**Abstract:** Live fuel moisture content (LFMC) plays a critical role in wildfire dynamics, but little is known about responses of LFMC to multivariate climate change, e.g., warming temperature, $CO_2$ fertilization and altered precipitation patterns, leading to a limited prediction ability of future wildfire risks. Here, we use a hydrodynamic demographic vegetation model to estimate LFMC dynamics of chaparral shrubs, a dominant vegetation type in fire-prone southern California. We parameterize the model based on observed shrub allometry and hydraulic traits, and evaluate the model's accuracy through comparisons between observed and simulated LFMC of three plant functional types (PFTs) under current climate conditions. Moreover, we estimate the number of days per year of LFMC below 79% (which is a critical threshold for wildfire danger rating of southern California chaparral shrubs) from 1960 to 2099 for each PFT, and compare the number of days below the threshold for medium and high greenhouse gas emission scenarios (RCP4.5 and 8.5). We find that climate change could lead to more days per year (5.2-14.8% increase) with LFMC below 79% between the historical (1960-1999) and future (2080-2099) periods, implying an increase in wildfire danger for chaparral shrubs in southern California. Under the high greenhouse gas emission scenario during the dry season, we find that the future LFMC reductions mainly result from a warming temperature, which leads to 9.1-18.6% reduction in LFMC. Lower precipitation in the spring leads to a 6.3-8.1% reduction in LFMC. The combined impacts of warming and precipitation change on fire season length are equal to the additive impacts of warming and precipitation change individually. Our results show that the $CO_2$ fertilization will mitigate fire risk by causing a 3.5-4.8% increase in LFMC. Our results suggest that multivariate climate change could cause a significant net reduction in LFMC and thus exacerbate future wildfire danger in chaparral shrub systems.

**Keywords:** FATES-HYDRO, chaparral shrubs, plant functional types, southern California, $CO_2$ enrichment, climate change

## 1. Introduction

Historical warming and changes in precipitation have already impacted wildfire at a global scale (e.g. Stocks et al. 1998; Gillett et al. 2004; Westerling et al. 2003, 2006) and it is expected that accelerating future warming will continue to significantly influence global wildfire regimes (e.g. Flannigan et al. 2009; Liu et al. 2010; Moritz et al. 2012). So far, prior studies have mainly focused on impacts of dead fuel moisture, fuel loads, and weather conditions on wildfire. Limited studies have applied proxies of live fuel moisture in global-fire models. For example, dead fuel moisture is found to be related to fire ignition and fire spread potential (or potential area burnt) (Aguado et al. 2007), specific weather conditions such as increased vapor pressure deficit (Williams et al. 2019) can lead to a vast increase in fire activity (Goss et al. 2020), and wildfire fuel loads are projected to increase under climate change (Matthews et al. 2012; Clarke et al. 2016). In global-fire models, studies have used proxies of live fuel moisture (Bistinas et al. 2014; Kelley et al. 2019) as well as explicit representation of live fuels (Hantson et al. 2016; Rabin et al. 2017). While previous studies provide great insights into fire risks with changes in climate, dead fuel moisture, fuel loads, and representation of live fuel moisture, there is still limited understanding of how climate change influences live fuel moisture content (LFMC) and the consequent wildfire risks. This is particularly true for the combined impacts of warming temperature, altered precipitation, and increasing $CO_2$ fertilization (Chuvieco et al. 2004; Pellizzaro 2007; Caccamo et al. 2012a, b; Williams et al. 2019; Goss et al. 2020).

A measure of water content within living plant tissue in relation to their dry weight, LFMC has been found to be one of the most critical factors influencing combustion, fire spread,

and fire consumption (e.g. Agee et al. 2002; Zarco-Tejada et al. 2003; Bilgili & Saglam 2003; Yebra et al. 2008; Dennison et al. 2008; Anderson & Anderson 2010; Keeley et al. 2011). This is because a low LFMC leads to increased flammability and a higher likelihood of ignition (Dimitrakopoulos & Papaioannou 2001). For instance, LFMC was found to be a significant factor contributing to the occurrence of wildfires in Australia (Plucinski 2003; Nolan et al. 2016; Yebra et al. 2018; Rossa & Fernandes 2018; Pimont et al. 2019), Spain (Chuvieco et al. 2009) and California (Santa Monica Mountains; Dennison et al. 2008; Dennison & Moritz 2009; Pivovaroff et al. 2019). Dennison & Moritz (2009) found strong evidence of a LFMC threshold (79%) for southern California chaparral shrubs, which may determine when large fires can occur in this region.

