010) and Sutanto et al. (2012) used similar semi-controlled experimental setups equipped with soil liquid water (rhizon) samplers. They simulated the contributions to ET of soil E, plant T and canopy interception using an isotopic mass-balance model. In their framework, the destructive sampling of soil to retrieve the isotopic composition of soil E was not needed, while a number of simplified hypotheses had to be made regarding T. Wenninger et al. (2010) simulated a T/ET ratio value of 70% for teff (*Eragrostis tef*) during the course of their experiment. Sutanto et al. (2012) found a comparable value for a grass cover (T/ET = 87%). In both of these studies, the isotopic partitioning results were confronted with additional (e.g., micro-meteorological) measurements and independent models such as HYDRUS-1D. In two companion papers (Rothfuss et al., 2010; 2012), T/ET of a 0.2 m^2 surface area monolith was computed and simulated for five selected dates under strictly controlled conditions in a climate chamber along the development of a tall fescue cover (*Festuca arundinacea*). T/ET was determined to increase from 6% (16 days after sowing) to 95% (43 days after sowing). Rothfuss et al. (2012) further confronted the isotopic data with simulations with the SiSPAT-Isotope model (Braud et al., 2005). One year earlier, Haverd et al. (2011) used another isotopically enabled soil-vegetation-atmosphere transfer (SVAT) model, Soil-Litter-Iso (Haverd and Cuntz, 2010), using data from a field experiment (Eucalyptus forest, south eastern Australia) in a similar framework, i.e., by running a multi-objective calibration to estimate a given set of model parameters. However, in contrast to Rothfuss et al. (2012), they could show that the added information provided by the isotopic data (δ^2H) was not effective in better constraining the model for determination of T/ET (in their case equal to 85 ±2%). Another simulation study was published by Pei Wang et al. (2015), where a physically-based model solving the energy and water balance in the soil-plant-atmosphere continuum (Wang and Yamanaka, 2014) was coupled to an isotopic module accounting for fractionation processes during E and T. Noticeably, Wang et al. (2015) provided the first test of the 'Peclet effect' (Farquhar and Lloyd, 1993), formalizing in a physically-based matter the compartmentalization of leaf water (see also Piayda et al. (2017) for another example). Wang et al. (2015) simulated T/ET of a temperate grassland to spread over a wide range of values (i.e., 2-99%) during the course of a 190 day-long experiment. Wei et al. (2018) used a similar modelling framework as in Wang et al. (2015) and found that the 3-months ET-weighted T/ET values were equal to 74, 93, and 81 % for three different crops, i.e. rice, corn and wheat, respectively, grown in temperate (rice, Japan) and semi-arid monsoonal (corn and wheat, China) environmental conditions.

Wang et al. (2010; 2013) introduced the use of closed chambers to determine by mass balance the isotopic compositions of ecosystem water fluxes (E, T, and ET) in a non-destructive way (Wang et al., 2010; 2013). This allowed the authors not to rely on either (i) making the assumption of T at ISS for partitioning ET fluxes or (ii) modelling the isotopic composition of T at

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

Biogeosciences Discussions

NSS (see chapter 3.3). They also published the first ET partitioning study where water vapour hydrogen and oxygen isotopic compositions were measured online with an infrared laser spectrometer. Wang et al. (2010) calculated T/ET values for the mesquite tree (*Prosopis chilensis*) grown under controlled conditions (Biosphere 2 facililty, Arizona, USA, see for details: Barron-Gafford et al., 2007), ranging from 61 to 83% at 25 and 100% woody cover, respectively. Wang et al. (2013) compared T/ET ratio (65-77% vs. 83-86%) computed from control vs. warming plots, taking advantage of a long-term grassland multiple-factor climate control experiment in Oklahoma, USA.

Bijoor et al. (2011) investigated the partitioning of ET in a freshwater marsh dominated by *Typha latifolia* in California, USA. They found a good agreement between T/ET values estimated on the one hand from isotopic analysis and from micro-meteorological (e.g., EC) measurements on the other, while they highlighted the high uncertainty of the isotope estimates (i.e., standard error value > 37%). Zhang et al. (2018) investigated another marsh wetland in China and found out that the two dominant species (*Scirpus triqueter* and the invasive *Phragmites australis*) contributed each equally (20 %) to ET flux.

Dubbert et al. (2013) quantified the sensitivity of the partitioning of ET to a number of factors (e.g., value of the kinetic fractionation factor, assumption of steady-state T) during a field experiment in central Portugal. They also compared direct measurements of the isotopic composition of E (with gas exchange chambers coupled to a laser spectrometer) to simulations with the Craig and Gordon (1965) model. Similar to Rothfuss et al. (2010; 2012), the authors underlined the need to complement isotopic measurement with micro-meteorological and physiological observations. In the same open cork-oak (*Quercus suber* L.) savanna, Dubbert et al. (2014b) investigated the impact of the understorey vegetation (annual grass and forbs) on the total ecosystem water budget. They could discriminate between T of trees and grass and highlighted the stability of the former throughout the year and the strong decrease of the latter during the summer. Piayda et al. (2017) differentiated between open and shaded portions of the same experimental site and found T/ET ranging between 9 to 59% and between 17 to 66%, respectively. Good et al. (2014) studied the uncertainty of the T/ET values obtained for a grassland site, following a 30 mm isotopically enriched irrigation event, e.g., as a function of the uncertainty linked with the estimate of δ_{ET} obtained with the Keeling plot technique (according to Good et al., 2012). The authors found on average a value of 30 (±5) % for T/ET over the 15 days of the experiment.

Hu et al. (2014) determined a mean T/ET value of 83% in a semi-arid shrubland in China dominated by *Stipa kryroii* and *Artemisia frigida*. They tested for the first time the so-called flux-gradient approach (Lee et al., 2007; see section 3.1) for determination of δ_{ET}. They argued that the uncertainty of the δ_{ET} estimates had the strongest effect on T/ET uncertainty(?) in their case. Also Wei et al. (2015) found that the greatest source of uncertainty of T/ET of a rice paddy field was linked to the determination of δ_{ET}, this time using the Keeling plot technique. They could describe T/ET as an exponential function of leaf area index (LAI) (i.e., $T/ET[\%]=67 \cdot LAI^{0.25}$). Wu et al. (2017) found slightly different parameters of the same LAI model ($71 \cdot LAI^{0.14}$) for a maize crop grown under semi-arid conditions (Gansu Province, China).

Berkelhammer et al. (2016) compared the outcome of the isotopic partitioning method with EC-derived T/ET values. They underlined the goodness of fit of the two methods as well as the stability of the T/ET ratio as a function of LAI over multiannual time scales. Wen et al. (2016) investigated the contribution of spring maize T to ET in an arid artificial oasis part of the Heihe

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

Biogeosciences Discussions

river catchment (China) and reported it to be quite constant (mean T/ET value of 87 ± 5.2 %). Collected data was further used by Zhou et al. (2018) and Xiong et al. (2019). Zhou et al. (2018) showed similarities between results of the isotopic partitioning method and a coupled approach of EC and lysimeter data. They underlined, however, that both methods simulate higher T/ET ratios, with poor temporal dynamics not reflecting those of leaf area index, than their benchmark method, i.e., based on the incorporation of vapour pressure deficit into the expression of the water-use efficiency concept. Xiong et al. (2019) observed a good match between T/ET daily values (54-97%, with a mean value of 85 %) as obtained with their isotope method and with a net radiation and temperature-dependant model coupled to imaging radiometry.

Aouade et al. (2016) found a decreasing diurnal (i.e., morning vs. afternoon) amplitude of T/ET in a winter wheat field in Morocco under wet conditions after flood irrigation with a soil water content of approx. 0.35 $m^3\ m^{-3}$, and the opposite under dry conditions with a soil water content value of 0.15 $m^3\ m^{-3}$. Aouade et al. (2020) compared the T/ET results for dry conditions of Aouade et al. (2016) to independent assessments using the Interaction between Soil, Biosphere, and Atmosphere (ISBA) model (Masson et al., 2013) and found that they were within the same range (73-89 %). The study of Lu et al. (2017) focused on the efficiency of irrigation strategies in southern California (USA). They document that the investigated field of *Sorghum bicolor* was responsible for 46% of water consumption following the irrigation event. Quade et al. (2019) applied for the first time a non-destructive approach for determination of the isotopic composition of E by sampling the soil water vapour with gas-permeable tubing and measuring its isotopic composition online with a laser spectrometer as described in Rothfuss et al. (2013). They cross-compared the T/ET values obtained with different methods including the combination of EC and lysimeter flux data, and isotopic assessments based on either water δ^2H or δ^{18}O data. They further compared T/ET results obtained on the basis of the non-destructive method of Rothfuss et al. (2013) (for determination of the isotopic composition E) with those of traditional destructive soil sampling in combination with the Craig and Gordon (1965) model. They found significant differences in T/ET of a sugar beet (*Beta vulgaris*) field between the different methods on four days at different stages of the canopy development (0.7 < LAI < 6.7).

In a review on the use of water stable isotope analysis for determination of plant root water uptake dynamics (Rothfuss and Javaux, 2017), the authors underlined the need for field studies in croplands. This is not the conclusion of the present literature overview, as the three main land surface types, i.e., cropland, forests, and grassland (in monoculture or mixed culture) are rather equally represented with a relative proportion of 33, 32, and 41%, respectively (Fig. 2b). More than one third of the scientific publications analysed in the present review (i.e. 38 %) applied the isotopic methodology in semi-arid or desert regions (Fig. 1c). Nevertheless, a wide range of climate types (e.g., subtropical-humid, Mediterranean or subarctic, Fig. 1c) as well as regions (e.g., Northern America, sub-Saharan Africa or Eastern Asia, Fig. 1d) is investigated as well. 30 of the 39 reviewed studies were conducted in the field, and only eight (21 %) used a physically-based numerical model to simulate T/ET ratios on the basis of the collected isotopic (and water status) data (Fig 1e). Furthermore, 95 % of the field studies were conducted at natural isotopic abundance, either under normal precipitation regime (85 %) or in the framework of an irrigation experiment (10 %). The remaining 5 % of studies (Yepez et al., 2005; Good et al., 2014) applied a labelling pulse of ^{2}H-enriched water to the soil for better discrimination between the three terms of the mixing equation (Eq. (1)).

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

There is naturally a strong link between the temporal resolution in T/ET estimates and the temporal extent of the T/ET time series (Fig. 1b). The vast majority of the studies (85 %) provided T/ET values at hourly to subweekly resolution over periods of time not exceeding a few months. This is partly a sign of the limitation of the isotopic methodology, which was mentioned in the introduction, i.e., the labour-intensive and time-consuming destructive sampling of soil and plant material and the subsequent water extraction step. In two studies only (Hsieh et al., 1998; Ferretti et al. 2003), authors could calculate T/ET at weekly to monthly resolution overs several years. For doing this, they made a series of abovementioned simplifying hypotheses, which allowed them, amongst other things, not to rely on sampling of plant material, thereby significantly saving extraction and analysis time. The authors of the present work note that, on the other hand, the question of spatial variability or representativeness of the T/ET estimates is rarely addressed in the literature (but see section 3.1 for the issue of spatial representativeness of δ_{ET}).