Vegetation moisture content is dependent on both ecophysiological characteristics of the species and environmental conditions, including both climatic variables and soil water availability (Rothermel 1972; Castro et al. 2003; Castro et al. 2003; Pellizzaro 2007; Pivovaroff et al. 2019; Nolan et al. 2020). So far, little is known about the relative importance of different climate variables to future LFMC dynamics. On the one hand, warming could contribute to a higher atmospheric demand and higher evapotranspiration (Rind et al. 1990) and thus lead to a lower LFMC. On the other hand, higher $CO_2$ concentration will decrease stomatal conductance (Wullschleger et al. 2002) and plant water loss, and thus lead to a higher LFMC. The impacts of $CO_2$ and warming could be complicated by local changes in precipitation patterns and humidity (Mikkelsen et al. 2008).

The sensitivity of LFMC to climate change is likely to be affected by plant hydraulic traits (the plant properties that regulate water transport and storage within plant tissues), which affect plant water regulation (Wu et al. 2020). Variations in hydraulic traits reflect contrasting

plant drought adaptation strategies when responding to dry conditions. Two contrasting overall strategies are: 1) water stress avoiders and 2) water stress tolerators (Tobin et al. 1999; Wei et al. 2019). The "avoiders" are generally characterized by a more conservative hydraulic strategy under water stress by either closing stomata early, dropping leaves or accessing deep water to avoid more negative water potentials and therefore xylem cavitation. Meanwhile, the "tolerators" typically build xylem and leaves that are more resistant to cavitation so that they can tolerate more negative water potential and continue to conduct photosynthesis under water stress. Therefore, compared with the tolerators, the avoiders normally have a lower sapwood density and higher plant water storage capacity in their tissues to avoid cavitation (Meinzer et al. 2003, 2009; Pineda-Garcia et al. 2013). Because the avoiders rely on water storage capacity as one way to avoid cavitation thereby maintaining a relatively high LFMC, and water loss from storage should increase with warming, LFMC could be more sensitive to climate change in avoiders relative to tolerators.

While over half of terrestrial landscapes on Earth are considered fire-prone (Krawchuk et al. 2009), Mediterranean-type climate regions are routinely impacted by fire, often on an annual basis. This is partly because Mediterranean climate regions are characterized by winter rains followed by annual dry season, when little to no rainfall occurs for several months. Multiday periods of extreme high temperatures, as well as katabatic hot, dry, and intense winds, often punctuate the annual drought, leading to some of the worst fire weather in the world (Schroeder et al. 1964). This can result in wildfires that are large, high-intensity, and stand-replacing (Keeley 1995; Keeley & Zedler 2009; Balch et al. 2017). Globally, Mediterranean climate regions are characterized by evergreen sclerophyllous-leaved shrublands. The Mediterranean climate region in California is dominated by chaparral, which is adapted to the periodic fire

117 regime in California (Venturas et al. 2016). Previous studies have proposed a variety of
118 relationships between chaparral LFMC and fire danger in southern California (Dennison et al.
119 2008; Dennison & Moritz 2009), but less is known about how climate changes could alter LFMC
120 and fire danger. In chaparral, LFMC is usually high during the winter and spring (wet season)
121 and then gradually declines during the dry season (summer and fall), which leads to a typical fire
122 season approximately six months long in southern California (Pivovaroff et al. 2019). One key
123 risk is that severe drought conditions are becoming exacerbated under climate change, which
124 might lead to the occurrence of larger and higher-intensity fires in chaparral (Dennison et al.
125 2008; Dennison & Moritz 2009).

126 There has been a long history of wildfire modeling, with three types of models: 1) fine-
127 scale fire behavior models (e.g. FIRETEC by Linn et al. 2002); 2) landscape-scale fire
128 disturbance models (e.g. LANDIS-II by Sturtevant et al. 2009); and 3) global-scale fire dynamics
129 models (e.g. Hantson et al. 2016; Rabin et al. 2017; SPITFIRE by Thonicke et al. 2010). While
130 these models focus on simulation at different scales, fire measures of the simulation are mainly
131 calculated from climate and dead fuel moisture and currently lack prediction of LFMC dynamics.
132 One key limitation is that most previous models have not yet considered plant hydrodynamics
133 (Holm et al. 2012; Xu et al. 2013; Seiler et al. 2014), which is integral to LFMC prediction.
134 Recently, there have been important improvements to global dynamic and demographic
135 vegetation models by incorporating plant hydrodynamics (McDowell et al. 2013; Xu et al. 2016;
136 Fisher et al. 2018; Mencuccini et al. 2019). These models have been used to study the interaction
137 between elevated $CO_2$ and drought (Duursma & Medlyn, 2012), the impact of hydraulic traits on
138 plant drought response (Christofferson et al. 2016), the role of hydraulic diversity in vegetation
139 response to drought (Xu et al. 2016) and hydroclimate change (Powell et al. 2018), and

vegetation water stress and root water uptake (Kennedy et al. 2019). While the main purpose of the new hydraulic components is to improve the vegetation response to drought, the fact that hydrodynamic models consider tissue water content as a prognostic variable provides an opportunity to assess the climate impacts on LFMC.