3 Methodological review

In this section, the methods used for determination of the three terms in the partitioning equation (Eq. 1), i.e., δ_{ET}, δ_E and δ_T for final computation of the T/ET ratio will be covered (subsections 3.1.1, 3.2.1, and 3.3.1, respectively), with special emphasis on challenges and new technical and methodological developments (subsections 3.1.2, 3.2.2, and 3.3.2, respectively). Three main approaches emerge from the analysis: δ_{ET}, δ_E and δ_T can be either determined by

(i) solving the mass balances for the different water vapour isotopologues,

(ii) using physical models based on macroscopic analogies of Ohm's law, or

(iii) using a statistical framework (Fig. 2).

Note that it is not the present work's intention to give a thorough review of the physically-based and isotope-enabled soil-vegetation-atmosphere numerical models used by Haverd et al. (2011), Sutanto et al. (2012), and Rothfuss et al. (2012) for simulation of T/ET. For this, the readers may refer also to Haverd and Cuntz (2010) and Braud et al. (2005). Likewise, the authors choose not to describe one particular ensemble of methods in detail (used in seven different studies, see Table 2 and referred to as "water balance" in Fig. 1.) based on solving a water mass-balance equation and not relying on the sampling or monitoring of plant and soil water, and atmospheric water vapour.

3.1 Isotopic composition of evapotranspiration

3.1.1 Methods

The prevalent method (43 % of the reviewed studies, Fig. 1h) for determining the isotopic composition of ET is based on solving a mass balance equation (Fig. 2a-c). It was named after Charles D. Keeling who originally used it to quantify the CO_2 carbon isotopic composition in the atmosphere as a linear function of the reciprocal of the CO_2 concentration (Keeling, 1958). The so-called 'Keeling plot' technique simply considers that the water vapour measured in some ecosystem atmosphere

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

compartment (of concentration C_{atm}, dimension of M L^{-3}) originates from two sources, namely (i) the background water vapour (of concentration C_{bg} [M L^{-3}]), transported advectively, and (ii) evapotranspiration ET (of concentration C_{ET} [M L^{-3}]):

$$C_{\mathrm{atm}} = C_{\mathrm{bg}} + C_{\mathrm{ET}}. \quad (2)$$

Practically, laser-based spectrometers measure water vapour volume mixing ratio, χ[-], the ratio of water vapour pressure and total (dry) atmospheric pressure:

$$\chi_{\mathrm{atm}} = \chi_{\mathrm{bg}} + \chi_{\mathrm{ET}}. \quad (3)$$

A similar equation can be written for stable isotopes:

$$\delta_{\mathrm{atm}}\chi_{\mathrm{atm}} = \delta_{\mathrm{bg}}\chi_{\mathrm{bg}} + \delta_{\mathrm{ET}}\chi_{\mathrm{ET}}, \quad (4)$$

with δ_{atm} and δ_{bg} the isotopic compositions of the ambient air and background air, respectively. Combining Eqs. (3) and (4) and rearranging for δ_{atm} leads to the following expression (Eq. (5), see Fig. 2 for an illustration):

$$\delta_{\mathrm{atm}} = \frac{1}{\chi_{\mathrm{atm}}}\left[\chi_{\mathrm{bg}}\left(\delta_{\mathrm{bg}} - \delta_{\mathrm{ET}}\right)\right] + \delta_{\mathrm{ET}}. \quad (5)$$

To the conditions that

(i) both χ and δ-values of the background water vapour and ET remain constant during the measurement period and

(ii) there is no loss of water vapour from the atmosphere (e.g., during dewfall),

it is possible to determine δ_{ET} as the Y-intercept of the regression line of the relationship between δ_{atm} and $1/\chi_{atm}$. In this framework the sign of the linear regression slope s [M L^{-3}] $= C_{\mathrm{bg}}\left(\delta_{\mathrm{bg}} - \delta_{\mathrm{ET}}\right)$ is therefore constrained by the difference ($\delta_{bg} - \delta_{ET}$); s is generally negative, apart from some bare soil situations (Yakir and Sternberg, 2000) (Fig. 3a). Note that it is also possible to derive δ_{ET} by inverting the expression for s, although, to our knowledge, such a possibility has not yet been tested in the literature, certainly because the determination of C_{bg} and δ_{bg} is not straightforward in the field.

One important prerequisite for the applicability of the Keeling plot is a significant span in χ_{atm} values over the course of the measurements (Fig. 3b-c). High χ_{atm} values are especially needed to reduce the statistical uncertainty of δ_{ET} (Good et al., 2012). In case of a single observation height (Wei et al., 2018; Good et al., 2014; Wei et al., 2015), the time factor is critical. χ_{atm} variations should not be obtained at the expense of the validity of the aforementioned core assumption (i), i.e., steady values of ET and background χ and δ. Another option beside the one just described, which we could refer to as the 'temporal Keeling plot' technique, is to drastically increase the span of χ_{atm} values by collecting data at different observation heights during a short period of time (~ 1 hour), which could be referred to as 'spatial Keeling plot'. From our literature compilation, the spatial Keeling plot is preferred over the temporal one (i.e., 32 vs. 7 studies).

Another technique (18 % of the reviewed studies, Fig. 1h) for determining δ_{ET} requires the manipulation of transparent chamber systems to enclose and tightly seal the soil and vegetation (e.g., Yepez et al., 2005; Piayda et al., 2017). Two different applications exist, both based on the mass balance approach. In the first one (referred to as "Chamber (InOut)" in Table A2

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

and Fig. 1h), the chamber is flushed with ambient air, and δ_{ET} is deduced from the difference in water vapour mixing ratio and isotopic composition measured alternatingly at the inlet (subscript 'in') and outlet (subscript 'out') of the chamber (e.g., Wang et al., 2013; Dubbert et al., 2013):

$$\delta_{\mathrm{out}}\chi_{\mathrm{out}} = \delta_{\mathrm{in}}\chi_{\mathrm{in}} + \delta_{\mathrm{ET}}\chi_{\mathrm{ET}}. \quad (6)$$

Equation (6) is strictly valid only for conservative flow conditions. In other studies (e.g., Dubbert et al., 2014b), the change in flow rate (u [L^3 T^{-1}]) between in- and outlet due to the addition of water vapour originating from the soil and/or the plant is taken into account as follows:

$$\delta_{\mathrm{out}}\chi_{\mathrm{out}}u_{\mathrm{out}} = \delta_{\mathrm{in}}\chi_{\mathrm{in}}u_{\mathrm{in}} + \delta_{\mathrm{ET}}\chi_{ET}(u_{\mathrm{out}} - u_{\mathrm{in}}). \quad (6')$$

By conservation of dry air flow, i.e. $u_{\mathrm{out}}(1-\chi_{\mathrm{out}}) = u_{\mathrm{in}}(1-\chi_{\mathrm{in}})$ (Simonin et al., 2013), Eq. (6') becomes

$$\delta_{\mathrm{ET}} = \frac{\chi_{\mathrm{out}}\delta_{\mathrm{out}} - \chi_{\mathrm{in}}\delta_{\mathrm{in}}}{\chi_{\mathrm{out}} - \chi_{\mathrm{in}}} - \frac{\chi_{\mathrm{in}}\chi_{\mathrm{out}}(\delta_{\mathrm{out}} - \delta_{\mathrm{in}})}{\chi_{\mathrm{out}} - \chi_{\mathrm{in}}}. \quad (7)$$

The second term on the right-hand side of Eq. (7) therefore accounts for the increase of flow rate due to ET in the chamber. An alternative consists in flushing the chamber with dry air instead of ambient air, so that the isotopic composition of the outlet water vapour directly reflects that of ET. In the second application (named "Chamber (Keeling Plot)" in Fig. 1h), the chamber is flushed in a closed loop with ambient air, and δ_{ET} is obtained by linear regression of the isotopic composition of the chamber air versus the inverse of the water vapour mixing ratio using the Keeling (1958) plot technique.

In 10% of the referenced studies (Wen et al., 2016; Wei et al., 2018; Zhou et al., 2018), authors determined δ_{ET} values by analogy to Ohm's law. The so-called 'flux gradient method' (Lee et al., 2007) is based on the premise that the ET flux density rate (F_{ET} [L^3 L^{-2} T^{-1}, expressed typically in mol m^{-2} s^{-1}]) is proportional to $\Delta\chi_{\mathrm{atm}}/\Delta z_{\mathrm{atm}}$ [L^{-1}, typically in m^{-1}], the gradient of water vapour mixing ratio between two observation heights (with z_{atm} standing for height):

$$F_{\mathrm{ET}} = -K\,\frac{\rho_{\mathrm{atm}}}{M_{\mathrm{atm}}}\frac{\Delta\chi_{\mathrm{atm}}}{\Delta z_{\mathrm{atm}}}. \quad (8)$$

The water vapour transport is determined by the overall conductance of the air boundary layer expressed here as $-K\,\rho_{\mathrm{atm}}/M_{\mathrm{atm}}$ with ρ_{atm} [M L^{-3}] and M_{atm} [M L^{-3}, units of kg mol^{-1}] the dry air volumetric mass and molecular weight, and K [L^2 T^{-1}] the eddy diffusivity of water vapour. The isotopic ratio of ET (R_{ET} [–]), which can be defined as the ratio of the flux density rates of the rare (superscript i) and abundant (superscript j) isotopologues (${}^{i}F_{\mathrm{ET}}$ and ${}^{j}F_{\mathrm{ET}}$, respectively), can be therefore expressed as

$$R_{\mathrm{ET}} = {}^{i}F_{\mathrm{ET}}/{}^{j}F_{\mathrm{ET}} \approx \Delta^{i}\chi_{\mathrm{atm}}/\Delta^{j}\chi_{\mathrm{atm}}\,, \quad (9)$$

assuming that differences in K among water stable isotopologues are not significant, i.e. ${}^{i}K = {}^{j}K = K$ (Yakir and Wang, 1996; Griffis et al., 2005). ${}^{i}\chi_{\mathrm{atm}}$ and ${}^{j}\chi_{\mathrm{atm}}$ are the water vapour mixing ratio of rare and abundant isotopologues, respectively. Equation (9) can be further rearranged as

$${}^{i}\chi_{\mathrm{atm}} = R_{\mathrm{ET}}{}^{j}\chi_{\mathrm{atm}} + C, \quad (10)$$

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

where R_{ET} is the slope and C [-] the y-intercept of the linear relationship between ${}^{i}\chi_{atm}$ and ${}^{j}\chi_{atm}$. Equation (10) becomes in δ-notation:

$$\delta_{atm} = \delta_{ET} + C/R_{std}\frac{1}{{}^{j}\chi_{atm}} \quad (11)$$

by dividing its left and right terms by ${}^{j}\chi_{atm}R_{std}$ with R_{std}, the isotopic ratio of the internationally accepted water standard, namely the Vienna Standard Mean Ocean Water (V-SMOW) (Gonfiantini, 1978). We note that, by assuming ${}^{j}\chi_{atm} \approx \chi_{atm}$, the flux gradient and Keeling plot techniques are mathematically identical with $C = \chi_{bg}(\delta_{bg} - \delta_{ET})R_{std}$.

Griffis et al. (2010) and Good et al. (2012) used a combination of the EC technique and infrared tunable diode laser (TDL) water isotope spectroscopy to derive δ_{ET} values from simultaneous changes in wind velocity (ω [L T^{-1}]) and ${}^{i}\chi_{atm}$. In this statistical framework and by

(i) considering that air density and storage fluctuations are negligible during the measurement period (typically 30 minutes) and

(ii) changing the coordinate system so that the vertical wind velocity mean value ($\overline{\omega}$) equals zero,

F_{ET} is expressed as:

$$F_{ET} = \frac{\rho_{atm}}{M_{atm}}\overline{\omega'\chi_{atm}'}. \quad (12)$$

The term $\overline{\omega'\chi_{atm}'}$ is the average (overbar symbol) product of the differences between instantaneous and mean values (indicated by the prime symbols) of wind velocity and water vapour mixing ratio, in other words the covariance between the ω and χ_{atm} monitored variables. Similar to Eq. (11), we obtain after converting in δ-notation the expression for the isotopic composition of ET:

$$\delta_{ET} = \frac{{}^{i}F_{ET}/{}^{j}F_{ET}}{R_{std}} - 1 = \frac{\overline{\omega'{}^{i}\chi_{atm}'}/\overline{\omega'{}^{j}\chi_{atm}'}}{R_{std}} - 1 \quad (13)$$

An alternative to Eq. (13) consists in considering the high-frequency variations of δ_{atm} rather than those of the individual mixing ratios ${}^{i}\chi_{atm}$ and ${}^{j}\chi_{atm}$. For this the isoflux (Lee et al., 2009), defined as $\overline{\omega'\delta_{atm}'}$ [L^{3} L^{-2} T^{-1}], is introduced:

$$\delta_{ET} = \frac{\overline{\chi_{atm}}}{\overline{\omega'\chi_{atm}'}}\overline{\omega'\delta_{atm}'} + \overline{\delta_{atm}} \quad (14)$$

3.1.2 Progress and challenges

Good et al. (2012) provided a comprehensive comparison of the various techniques (Keeling plot, flux gradient and EC) for determination of δ_{ET}. In addition to the temporal and spatial Keeling plot variations, they tested a third option where, instead of instantaneous measurements of δ_{atm} and χ_{atm} collected during 30 min, the mean values of δ_{atm} and χ_{atm} are calculated at each observation height (n=4) and used for regression. After a detailed uncertainty analysis, they concluded that the use of mean values instead of individual data points increased the uncertainty associated with δ_{ET}, regardless of the kind (temporal vs.

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

Biogeosciences Discussions

spatial) of Keeling plot. In addition, the temporal and spatial Keeling plot techniques yielded significantly different values of δ_{ET} for the same time interval. The authors could not conclude which value was the most representative. In addition, they found a good agreement between the Keeling plot technique, applied at different heights, and the flux gradient method due to the aforementioned mathematical similarities.

As previously mentioned, Yepez et al. (2005) and Wang et al. (2013) combined the Keeling plot technique with their closed chamber systems. During the course of measurement (e.g., 6 min in Yepez et al. (2005)) and for the Keeling plot approach to be valid, the increase of chamber water vapour mixing ratio (10-15 mmol mol^{-1} in Yepez et al., 2005) should not induce changes in both ET flow rate and isotopic composition. The fulfilment of this requirement of the Keeling plot technique is verified in a first approach by the very existence of a linear relationship between chamber air $1/\chi$ and δ-values.

Another issue related to the use of chamber systems is the occurrence of water vapour condensation on the inside of the chamber or within the tubing system, e.g., following changes of incoming solar radiation during measurement. This may result in eventual isotopic fractionation leading to unreliable (i.e., unstable and underestimated) observations of chamber air δ-values. To avoid such problems, the volume of the chamber is critical (i.e., the bigger the less sensitive to abrupt changes of outside conditions) and active ventilation is mandatory. Ventilation not only prevents from condensation problems and pressure anomalies (Longdoz et al., 2000) but also guarantees the prevalence of turbulent mixing conditions in the chamber. The latter may not be ensured by a high turnover rate alone, i.e., the ratio of chamber volume and flow rate of flushed air. It is an important prerequisite of the application of both techniques based on the Keeling plot and alternating measurements of the water vapour mixing ratio and isotopic composition of inlet and outlet air (Eq. 7).

Measurements with dynamically purged chambers, which are combined with the latter type of mass balance applications, may reduce the problem of condensation inside the chamber, which are combined with the latter type of mass balance applications, may reduce the problem of condensation inside the chamber. A possibility is to flush the chamber with dry air, so that the increase in water vapour mixing ratio and (positive or negative) change of isotopic composition measured at the outlet relative to the inlet directly reflect the volume and isotopic composition of the moisture added by ET. Stable measurements over a certain time period, depending on both chamber volume and inflow rate, would indicate ISS, and δ_{ET} may be directly measured without any further calculations (e.g., Wang et al., 2010). However, dry air can stress the enclosed plants by artificially increasing the chamber air vapour pressure deficit, which ultimately can result in NSS conditions. In this case, a steady increase of chamber air χ should not be observed during the course of the measurement as it would be a sign of a significant difference of micrometeorological conditions (temperature, vapour pressure deficit, and wind speed values) between ambient and chamber air.

Both the temporal Keeling plot and the flux-gradient techniques suffer from the need of a high spatial gradient in the water vapour mixing ratio and isotopic composition between the soil/canopy surface and the free atmosphere to obtain precise values of δ_{ET}. One possible way forward is to use a small (~few meters high) field lift system, the modus operandi of which is based on the principles established by Mayer et al. (2009) and Noone et al. (2013), for a continuous monitoring of atmospheric height profiles of the water vapour isotopic composition. To the authors' knowledge, only one study on an evergreen forest made use of the principle in the context of ET partitioning (Berkelhammer et al., 2016). Ney and Graf (2018) designed a portable lift system for measuring the atmospheric water vapour and CO_2 mixing ratios in the field for various crops at a half-hourly temporal resolution. Their system should allow for measuring highly vertically resolved water vapour isotopic profiles. For this, however, high-throughput and high-frequency isotopic analysers are needed to provide reliable information on ecosystem fluxes. Commercially available cavity ring-down laser spectrometers operate at low flow rate (φ) and frequency (f) (e.g., $25 \leq \varphi \leq 35$ ml min^{-1} and $f \approx 1$ Hz for the L2120-*i*, L2130-*i* and L2140-*I* by Picarro, Inc., Santa Clara, CA, USA) and are, thus, not suitable for such measurements. To our knowledge only two instruments are able to monitor water vapour stable isotopic compositions at higher flow rate and higher frequency: the lead-salt tunable diode laser spectrometer TGA200A (Campbell Scientific, Inc., Logan, Utah, USA; $\varphi = 1.7$ l min^{-1} at $f = 10$ Hz) and the Quantum Cascade Laser (QCL) Trace Gas Monitor (Aerodyne, Inc., Billerica, MA, USA; $\varphi \leq 250$ l min^{-1} and $f = 10$ Hz), although for the latter no published results are available. These instruments could be used for EC measurements of water vapour isotopologues, which are not common within the isotopic source-partitioning community. To the authors' knowledge, only two studies (Griffis et al., 2010; Griffis et al., 2011) demonstrated that water vapour mixing ratio and ET measured with the traditional EC technique (with infrared laser analyser, e.g., LI-7500, Licor, Inc., Lincoln, NB, USA) agreed well with the combined EC/TGA200 measurements, which suggests that the measured ET isofluxes were realistic. The important advantage of the EC isotope technique resides in its ability to provide δ_{ET} estimates at the field scale and therefore demarks itself from the plot-scale Keeling plot and chamber-based approaches. Especially the spatial Keeling plot approach suffers from the fact that the different heights at which the isotopic composition of water vapour is measured are representative for differently large areas of the studied ecosystem. The main disadvantage is that the aforementioned instruments are quite large and difficult to handle in situ. In addition, they need stable environmental conditions (especially temperature) during field deployment.

Biogeosciences Discussions

3.2 Isotopic composition of evaporation

3.2.1 Methods

Two options are found in the literature (Fig. 1i) for determining the isotopic composition of the E flux, δ_E:

(i) by solving one of either mass balance equations (Eqs (7) or (11), see section 3.1) in combination with dynamically purged closed bare soil chambers (15 % of the reviewed studies, e.g., Dubbert et al., 2013; 2014b).

(ii) by solving the so-called 'Craig and Gordon equation' (Eq. (18) below), which is derived from the atmospheric part of a transport model of water stable isotopologues, based on an analogy to Ohm's law (Craig and Gordon, 1965) (69 % of the studies), or

The two approaches differ in numerous aspects: while the first is non-destructive and requires on-line and continuous measurements of a few variables (i.e., water vapour mixing ratio and isotopic composition of the chamber inlet and outlet air), the second relies on destructive sampling of the soil and offline analysis of the extracted water. The Craig and Gordon equation demarks itself from Eqs. (7) and (11) also due to its complex parametrization. Craig and Gordon (1965) classically interpreted the temporal changes in δ_E of a free water body with the help of a linear resistance model. We will shortly present the widely used model variation for water bound to the soil media (For an in-depth review, the reader is kindly referred to Horita et al., 2008). The only significant difference to the original model is the evaporating front vertical coordinate (z_{EF}), which may not correspond to that of the soil surface depending on the evaporation stage (Or et al., 2013; Merz et al., 2018). The isotopic ratio of evaporation, R_E, is expressed as the ratio of ${}^iF_E$ and ${}^jF_E$, i.e., the water vapour flux density rates [L^3 L^{-2} T^{-1}] in rare and abundant isotopologues, respectively, originating from the EF:

$$R_E = \frac{{}^jF_E}{{}^jF_E} = \frac{\Delta^i\chi_{atm}}{\Delta^j\chi_{atm}} = \frac{1}{{}^ir/\,{}^jr}\cdot\frac{{}^i\chi_{atm}(z_{EF})-{}^i\chi_{atm}(z_{atm})}{{}^j\chi_{atm}(z_{EF})-{}^j\chi_{atm}(z_{atm})}. \quad (15)$$

We note that Eq. (15) is analogous to Eq. (9) (Lee et al., 2007, see section 3.1), with the exception that the bulk resistances to vapour transport of the rare and abundant isotopologues (${}^ir$ and ${}^jr$ [T L^{-1}], respectively) are not assumed equal. It follows from the fact that ${}^ir$ and ${}^jr$ relate to the air layer delimited between z_{EF} and z_{atm} (and not between the two observation heights in Eq. (9)) where not only purely turbulent transport or eddy diffusivity, but also molecular diffusion and laminar flow are relevant. Furthermore, Craig and Gordon (1965) conceptualized the existence of a water vapour-saturated (superscript 'sat') air layer at the EF where isotopic thermodynamic equilibrium prevails:

$${}^j\chi_{atm}(z_{EF}) = {}^j\chi_{atm}^{sat} \quad (16a)$$

$${}^i\chi_{atm}(z_{EF}) = {}^i\chi_{atm}^{sat} = {}^j\chi_{atm}^{sat}R_{sat} = {}^j\chi_{atm}^{sat}\frac{R_{EF}}{\alpha_{eq}} \quad (16b)$$

where R_{sat} and R_{EF} are the isotopic ratios of the saturated air layer and of the soil liquid water at the EF, respectively. α_{eq} [-] is the isotopic equilibrium fractionation factor, first empirically determined by Majoube (1971) and later by Horita and Wesolowski (1994). α_{eq} depends on the soil temperature at the EF:

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

$$\alpha_{\mathrm{eq}}(T_{\mathrm{EF}}) = \exp\left(\frac{A}{T_{\mathrm{EF}}^2} + \frac{B}{T_{\mathrm{EF}}} + C\right) \tag{17}$$

with constants A = 24844, B = –76.248 and C = 0.052612 for ^{2}H and A = 1137, B = –0.4156 and C = –0.0020667 for ^{18}O. Craig and Gordon (1965) identified the ratio of bulk resistances ${}^{i}r/{}^{j}r$ as the isotopic kinetic fractionation factor (α_{K} [-]). Finally, by

(i) considering that ${}^{i}\chi_{\mathrm{atm}}(z_{\mathrm{atm}}) = {}^{j}\chi_{\mathrm{atm}}(z_{\mathrm{atm}})R_{\mathrm{atm}}$,

(ii) dividing Eq. (15)'s right hand term numerator and denominator by ${}^{j}\chi_{\mathrm{atm}}^{\mathrm{sat}}$, and

(iii) converting R_{E} into δ_{E}, we obtain:

$$\delta_{\mathrm{E}} = \frac{1}{\alpha_{\mathrm{K}}(1-h_{\mathrm{atm}})}\left(\frac{\delta_{\mathrm{EF}}+1}{\alpha_{\mathrm{eq}}} - (\delta_{\mathrm{atm}}+1)h\right) - 1, \tag{18}$$

where h_{atm} [-] is the relative humidity of the ambient atmosphere measured at vertical coordinate z_{atm} and defined as the ratio ${}^{j}\chi_{\mathrm{atm}}(z_{\mathrm{atm}})/{}^{j}\chi_{\mathrm{atm}}^{\mathrm{sat}}$. The possible difference in temperature measured at z_{atm} and z_{EF} should be accounted for by normalizing h_{atm} to the saturated vapour pressure ([M L^{-1} T^{-2}], usually expressed in Pa) at the temperature of the EF (Rothfuss et al., 2010; Quade et al., 2019).

Craig and Gordon (1965) argued that the kinetic fractionation factor was inversely proportional to the ratio of the molecular diffusivities of $^1H_2{}^{16}O$ (${}^{j}D$) and of either $^1H^2H^{16}O$ or $^1H_2{}^{18}O$ (${}^{i}D$):

$$\alpha_{\mathrm{K}} = \frac{{}^{i}r}{{}^{j}r} = \frac{{}^{j}D}{{}^{i}D} \quad . \tag{19}$$

Merlivat (1978) and later Luz et al. (2009) quantified the diffusivity ratios at 1.0251 and 1.0285 for $^1H^2H^{16}O$ or $^1H_2{}^{18}O$ isotopologues, respectively. Dongmann et al. (1974) (but see also Brutsaert, 1975) extended Eq. (19) to different aerodynamic regimes in the air boundary layer delimited by z_{EF} and z_{atm}:

$$\alpha_{\mathrm{K}} = \left(\frac{{}^{j}D}{{}^{i}D}\right)^{n} \tag{19'}$$

where n [-] is an unitless factor ranging from 0.5 (corresponding to fully turbulent conditions) to 1 (fully diffusive), with a value of 2/3 representative of laminar flow conditions. Mathieu and Bariac (1996) proposed to define n in the case of evaporation from soil as a linear function of soil volumetric water content observed in the surface layer (θ_{surf} [L^3 L^{-3}], typically in cm^3 cm^{-3}). n would range between 0.5 when θ_{surf} reaches θ_{sat}, the water content value at saturation, and 1 for $\theta_{\mathrm{surf}} = \theta_{\mathrm{res}}$, the value of residual water content (see Fig. 4):

$$n = \frac{(\theta_{\mathrm{surf}}-\theta_{\mathrm{res}})n_{\mathrm{atm}} + (\theta_{\mathrm{sat}}-\theta_{\mathrm{surf}})n_{\mathrm{soil}}}{\theta_{\mathrm{sat}}-\theta_{\mathrm{res}}} \tag{20}$$

In Mathieu and Bariac's conceptual framework the establishment of a dry soil surface layer results in added isotopic resistance by increasing the relative importance of gaseous molecular diffusion (i.e., in the tortuous soil pores network) in the overall

Preprint. Discussion started: 19 November 2020

Biogeosciences Discussions

transport of water vapour from the EF towards the well mixed atmosphere. In case of a fully water-saturated layer in contact with the free atmosphere, the opposite happens: water vapour leaving the rough surface is preferentially transported in a turbulent manner, leading to smaller *n* values.

3.2.2 Progress and challenges

To calculate δ_E with the Craig and Gordon equation requires simultaneous observations of h_{atm}, T_{EF}, δ_{atm} and δ_{EF}. The first two variables are typically monitored with time domain reflectometry or capacitive sensing. As for δ_{atm}, its value is determined from online or offline isotopic analysis after sampling of the atmospheric water vapour (see section 3.1).

The variable most challenging to estimate is δ_{EF} (Fig. 4b and e). It greatly depends on how soil is sampled at the EF. However, there is no consensus on how this should be done in the literature (see column “Isotopic measurements” of Table A2). Some studies do not precisely report the soil depth, which is considered to be the EF (e.g., Wang and Yakir, 2000; Yepez et al., 2003; Williams et al., 2004). In others studies (Yepez et al., 2005; Zhang et al., 2011; Dubbert et al., 2013) soil profiles are partially or entirely sampled at higher vertical (cm) resolution. Pioneer works on isotopic transport in saturated/non-saturated isothermal soils under steady-state evaporation (Zimmermann et al., 1967; Allison, 1982; Barnes and Allison, 1983) showed that the EF, i.e., the theoretical and continuous boundary between the soil ‘regions’ dominated by either liquid or vapour flow (Fig. 4a and f), is associated with the highest isotopic composition (δ_{soil}^{liq}) value of the liquid soil water (Fig. 4d-f). Later this family of models was extended to unsaturated soil water conditions, non-isothermal conditions, and time-variable evaporation flux (e.g., Barnes and Allison, 1988; Barnes and Walker, 1989). More recently, Braud et al. (2005) and Haverd and Cuntz (2010) implemented isotopic transport in both liquid and vapour phases of the soil, with a coupling to temperature dynamics, in numerically solved SVAT models (SiSPAT-Isotope and Soil-Litter-Iso). All the above-mentioned studies underline the localized character of the EF and the strong isotopic gradient in liquid water at its location. The determination of the EF location may be problematic, especially in the case of a receding EF ($z_{EF} \neq z_{surf}$, Fig 4d), which is generally the case in arid regions between rare precipitation events. Thus, sampling soil roughly from the surface does not allow for a precise determination of δ_{EF} and may lead to errors in δ_E estimates. Rothfuss et al. (2010) could demonstrate for a well-watered soil (i.e., with $z_{EF} = z_{surf}$, Fig 4b) that sampling of only a few cm of soil at the surface and using the corresponding δ_{surf} in Eq. (18) could lead to a significant underestimation of δ_E. This would lead in turn to an overestimation of the T/ET ratio, since negative changes in δ_E translate into positive changes in T/ET, i.e., $\frac{\partial\left(\frac{T}{ET}\right)}{\partial(\delta_E)} = \frac{\delta_{ET}-\delta_T}{(\delta_T - \delta_E)^2} < 0$ (when $\delta_{ET}<\delta_T$, which is generally the case). The spatial (vertical) resolution of the soil sampling should therefore be as high as possible to be able to identify z_{EF} precisely. For their specific case, Brunel et al. 1997 estimated also that the determination of the δ_{EF} value was the greatest source of uncertainty of T/ET.

After sampling in the field, water is recovered from the soil in the laboratory using one of six extraction methods: cryogenic vacuum extraction (Araguás-Araguás et al., 1995; West et al., 2006), azeotropic distillation (Revesz and Woods, 1990), direct vapour equilibration (Wassenaar et al., 2008), high pressure mechanical squeezing (Kelln et al., 2001), centrifugation

Preprint. Discussion started: 19 November 2020

Biogeosciences Discussions

(Mubarak and Olsen, 1976), or microwave extraction (Munksgaard et al., 2014). Other methods include the use of soil liquid water samplers (Wenninger et al., 2010; Sutanto et al., 2012). Finally, δ_{EF} is measured by isotope ratio mass spectrometry (IRMS) or isotope ratio infrared spectrometry (IRIS). Note that an alternative consists in letting soil water directly equilibrate with CO_2 without the need for water extraction (one study: Ferretti et al., 2003; after the method of Scrimgeour, 1995). In this framework, pure CO_2 is injected in the exetainer containing the soil sample following evacuation. After a three day-long water-CO_2 equilibration period, the $\delta^{18}O$ value of CO_2 is measured by isotope mass spectrometry and used to infer that of water at equilibrium. Orlowski et al. (2016a; 2016b) provided evidence from laboratory benchmarks of the different techniques that the isotopic composition of the recovered water could be sensitive to the extraction approach and extraction time as well as to the soil type, and water and organic content values. The same authors also observed that IRMS and IRIS techniques yielded different results in general, and especially for clay loam soil water, which they related to interferences in the absorption spectrum during analysis with the latter technique. In addition, Orlowski et al. (2018) concluded from a worldwide inter-comparison of cryogenic vacuum extraction facilities that the general consensus in the isotopic ecohydrology community, stating that cryogenic vacuum extraction is the standard water recovery technique, should be questioned. Orlowski et al. (2016a; 2016b; 2018) highlighted the limitations of the most popular extraction approach, i.e. based on the combination of destructive sampling and vacuum extraction (69 % of the reviewed studies), which calls for the development of other techniques for a precise quantification of δ_{EF}.

In the last few years Rothfuss et al. (2013), Volkmann and Weiler (2014) and Gaj et al. (2016) successfully validated and tested alternatives to destructive sampling and offline isotopic analysis approaches. They developed systems based on the combination of gas-permeable membranes (e.g., rigid hydrophobic microporous polypropylene, Membrana GmbH, Germany, or polyethylene, Porex Technologies, Aachen, Germany) with laser-based spectrometry for the non-destructive collection of the soil atmosphere and the online monitoring of its water vapour isotopic composition (δ_{soil}^{vap}). For this, the soil atmosphere is either

(i) flushed with a carrier gas (dry synthetic air, i.e., 20.5% in N_2, or 100 % N_2) at low flow rate in the range of 50-100 ml min^{-1} (Rothfuss et al., 2013; Volkmann and Weiler, 2014; Gaj et al., 2016) or

(ii) extracted with a vacuum pump (Volkmann and Weiler, 2014).