The objective of this study is to quantify LFMC dynamics and associated changes in fire season duration for a chaparral ecosystem in southern California under climate change using a vegetation demographic model (that resolves the size and age-since-disturbance structure of plant populations) (Xu et al. 2016; Fisher et al. 2018) that incorporates plant hydraulics. We test one overarching hypothesis: future climate change will decrease LFMC and consequently result in a longer fire season as determined by a critical threshold of LFMC ($H_0$). Specifically, we test the following four sub-hypotheses: 1) warming has a stronger impact on LFMC than $CO_2$ fertilization ($H_1$); 2) the reductions in spring and autumn precipitation lead to a longer fire season as determined by LFMC ($H_2$); 3) the combined impacts of warming and precipitation on fire season length are equal to the additive impacts of warming and precipitation change individually ($H_3$); and 4) LFMC for plants with more conservative hydraulic strategies ("avoiders") will be more vulnerable to warming ($H_4$).

## 2. Materials and Methods

To understand climate change impacts on LFMC for the chaparral ecosystem, we applied the Functionally Assembled Terrestrial Simulator (FATES; Fisher et al. 2015; Massoud et al. 2019; Koven et al. 2020) coupled with a hydrodynamic vegetation module (FATES-HYDRO; Christoffersen et al. 2016) in the Santa Monica Mountains in California. We validated the model using the observed LFMC for three chaparral shrub plant functional types (PFTs). Then, we applied FATES-HYDRO to estimate long-term dynamics of leaf water content (LWC) during

1960-2099 for each PFT using downscaled Earth System Model (ESM) climate scenarios. We converted simulated leaf water content (LWC) to LFMC within leaves and shoots. Based on the simulated LFMC, we evaluated wildfire danger based on the number of days per year of LFMC below the critical value of 79% from 1960 to 2099 for each PFT under RCP 4.5 and 8.5. Finally, we assessed the relative importance of changes in individual and combined climate variables including $CO_2$, temperature, precipitation, and tested the corresponding hypotheses.

## 2.1 Study site

The study site is located at the Stunt Ranch Santa Monica Mountains Reserve, in the Santa Monica Mountains in California, USA (N 34° 05', W 118° 39'). Stunt Ranch is dominated by chaparral vegetation, with an elevation of approximately 350 m, a west-facing slope, and a Mediterranean-type climate. The study site harbors an abundance of fauna, particularly birds and reptiles. The mean annual temperature is 18.1°C. The mean annual precipitation is 478 mm, occurring mostly during the wet season (i.e. November-March) with almost no rainfall during the dry season (i.e. April-October). Stunt Ranch last burned in year 1993. We focused on PFTs representing 11 study species (Fig. 1), including chamise (*Adenostoma fasciculatum* - Af), red shank (*Adenostoma sparsifolium* - As), big berry manzanita (*Arctostaphylos glauca* - Ag), buck brush (*Ceanothus cuneatus* - Cc), greenbark ceanothus (*Ceanothus spinosus* - Cs), mountain mahogany (*Cercocarpus betuloides* - Cb), toyon (*Heteromeles arbutifolia* - Ha), laurel sumac (*Malosma laurina* - Ml), scrub oak (*Quercus berberidifolia* - Qb), hollyleaf redberry (*Rhamnus ilicifolia* - Ri), and sugar bush (*Rhus ovata* - Ro). Detailed information about the study site and species characterizations found at Stunt Ranch can be found in Venturas et al. (2016) and Pivovaroff et al. (2019).