Both modi operandi allow for long-term and repeated measurements across the soil profile provided that condensation is avoided in the sampling line. For this, the collected air, which is (quasi-)saturated with water vapour, is diluted with the carrier gas and the sampling lines are heated, if necessary (Quade et al., 2019; Kühnhammer et al., 2019). Rothfuss et al. (2013) observed near-isotopic equilibrium conditions between liquid and vapour in the soil pore space, and provided temperature calibration equations yielding results analogous to those of Majoube (1971) and Horita and Wesolowski (1994) for converting δ_{soil}^{vap} into δ_{soil}^{liq} values. They further show that isotopic equilibrium conditions still prevailed at low soil volumetric water content, possibly also for soil water vapour relative humidity values lower than one. Their method was successfully applied to laboratory experiments with sand (Gangi et al., 2015; Rothfuss et al., 2015) and silt loam (Quade et al., 2018). Oerter et al.

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

(2017) compared $\delta_{\mathrm{soil}}^{\mathrm{liq}}$ values estimated with the monitoring method of Rothfuss et al. (2013) on the one hand, and the direct equilibrium and vacuum extraction methods on the other hand. They found a good correlation between the two approaches (root mean square error – RMSE equal to 0.6 ‰ for $\delta^{18}O$ and within 1.7-3.1 ‰ for δ^2H). Volkmann and Weiler (2014) tested their own design of a water vapour probe under field conditions and could show that it produced $\delta_{\mathrm{soil}}^{\mathrm{liq}}$ values in agreement with those following destructive sampling and isotopic analysis with the direct equilibration method (Garvelmann et al., 2012). The inter-method (destructive vs. non-destructive) RMSE values were comparable to the intra-method variability of soil water δ-values. The latter variability could not be disentangled into systematic methodological error and natural (lateral) heterogeneity in soil water isotopic composition. Kübert et al. (2020) conducted a comparison study of the method of Rothfuss et al. (2013) with cryogenic vacuum extraction and centrifugation during an irrigation pulse-labelling experiment in a semi-natural temperate grassland. They highlighted that the non-destructive method could capture temporal dynamics of the isotopic composition, while destructive sampling included both the temporal change and spatial heterogeneity.

To date there are two ET partitioning studies, in which δ_{E} was determined from non-destructive isotopic analysis using soil liquid water-water vapour equilibration. Quade et al. (2019) applied the method of Rothfuss et al. (2013) in a sugar-beet field in a temperate climate (Germany), while Gaj et al. (2016) used commercially available soil gas probes (BGL-30, METER Group, Munich, Germany), following the same modus operandi as Volkmann and Weiler (2014), during a field study in central Namibia under semi-arid conditions. Such applications are promising for the specific purpose of partitioning ET, as they provide insights into sub-daily dynamics of δ_{E} from the online assessment of the positioning and isotopic composition of water at the EF. However, one noticeable disadvantage is the need for deploying a laser spectrometer at the experimental site. A possible way around has been lately proposed by Havranek et al. (2020) as a compromise: water vapour samples are collected and stored automatically in flasks from the soil profile in the field following the approach of Rothfuss et al. (2013) and transported back to the laboratory where the isotopic analyses are performed.

Another important factor that influences the precision of δ_{E} estimates is the choice of the value of the kinetic fractionation factor α_{K}. Only a handful of studies attempted to estimate or model α_{K} for soil E. Braud et al. (2009) simulated α_{K} values during long-term laboratory experiments with the SVAT model SiSPAT-Isotope. They found a decreasing trend in α_{K} value from saturated to unsaturated soil conditions, which contradicts the model of Mathieu and Bariac (1996). Results similar to the study by Braud et al. (2009a) were obtained by Rothfuss et al. (2015) during a long-term soil column laboratory experiment. Quade et al. (2018) tested two different methods for quantifying α_{K} during a series of bare soil evaporation experiments on monoliths (100 L soil volume) under semi-controlled conditions, i.e.,

(i) by inversion of the Craig and Gordon equation (Eq. (18)) in a single isotope-framework (i.e., based on either $\delta^{18}O$ or δ^2H values) with input variables h_{atm}, T_{EF}, δ_{atm}, δ_{EF}, and δ_{E};

(ii) by inversion of the Craig and Gordon equation in a dual isotope-framework. More specifically, α_{K} is determined from the approximation of the slope of the soil E line ($S_{\mathrm{E}}[-] = \Delta\delta^2\mathrm{H}_{\mathrm{soil}}^{\mathrm{liq}}/\Delta\delta^{18}\mathrm{O}_{\mathrm{soil}}^{\mathrm{liq}}$) in a [$\delta^{18}O$, δ^2H] coordinate system following Gat (2000):

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

$$S_{\mathrm{E}}(t) = \frac{\left[h(t)\left(\delta_{\mathrm{atm}}(t) - \delta_{\mathrm{EF}}(t-1)\right) + \varepsilon_{eq}(t) + \Delta\varepsilon(t)\right]_{^2H}}{\left[h(t)\left(\delta_{\mathrm{atm}}(t) - \delta_{\mathrm{EF}}(t-1)\right) + \varepsilon_{eq}(t) + \Delta\varepsilon(t)\right]_{^{18}O}}, \tag{21}$$

with t the time stamp and $\Delta\varepsilon$ [-], the so-called kinetic effect, is defined as

$$\Delta\varepsilon = (1 - h_{\mathrm{atm}})\left({}^{j}D/\,{}^{i}D - 1\right)n. \tag{22}$$

with superscripts i and j standing for the least and most abundant isotopologues, respectively. Equation (21) is solved in an implicit manner, in other words, S_{E} values simulated for time stamp t depend on δ_{EF} observation made at time stamp (t –1). The n value is then extracted from Eq. (21) from the confrontation of measured and simulated S_{E}, and finally fed into Eq. (19') to retrieve α_{K} values. Quade et al. (2018) showed that α_{K} could not be considered as a constant value solely depending on flow conditions as proposed by Dongmann et al. (1974) or determined from soil water content following Mathieu and Bariac (1996) (Eq. (20)). The second approach yielded α_{K} values in agreement with the literature (e.g., Merlivat, 1979). Quade et al. (2018) concluded that turbulent transport still played a significant role during the evaporation process, also under non-saturated conditions. These studies show that further sensitivity analyses of α_{K} to environmental conditions are needed to provide realistic estimates of δ_{E} and ultimately of T/ET ratios. To our knowledge, there is no ET partitioning study in the field where α_{K} was considered to dynamically change (other than via the model of Mathieu and Bariac, 1996) depending on the contribution of air turbulence to water vapour transport in the free and canopy atmosphere, e.g., from measurements of the wind profile within and above the canopy (Brutsaert, 1975).

Another source of uncertainty arises from a lack of precise knowledge of the state of water vapour saturation at the EF. In the Craig and Gordon equation, the kinetic fractionation factor is weighed by the term ($h_{\mathrm{EF}} - h_{\mathrm{atm}}$) where h_{EF} is generally assumed equal to 1, representative of saturated conditions at the EF. However, this assumption may not stand for dry soils considering the relationship between soil water matric potential ψ_{EF} [M L^{-1} T^{-2}, typically expressed in hPa or cm water height] and pore space relative humidity at the EF (h_{EF}), as given by the Kelvin law:

$$h_{\mathrm{EF}} = \exp\left(\frac{\psi_{\mathrm{EF}} M_{\mathrm{w}}}{\rho_{\mathrm{w}} R_{\mathrm{gas}} T_{\mathrm{EF}}}\right). \tag{23}$$

M_{w} and ρ_{w} [M L^{-3}] are the molar and volumetric masses of water, respectively, and R_{gas} [M L^{-1} T^{-3}] the universal gas constant. Table 1 presents three different degrees of saturation of the soil vapour phase under isothermal conditions (T_{EF} = 20°C) and their corresponding hydrogen and oxygen isotopic composition values of the E flux (δ^2H_{E} and $\delta^{18}O_{\mathrm{E}}$). A decrease in h_{EF} from 100 to 99.9 %, corresponding to an increase in the absolute ψ_{EF} value from 0 to 1000 hPa (i.e., from saturation to pF=3) leads, for example, to an increase of 1.5 ‰ in δ^2H_{E} and $\delta^{18}O_{\mathrm{E}}$. A decrease in h_{EF} from 100 to 99.3 (increase from 0 to 10000 hPa, i.e. pF=4) would translate into an increase of 13 ‰ in δ^2H_{E} and $\delta^{18}O_{\mathrm{E}}$. Both δ^2H_{E} and $\delta^{18}O_{\mathrm{E}}$ are affected in the same way by the change in value of the factor $\frac{1}{\alpha_{\mathrm{K}}(h_{\mathrm{EF}} - h_{\mathrm{atm}})}$ (see Eq. (18)), i.e., approximatively 2.0‰ per 0.1% relative humidity. This may have a noticeable effect on the computation of the T/ET ratio, especially for $\delta^{18}O$, for which the difference $\delta_{\mathrm{T}} - \delta_{\mathrm{E}}$ is usually smaller than for δ^2H.

3.3 Isotopic composition of transpiration

3.3.1 Methods

The determination of the isotopic composition of T, δ_T, in the reviewed literature is mainly depending on the underlying hypothesis on isotopic steady or non-steady state (NSS) of T. While 42 % of all reviewed studies assume isotopic steady state (ISS), in other words that δ_T is time-invariant, 58 % do not make such an assumption but assume a transient state, i.e. NSS (Fig. 1j). This has substantial implications for the materials and methods used for the determination of δ_T. In the ISS approach, δ_T is directly inferred from the isotopic value of the leaf water source (δ_{xyl}), i.e., the water in the xylem vessels supplying the leaf water reservoir. This assumption is based the fact that at ISS the flux density rate of the least abundant (${}^{i}F_{xyl}$) (respectively most abundant, ${}^{j}F_{xyl}$) isotopologue entering the leaf equals the flux density rate of the least abundant (${}^{i}F_{T}$) (most abundant, ${}^{j}F_{T}$) isotopologue leaving it by transpiration:

$$ {}^{j}F_{xyl} = {}^{j}F_{T}, \tag{24a} $$

$$ {}^{i}F_{xyl} = {}^{i}F_{T} \Rightarrow {}^{j}F_{xyl}\delta_{xyl} = {}^{i}F_{T}\delta_{T} \Rightarrow \delta_{xyl} = \delta_{T}. \tag{24b} $$

Note that in this framework an instantaneous change in ${}^{j}F_{T}$, if compensated by a corresponding change in ${}^{j}F_{xyl}$, should maintain the relationship $\delta_{xyl} = \delta_T$ (Eq. (24b)). In reality, a change in ${}^{j}F_{T}$, due to variations in environmental factors (e.g., vapour pressure deficit of the free atmosphere and incoming solar radiation) implies a change in root water uptake depth profile, which in turn affects δ_{xyl} in case of a heterogeneous distribution of the soil water isotopic composition (Rothfuss and Javaux, 2017). A new ISS is eventually reached, depending on the leaf water turnover time, i.e. the ratio of leaf water volume and transpiration rate (Dongmann et al., 1974; see below). To access xylem water, authors destructively sample stems (e.g., Wei et al., 2018; Quade et al., 2019), branches (e.g., Williams et al., 2004), or root water (Bijoor et al., 2011), and recover their water by, e.g., cryogenic vacuum extraction.

The NSS approach for determining δ_T relies either on direct non-destructive monitoring (i.e., leaf chamber-based measurements, e.g., Wang et al., 2010) or on destructive sampling of plant material and subsequent extraction of water (e.g., Dubbert et al., 2013). In the former case, the modus operandi is the same as when operating ET and E chambers coupled to mass balance equations (see sections 3.1 and 3.2, respectively), except that one single leaf or several leaves are enclosed in the chamber (with a volume ranging from 150 to 190 cm^3 in the literature), rather than the entire plant. It is then generally assumed that the leaf-scale δ_T estimate is also representative for the whole plant (e.g., Good et al., 2014). In the case of destructive sampling, δ_T is modelled on the basis of environmental factors (leaf temperature and free atmosphere relative humidity) and isotopic variables. Two cases can be distinguished:

(i) δ_T is determined from the value of the isotopic composition of the leaf bulk water, δ_L, with the Craig and Gordon equation adapted to plant T (Sun et al., 2014; Hu et al., 2014):

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

$$\delta_{\mathrm{T}} = \frac{1}{\alpha_{\mathrm{K}}(1-h)}\left(\frac{\delta_{\mathrm{L}}+1}{\alpha_{\mathrm{eq}}} - (\delta_{\mathrm{atm}}+1)h\right) - 1; \quad (18')$$

(ii) the isotopic composition of leaf water may not be available, but that of its source, δ_{xyl}. The δ_{T} value is calculated after the relationship of Dongmann et al. (1974), which describes the temporal course of δ_{L} at constant transpiration rate value (i.e., at permanent flow for T). The authors expressed the rate of change in δ_{L} as a function of the instantaneous difference between δ_{xyl} and δ_{T} at time t, by considering the leaf bulk water (delimited by volume per unit leaf area V_{L} [L^3 L^{-2}]) to be transpired into ambient air at permanent flow (i.e., at density rate ${}^{j}F_{\mathrm{T}} = {}^{j}F_{\mathrm{xyl}}$, as in Eq. (24a)):

$$d\delta_{\mathrm{L}} = \frac{{}^{j}F_{\mathrm{T}}}{V_{\mathrm{L}}}\left(\delta_{\mathrm{xyl}}(t) - \delta_{\mathrm{T}}(t)\right)dt \quad (25)$$

By combining Eqs. (18') and (25) and considering that δ_{xyl} is time-invariant, we obtain a first-order differential equation for δ_{L}, which yields after integration to:

$$\delta_{\mathrm{L}}(t) = \delta_{\mathrm{L}}(t \to +\infty) - \left(\delta_{\mathrm{xyl}} - \delta_{\mathrm{L}}(t \to +\infty)\right)\exp\left(-\frac{t}{\tau_{\mathrm{L}}}\frac{1}{\alpha_{\mathrm{eq}}\alpha_{\mathrm{K}}(1-h_{\mathrm{atm}})}\right) \quad (26)$$

where the leaf water turnover time, τ_{L}, is defined as the ratio $\frac{V_{\mathrm{L}}}{{}^{j}F_{\mathrm{T}}}$ and $\delta_{\mathrm{L}}(t \to +\infty) = \delta_{\mathrm{L\_ISS}}$, the isotopic composition of leaf bulk water when an isotopic steady state is reached. The latter term is expressed as:

$$\delta_{\mathrm{L\_ISS}} = \alpha_{\mathrm{eq}}\left[\alpha_{\mathrm{K}}(1-h)(\delta_{\mathrm{xyl}}+1) + h_{\mathrm{atm}}(\delta_{\mathrm{atm}}+1)\right] - 1. \quad (27)$$

By (i) noting $\alpha_{\mathrm{eq}} = \varepsilon_{\mathrm{eq}} + 1$ and $\alpha_{\mathrm{K}} = \varepsilon_{\mathrm{K}} + 1$, where $\varepsilon_{\mathrm{eq}}$ and ε_{K} [-] are the equilibrium and kinetic fractionations, respectively, and (ii) dropping terms with products $\varepsilon_{\mathrm{eq}} \times \varepsilon_{\mathrm{K}}$, we obtain the following expression of the difference in isotopic composition between leaf and source waters at ISS:

$$\delta_{\mathrm{L\_ISS}} - \delta_{\mathrm{xyl}} = \varepsilon_{\mathrm{eq}} + \varepsilon_{\mathrm{K}} + h_{\mathrm{atm}}(\delta_{\mathrm{atm}} - \delta_{\mathrm{xyl}} - \varepsilon_{\mathrm{K}}) \quad (27')$$

We note that Eq. (27') is the inversion of the Craig and Gordon equation at ISS, i.e., when $\delta_{\mathrm{T}} = \delta_{\mathrm{xyl}}$. Finally, δ_{T} is computed with the NSS-Craig and Gordon equation, i.e., Eq. (18'). Eq. (26) states that, at permanent state for transpiration, the degree of attainment of ISS conditions in the leaf is a function of time, leaf internal dynamics (τ_{L}) and (isotopic) aerodynamic boundary conditions. The formula of Dongmann et al. (1974) requires two additional parameters as compared to the more 'straightforward' application of the Craig and Gordon equation, namely leaf transpiration (${}^{j}F_{\mathrm{T}}$) and volume (V_{L}), both labour-intensive to obtain and associated with high uncertainties.

Both case scenarios (i) and (ii) make the assumption that leaf water is a well-mixed reservoir, in other words that only convective transport of the water isotopologues occurs, leading to $\delta_{\mathrm{L}} = \delta_{\mathrm{Lts}}$, where δ_{Lts} is the isotopic composition of water at the leaf transpiration sites. However, a number of studies reported strong isotopic variations within the leaf water pool (i.e., among different compartments such as leaf veins, cell walls, and symplastic water, see e.g., Yakir et al., 1989; Wang et al., 1998; 1994; Bariac et al., 1994), which can be related to hydraulic separation of water pools and diffusive transport from the

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

Biogeosciences Discussions

transpiration sites towards the petiole of the leaf. Another explanation may be found in the heterogeneity in opening of the leaf stomata (Farquhar et al., 2007). More specifically, δ_{Lts} should be significantly higher than the bulk leaf water isotopic composition value δ_{L}, which leads to an underestimation of δ_{T} by the direct application of the Craig and Gordon equation. Walker et al. (1989), Walker and Brunel (1990), and Flanagan et al. (1991) considered in a first approach two distinct water pools in the leaf, one in isotopic equilibrium with water vapour in the stomatal cavity (of isotopic composition $\delta_{\mathrm{Lts\_ISS}}$) and one isotopically undistinguishable from xylem water (of isotopic composition δ_{xyl}) in respective proportions p and (1–p). In these three studies, an analogous expression to Eq. (27') is used where p is accounted for:

$$\delta_{\mathrm{Lts\_ISS}} - \delta_{\mathrm{xyl}} = \frac{\delta_{\mathrm{L_{ISS}}} - \delta_{\mathrm{xyl}}}{p} = \varepsilon_{\mathrm{eq}} + \varepsilon_{\mathrm{K}} + h_{\mathrm{atm}}\left(\delta_{\mathrm{atm}} - \delta_{\mathrm{xyl}} - \varepsilon_{\mathrm{K}}\right) \quad (27'')$$

They suggested that there was a midday maximum for T density rate from the corresponding minimum value for p. Cernusak et al. (2002) and Farquhar and Cernusak (2005) proposed a similar equation to that of Dongmann et al. (1974) for the evaporative isotopic enrichment in leaves in NSS conditions, but without considering the leaf water volume per unit area constant in time. Eq. (25) becomes in their case:

$$d(V_{\mathrm{L}}\delta_{\mathrm{L}}) = {}^{j}F_{\mathrm{T}}\left(\delta_{\mathrm{xyl}}(t) - \delta_{\mathrm{T}}(t)\right)dt. \quad (25')$$

By replacing δ_{xyl} and δ_{T} in the right hand-term of Eq. (25') by the ISS- and NSS-Craig and Gordon equation forms, respectively, the authors give an expression relating the rate of change of δ_{L} with the difference between $\delta_{\mathrm{Lts\_ISS}}$ and δ_{Lts}:

$$\frac{d(V_{\mathrm{L}}\delta_{\mathrm{L}})}{dt} = \frac{{}^{j}\chi_{\mathrm{int}}}{{}^{j}r \times \alpha_{\mathrm{K}}\alpha_{\mathrm{eq}}}\left(\delta_{\mathrm{Lts\_ISS}} - \delta_{\mathrm{Lts}}\right), \quad (28)$$

where ${}^{j}\chi_{\mathrm{int}}$ and ${}^{j}r$ are the water vapour mixing ratio in the intercellular space and, as in section 3.2, the resistance to vapour flow of the ${}^{1}H_2{}^{16}O$ isotopologue in air, respectively. It is therefore possible, by fitting the time course of the bulk leaf water isotopic composition δ_{L} to deduce δ_{Lts}, on the basis of which δ_{T} is finally determined using Eq. (18') (Yepez et al., 2005). α_{eq} is, as in section 3.2, calculated following the closed-form equations of, e.g., Horita and Wesolowski (1994) (Eq. (17)). As for α_{K}, its expression is adapted to include the series of flow resistances of water vapour isotopologues inside the stomatal cavity/through the stomatal opening (${}^{i}r_{\mathrm{sto}}$ and ${}^{j}r_{\mathrm{sto}}$ [T L^{-1}]) and in the leaf boundary layer (${}^{i}r_{\mathrm{bdl}}$ and ${}^{j}r_{\mathrm{bdl}}$ [T L^{-1}]) (Jarvis, 1976; Stewart, 1988). Farquhar et al. (1989) (and see also Cernusak et al., 2005; Farquhar et al., 2007) considered that molecular diffusion drives the transport of the different water vapour isotopologues in the first case, and that turbulence prevails in the second, leading to n exponent values of 1 and ½, respectively (Dongmann et al., 1974; Eq. (19')). In this framework, α_{K} is decomposed as:

$$\alpha_{\mathrm{K}} = \frac{{}^{i}r}{{}^{j}r} = \frac{{}^{i}r_{\mathrm{sto}} + {}^{i}r_{\mathrm{bdl}}}{{}^{j}r_{\mathrm{sto}} + {}^{j}r_{\mathrm{bdl}}} = \frac{\left(\frac{{}^{j}D}{{}^{i}D}\right)^{1} \cdot {}^{j}r_{\mathrm{sto}} + \left(\frac{{}^{j}D}{{}^{i}D}\right)^{1/2} \cdot {}^{j}r_{\mathrm{bdl}}}{{}^{j}r_{\mathrm{sto}} + {}^{j}r_{\mathrm{bdl}}} \quad (29)$$

Cuntz et al. (2007) proposed a general iterative solution of Dongmann et al. (1974)'s formulation revisited by Cernusak et al. (2002) (Eq. (28)) under various scenarios depending on considerations regarding leaf water reservoir isotopic homogeneity ($\delta_{\mathrm{L}} = \delta_{\mathrm{Lts}}$ or $\delta_{\mathrm{L}} \neq \delta_{\mathrm{Lts}}$) and volume ($dV_{\mathrm{L}}/dt = 0$ or $dV_{\mathrm{L}}/dt \neq 0$). Dubbert et al. (2013) applied their solution in the case of an isotopically well-mixed leaf water pool transpiring at constant volume, and expressed the incremental change in δ_{L} from time step t to $t+dt$ as:

$$\delta_{\mathrm{L}}(t+dt) = \delta_{\mathrm{L\_ISS}} + \left(\delta_{\mathrm{L}}(t) - \delta_{\mathrm{L\_ISS}}\right) \exp\left(-\frac{g_{\mathrm{s}}{}^{j}\chi_{\mathrm{int}}}{\alpha_{\mathrm{K}}\alpha_{\mathrm{eq}}V_{\mathrm{L}}} dt\right) \quad (30)$$

where g_{s} [L T^{-1}] is the total stomatal conductance.

3.3.2 Progress and challenges

The isotopic composition of T may be derived under NSS conditions from plant chamber measurements following Eq. (7) (section 3.1), either at the leaf level or at the branch level. While most studies developed and operated custom-made chambers, only few (e.g., Wang et al., 2010) used commercially available leaf chambers (e.g., LICOR-6400, Nebraska, USA). Chamber measurements have several disadvantages as discussed in section 3.1, but are essential for monitoring δ_{T} directly without relying on additional modelling steps using either δ_{xyl} or δ_{L}, the determination of which, i.e., based on destructive sampling and water recovery with, e.g., cryogenic vacuum extraction, is also associated with uncertainty (e.g., Orlowski et al., 2016a; 2016b; Millar et al., 2018). The important two features of the chamber-based method are that it does not require the assumption of ISS, and that it allows for repeated (i.e., non-destructive) measurements on the same leaf or ensemble of leaves during the course of the day.

A novel type of non-destructive method, first published by Volkmann et al. (2016) and lately by Marshall et al. (2020), could enable monitoring δ_{T} of trees at an equivalent temporal resolution and even greater temporal coverage than with leaf- or plant-scale chamber systems. In the former study, several 10-mm outer diameter gas probes designed after Volkmann and Weiler (2014) (see section 3.2) were inserted into pre-drilled holes in the trunk sapwood of two individuals of *Acer campestre* L. The probes were positioned at breast-height in various azimuths. By assuming isotopic equilibrium between the water vapour sampled by the probe and flushed to the laser spectrometer and the xylem (liquid) water, the authors computed δ_{xyl} values from the temperature-dependent relationships given by, e.g., Majoube (1971) and Horita and Wesolowski (1994). For comparison, tree sapwood was destructively sampled and its water isotopic composition measured with IRMS after cryogenic vacuum extraction. A good agreement was found between online measurements and offline analysis of xylem water hydrogen isotopic composition. The inter-method bias regarding the determination of xylem water δ^{18}O was thought to be due to spectral interferences during online analysis with the laser spectrometer. The experimental natural conditions did not allow the authors to conclude if differences in δ_{xyl} among the different gas probes reflected actual diurnal variations in root water uptake or preferential connection between xylem vessels and specific parts of the root system that were not affected by the labelling pulse. The authors underline the difficulty with their experimental design to precisely measure the temperature of equilibration

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

in the gas probe (needed for converting sample water vapour to xylem water isotopic composition), due to the high lateral temperature gradient and its daily course. Marshall et al. (2020) tested a cruder way (which they entitled the "Borehole Equilibration") to sample water vapour originating from xylem water of two pine tree species (*Pinus sylvestris* L. and *Pinus pinea* L.) under semi-controlled conditions. Contrary to Volkmann et al. (2016), the authors (i) did not use a gas probe but simply connected a hole drilled horizontally through the trunk to a laser spectrometer with gas sampling lines. Furthermore, (ii) the experiments were performed in hydroponic water solutions to enable a quasi-instantaneous change of the isotopic composition of the water source, thereby setting defined lower isotopic boundary conditions for further modelling efforts. To test the practicability of the method, the experimental results were confronted with a 'Dongmann-like' NSS formulation of the isotopic composition of the water vapour stream, in which the geometry and its consequence on the diffusion from the borehole surface and on the establishment of laminar flow transport were explicitly accounted for. With their model, the authors tested whether the sampled water vapour was in isotopic equilibrium with xylem water or was the product of evaporation from it. It was shown that the prevalence of a full isotopic equilibrium was a reasonable assumption and that the flow-through time (i.e., borehole volume divided by the flow rate) was 20 times greater than the time needed for diffusion of water vapour originating from the xylem vessels into the laminar flow region in the middle of the borehole section. Both methods present a drastic advancement in isotopic analysis of xylem water and have great potential in the context of ET partitioning of forest ecosystems, on the pivotal condition that the steady state assumption ($\delta_{\mathrm{xyl}} = \delta_{\mathrm{T}}$) applies during periods of measurements. The long-term applicability of the method, i.e., the ability of the investigated tree species to withstand the invasive and destructive installation of the probe, still needs to be proven at this point.

While the coupling between gas-exchange chambers and laser spectrometers has the advantage of directly measuring δ_{T}, the aforementioned destructive sampling method and in-situ monitoring technique quantify δ_{L} or δ_{xyl}, therefore may require a modelling step to obtain δ_{T}. While a number of studies (e.g., Zhou et al., 2018; Wei et al., 2015; Aouade et al., 2016; Volkmann et al., 2016) assume ISS and hence argue that δ_{xyl} equals δ_{T}, there is growing evidence that plants rarely reach ISS throughout the day (Simonin et al., 2013; Dubbert et al., 2014b; 2017). Moreover, the leaf water turnover time, which can effectively be described by stomatal conductance (g_{s}), vapour pressure deficit and leaf water volume, is species-specific and ranges from several minutes to several hours (Song et al., 2015). As the leaf water turnover time describes the necessary time for leaf water to reach ISS (see exponent terms in Eqs. (26) and (30)), ISS can either be observed for large parts of the day (e.g., in many herbaceous species) or not at all (e.g., in plant species strongly controlling their g_{s}, see Dubbert et al. (2017) and Dubbert and Werner (2019) for an overview). Therefore, the validity of assuming ISS for the purpose of ET partitioning will largely depend on the desired temporal scale: considering NSS is definitely necessary at sub-diurnal to diurnal scale, but unimportant at larger time scales. In case NSS is likely to occur, δ_{T} can be modelled using a 'Dongmann version' of the Craig and Gordon equation, as shown in the previous sub-section 3.3.1 (Dongmann et al., 1974). However, this complicates the partitioning approach considerably in comparison to direct chamber measurements of δ_{T}, as a large number of additional observations are necessary. In particular, g_{s} and the canopy temperature are important input parameters. Therefore, the use of chamber measurements is highly recommended in any case.

The choice of an appropriate method for measuring the isotopic composition of unfractionated xylem water is crucial for a correct determination of δ_T. For example, herbaceous, grass or crop species do not have suberized stems, thus destructive sampling would have to rely on leaf water sampling or sampling the plant culm belowground, which is highly destructive and not possible on plots of common size. Moreover, while the majority of studies still provide evidence for an unfractionated root uptake and transport of xylem water through plants, there is growing evidence of fractionation of xylem water during times with low transpiration rate (drought condition, see e.g., Martin-Gomez et al., 2017) for deciduous species.

4 Possible ways forward

The isotopic methodology for partitioning ET relies on a number of possible combinations of different techniques, which differ in numerous aspects. While some of them are based on destructive sampling and water recovery using one of the aforementioned methods (e.g., cryogenic vacuum extraction, direct liquid-vapour equilibration, see section 3.2) and *a posteriori* analysis in the laboratory (e.g., for determination of δ_E using the Craig and Gordon equation), other methods are non-destructive, provide online measurements and do not include a strong modelling component (e.g., determination of δ_T with plant chambers with one of two mass-balance techniques). Destructive approaches do not require the handling of soil, plant, or soil & plant chambers, nor the deployment of a laser spectrometer along with its conditioning system in the field. They should also allow for capturing the inherent spatial variability with repeated sampling (however, at the cost of long hours spent in sample preparation and water extraction). Non-destructive methods, such as chambers, may on the other hand provide environmental conditions for the enclosed plant that are not representative of ambient conditions.

Up to now only indirect methods, e.g., based on Scanlon and Kustas (2010), might be able to provide continuous and sub-daily estimates of T/ET. Some methods, such as the Keeling plot technique, can provide long-term continuous estimates of δ_{ET} once a meteorological mast is installed in the field. It is, on the other hand not advisable to enclose a plant in a chamber over longer time periods. Within the realm of destructive techniques, the user may assume ISS or test its existence when determining the isotopic composition of T. The techniques, with which δ_{ET} is estimated generally differ in terms of spatial significance as compared to those for determining δ_E and δ_T. Estimates of δ_{ET} obtained either with the EC, Keeling plot, or flux-gradient technique are thought to be representative at the field scale (e.g., as represented by the EC footprint). Note that this is also a problem encountered in (non-isotopic) instrumental approaches for partitioning ET, including EC, micro-lysimeters and soil chambers (Kool et al., 2014). To account for these discrepancies in spatial representativeness, several micro-lysimeters and (if possible automated) chambers are deployed on site, e.g., within the framework of global networks (e.g., FLUXNET; Law et al., 2002). On the contrary, there is no consensus to date on a common methodological ground for partitioning ET in the field on the basis of water stable isotopic measurements, depending on the type of land cover and use (agricultural, grassland or forest ecosystems).

Preprint. Discussion started: 19 November 2020

It is the authors' belief that non-destructive and online methods integrated into automated sampling platforms and part of long-term (e.g., multi-year) water flux observatories should be preferred over destructive and punctual assessments of T/ET ratios. In this (ideal) framework, we propose that

(i) the seminal effort in applying the EC technique by Griffis et al. (2010) should be continued to provide half-hourly and continuous ecosystem-scale δ_{ET} estimates. The δ_{ET} estimates obtained with the EC technique should be corroborated/confronted with the Keeling plot and the flux-gradient approaches to identify possible scale-dependent disparities in surface isotopic signals as in Good et al. (2012);

(ii) δ_{E} should be monitored by installing gas-permeable membranes or tubing (see section 3.2) in the upper layers of the soil, depending on site-specific knowledge regarding the receding of the EF. While the gas probes of Volkmann and Weiler (2014) and Gaj et al. (2016) are better-suited for insertion at different locations in a soil profile, the membrane tubing used by Rothfuss et al. (2013), Oerter and Bowen (2019) and Kübert et al. (2020) allow to cover more ground surface by using a customized length of tubing. This should help to increase the representativeness of the δ_{E} value estimated from the soil water vapour isotopic composition and the use of the Craig and Gordon equation. When using the model of Craig and Gordon (1965), authors should systematically perform sensitivity analyses of

a. the depth of the EF and its water isotopic composition, and

b. the value of the kinetic fractionation factor, α_{K}.

These analyses will provide insights into the uncertainty of the T/ET ratio, in addition to the uncertainty originating from the solution of the two end-member equation (Eq. (1)) (Rothfuss et al., 2010). This is, however, under-investigated according to our literature review. The α_{K} value may be derived in a dual-isotope space using the formulation of Gat (2000), rather than based on unclear assumptions regarding the type of transport (molecular diffusion, laminar or turbulent transport) controlling the flow of water stable isotopologues (see section 3.2). As a side note (and without a proof of concept for this), the δ_{E} value may be directly determined in the case of a well-developed dry surface on the basis of non-destructive measurements of the soil water vapour isotopic composition ($\delta_{\mathrm{soil}}^{\mathrm{vap}}$) at two depths ($z_1$ and z_2) located between the EF and the soil surface. For this, the Craig and Gordon equation may be used without the need to locate the soil EF nor to assume liquid-vapour equilibrium:

$$\delta_{\mathrm{E}} = \frac{\delta_{\mathrm{soil}}^{\mathrm{vap}}(z_1)\cdot h(z_1) - \delta_{\mathrm{soil}}^{\mathrm{vap}}(z_2)\cdot h(z_2)}{\frac{j_D}{i_D}(h(z_1)-h(z_2))} - 1; \quad (18'')$$

(iii) several transparent flushed plant-size chambers should be operated at the study site to characterize the *in situ* natural lateral heterogeneity of δ_{T}, due to differences in root water uptake, plant physiological state, as well as lateral heterogeneity in soil water isotopic composition profiles. Developments should be made towards designing chambers able to mimic the dynamic states of ambient air (temperature and relative humidity, wind turbulence) to avoid biases in δ_{T} estimation. This could be done by cooling of the inlet air to avoid over-heating of the air inside the chamber, and an adaptive active ventilation system. In situations where parts of the field are bare, e.g., between crop rows, soil

https://doi.org/10.5194/bg-2020-414
Preprint. Discussion started: 19 November 2020

chambers should be installed as well to evaluate differences in δ_E between areas covered or not covered with vegetation;

(iv) the methods for monitoring of δ_{xyl} and its potential use in determining δ_T (that is, by assuming ISS conditions) have been tested and validated with tree species exclusively. The same principle is yet to be minimized and applied to crops able to survive the installation and carry the instrumentation, such as a well-developed maize plant.

Lastly, the lift system principle, as operated by Noone et al. (2013), Mayer et al. (2009), and recently for agricultural crops by Ney and Graf (2018) has the potential to provide half-hourly concomitant values of δ_{ET}, δ_T , and δ_E in the field. The principle is illustrated in Fig. 5, further developing that of Yepez et al. (2003). The Keeling plot technique is applied to data collected at high vertical resolution (ultimately implying high-frequency data acquisition of the analyser, typically equal or greater than 5Hz, see Ney and Graf, 2018) in three distinct atmospheric regions, i.e. (i) the region spreading from the fully turbulent atmosphere to the canopy height, (ii) the region comprised between canopy height (here fixed at 1.25 m) and the local maximum in δ_{atm}, and (iii) the region delimited by the δ_{atm} local maximum and the ground level (Fig 5a). The y-intercepts of the three Keeling plots give the concomitant values of the isotopic compositions of ET (Fig. 5b), T (Fig. 5c) and E (Fig. 5d). In this synthetic experiment, which cannot be construed as a proof of concept, $\delta^{18}O_{ET}$, $\delta^{18}O_T$, and $\delta^{18}O_E$ are equal to –4.7 (±1.5), –0.7 (±1.4), and –18.5 (±0.4) ‰, respectively, corresponding to a T/ET of 77 (±10) %.

5 Conclusion

Water stable isotopes are often described in the present literature compilation as “powerful” (or “insightful”) tools for separating evaporation and transpiration fluxes. However, the number of ET partitioning studies, which the authors listed here, remains low when compared to the number of publications utilizing water stable isotopes for, e.g., determining plant water use strategies (30 versus 158 over the period 1990-2016, see Rothfuss and Javaux, 2017). The apparent contrast between the announced potential and the number of study cases is explained partly by both the complexity and multifaceted character of the isotopic methodology. Unfortunately, and despite great efforts of the researchers, the spatial representativeness as well as temporal extent of the obtained T/ET data series are usually not well comparable with those of other non-isotopic methods (see Figure 1g).

The authors believe that, while ultimately increasing the complexity in terms of modus operandi, novel non-destructive monitoring methods are key to providing long-term T/ET data at the plot to the field scale and to upscaling local process understanding to address large-scale ecohydrological issues in a changing climate.

Table 1. Effect of the consideration of non-saturated soil water vapour phase on the estimation of the isotopic composition of evaporation (δ_E) using the model of Craig and Gordon (1965). Conditions of pure diffusive water vapour transport (n=1) prevail, leading to values of the kinetic fractionation factor (α_K) of 1.0251 und 1.0285 for ^2H and ^{18}O. Values for T_{EF}, h_{atm}, δ_{EF} and δ_{atm} are chosen exemplarily.

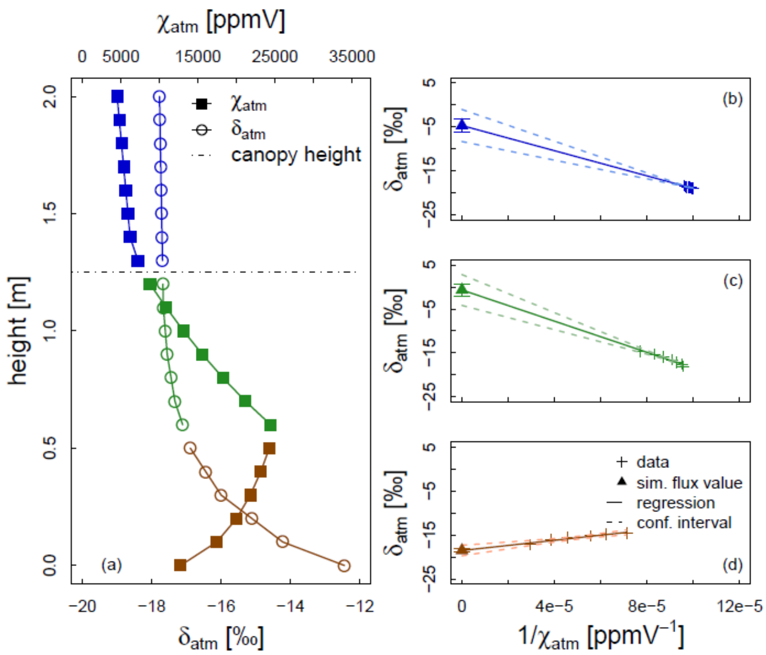

Figure 5. One example of application of the Keeling (1958) plot technique to synthetic data that would be collected with a field-deployable lift at high vertical resolution (0.1 m) (for implications on measurement frequency, which also needs to be high (≥5Hz), see sections 3.1 and 4 of Ney and Graf (2018)). The oxygen isotopic compositions of evapotranspiration, transpiration, and evaporation are estimated by the values of the y-intercepts of the linear regressions between the isotopic composition of the atmospheric water vapour (δ_{atm}) and the inverse of the water vapour mixing ratio (χ_{atm}) in three non-overlapping regions, i.e., (i) the "free atmosphere" (indicated by the blue symbols), (ii) the region spreading from the canopy height to the height of local maximum in δ_{atm} (green symbols), and (iii) the region delimited by the δ_{atm} local maximum height and the ground level (brown symbols). Also shown: 95 % confidence interval envelopes of the linear regressions (dashed lines) as well as error bars (1 standard error) of the y-intercepts.

Table A1: List of Symbols and Abbreviations used in the main document and Table A2

Symbol or abbreviation	Description	Dimension or unit
C_{atm}, C_{bg}, C_{ET}	Atmospheric and background water vapour concentration, rise in atmospheric water vapour concentration due to evapotranspiration flux	M L^{-3}
E, E_{Lys}, E_{pot}	Soil evaporation rate, soil evaporation (micro-lysimeter), potential evaporation	L^3 T^{-1}
EC	Eddy Covariance	
ET	Evapotranspiration rate	L^3 T^{-1}
f	Measurement frequency	T^{-1}
F_{ET}, $^jF_{ET}$, ^iF_E, F_E, ^jF_E, ^jF_T, ^iF_T, $^jF_{xyl}$, $^iF_{xyl}$	Evapotranspiration water vapour flux density rate, Evapotranspiration, evaporation, transpiration, and xylem water flux density rates of the rare (i) and abundant (j) isotopologue	L^3 L^{-2} T^{-1}
g_s	Leaf stomatal conductance	mmol m^{-2} s^{-1}
GPP	Gross primary production	M L^{-2} T^{-1}
h_{atm}, h_{EF}	Atmospheric relative humidiy and soil pore space relative humidity at the evaporating front	-
K	Eddy diffusivity of water vapour	L^2 T^{-1}
LAI	Leaf area index	L^2 L^{-2}
L_{ET}	latent heat flux of evapotranspiration	M T^{-3}
M_{atm}, M_w	Dry air and water molecular weight	M L^{-3}
n	Adimensional factor accounting for flow conditions above the liquid water-water vapour equilibrium layer	-
NEE	Net ecosystem exchange	M L^{-2} T^{-1}
P	Precipitation amount	L^3 L^{-2}
p	Proportion of leaf water in isotopic equilibrium with water vapour in the stomatal cavity	-
PPFD	Photosynthetic photon flux density	µmol s^{-1} m^{-2}
Q_s	Sensible heat flux	M T^{-3}
R	Universal gas constant	M L^{-1} T^{-3}
R_{std}, R_{EF}, R_{sat}	Isotopic ratio of the Vienna Standard Mean Ocean Water (V-SMOW), soil water at the evaporating front, and of saturated water vapor	-
R_n, R_s, R_d	Net and solar radiation, and radiation flux density	M T^{-3}
R_{gas}	Universal gas constant	M L^{-1} T^{-3}
^jr, ^ir ^jD, ^iD	Bulk resistances to vapour transport of the rare (i) and abundant (j) isotopologues Molecular diffusivities of the rare (i) and abundant (j) water vapour isotopologues	
S	Sap-flux density	M L^{-2} S^{-1}
T	Transpiration rate	L^3 T^{-1}
T_{atm}, T_{soil}, T_{EF}, T_L, T_{can}	Temperature of the atmosphere, soil, soil at the evaporating front, leaf surface, and canopy atmosphere	°C
T/ET	Transpiration fraction	-
u_{in}, u_{out}	Flow rate measured at the inlet and outlet of a gas exchange chamber	L^3 T^{-1}
v (v_d)	Wind speed (wind direction)	L T^{-1}
VFC	Vegetation fractional coverage	L^2 L^{-2}
VPD	Vapour pressure deficit	P
z, z_{atm}, z_{EF}	Vertical coordinate, atmospheric height, and soil evaporating front depth	M
α_{eq} α_K	Equilibrium isotopic fractionation factor Kinetic isotopic fractionation factor	-

Biogeosciences Discussions

Acknowledgements

Youri Rothfuss and Maren Dubbert acknowledge funding by the German Science Foundation DFG (grant numbers RO 5421/1-1 and #DU1688/1-1). Maria Quade was funded by the German Ministry of Education and Research BMBF within the project IDAS-GHG (Instrumental and Data-driven Approaches to Source Partitioning of Greenhouse Gas Fluxes: Comparison, Combination, Advancement, grant number 01LN1313A).

Competing interests

The authors declare that they have no conflict of interest.

Author contribution

Youri Rothfuss, Maria Quade, and Maren Dubbert reviewed the published literature and prepared the manuscript. All authors reviewed the manuscript.