## 2.2 FATES-HYDRO model

FATES is a vegetation demographic model (Fisher et al. 2015), which uses a size-structured group of plants (cohorts) and successional trajectory-based patches based on the ecosystem demography approach (Moorcroft et al. 2001). FATES simulates the demographic process including seed production, seed emergence, growth and mortality (Koven et al. 2020). Because the main purpose is to assess LFMC, we controlled for variation in plant size structure that could arise from plant traits or climate differences between model runs by using a reduced-complexity configuration of the model where growth and mortality are turned off and ecosystem structure is held constant. FATES has to be hosted by a land surface model to simulate the soil hydrology, canopy temperature and transpiration. These host land models include the Exascale Energy Earth System Model (E3SM, Caldwell et al., 2019) land model (ELM) as well as the Community Earth System Model (Fisher et al 2015) and the Norwegian Earth system model (NorESM, Tjiputra et al 2013). In this study, we used the DOE-sponsored ELM as our host land model. The time step of FATES to calculate carbon and water fluxes is 30 minutes and it can downscale the data from 6-hourly climate drivers.

A key component of FATES, the plant hydrodynamic model (HYDRO, based on Christoffersen et al. 2016), simulates the water flow from soil through root, stem and leaf to the atmosphere. In this model, water flow is calculated based on water pressure gradients across different plant compartments (leaf, stem, transporting roots, absorbing roots and rhizosphere). Specifically, flow between compartment $i$ and $i + 1$ ($Q_i$) is given by

$$Q_i = -K_i \Delta h_i, \quad (1)$$

where $K_i$ is the total conductance (kg $MPa^{-1}$ $s^{-1}$) at the boundary of compartments $i$ and $i + 1$ and $\Delta h_i$ is the total water potential difference between the compartments:

$$\Delta h_i = \rho_w g(z_i - z_{i+1}) + (\psi_i - \psi_{i+1}), \quad (2)$$

where $z_i$ is compartment distance above (+) or below (-) the soil surface (m), $\rho_w$ is the density of water ($10^3$ kg m$^{-3}$), $g$ is acceleration due to gravity (9.8 m s$^{-2}$), and $\psi_i$ is tissue or soil matric water potential (MPa). $K_i$ is treated here as the product of a maximum boundary conductance between compartments $i$ and $i+1$ ($K_{max,i}$), and the fractional maximum hydraulic conductance of the adjacent compartments ($FMC_i$ or $FMC_{i+1}$), which is a function of the tissue water content. A key parameter that controls $FMC$ is the critical water potential ($P_{50}$) that leads to 50% loss of hydraulic conductivity. The tissue water potential is calculated based on pressure-volume (PV) theory (Tyree & Hammel, 1972; Tyree & Yang, 1990; Bartlett et al., 2012). For leaves, it is described by three phases: 1) capillary water phase with full turgor, 2) elastic drainage phase before reaching turgor loss point; and 3) post-turgor loss phase. For other tissues, it only has phases 2 and 3. Compared to a non-hydrodynamic model, this formulation allows the simulation of plant water transport limitation on transpiration. For the non-hydrodynamic version of FATES, the water limitation factor for transpiration ($B_{tran}$) is calculated based on the soil moisture potential (Fisher et al. 2015). For the hydrodynamic version, $B_{tran}$ is calculated based on the leaf water potential ($\psi_l$) (Christoffersen et al. 2016) as follows,

$$B_{tran} = [1 + (\frac{\psi_l}{P_{50\_gs}})^{a_l}]^{-1} \quad (3)$$

where $P_{50_gs}$is the leaf water potential that leads to 50% loss of stomatal conductance and $a_l$ is the shape parameter. Please refer to Christoffersen, et al. 2016 for details of formulations of $FMC$ for different plant tissues.

## 2.3 Allometry and trait data for model parameterization

FATES-HYDRO has a large number of parameters (>80; see Massoud et al. 2019 for a complete list except for hydraulic parameters). Based on a previous sensitivity analysis study (Massoud et al. 2019), we focused our parameter estimation efforts on the most influential parameters for allometry, leaf and wood traits, and hydraulic traits from observations of 11 chaparral shrub species (see Supplementary, Table S2), collected from Jacobsen et al. (2008) and Venturas et al. (2016). For this study, we assumed that the allometry of a shrub is analogous to that of a small tree. However, we did make several important modifications to accommodate the allometry of shrub as their height and crown area relationships to diameter could be different from trees. First, instead of using the diameter at breast height as the basis for allometry to calculate the height, crown area and leaf biomass, we used the basal diameter as the basis for shrubs. Second, in the allometry of trees, the diameter for maximum height ($d_1$: Fates_allom_dbh_maxheight, Table S1) is the same as the diameter for maximum crown area ($d_2$: Fates_allom_d2ca_max, Table S1). As our data showed that $d_1$ and $d_2$ are different for shrubs, we have modified the codes so that the $d_1$ and $d_2$ can be set for different values. It is possible that different branching and path length patterns for stems of chaparral species could impact the hydraulics compared to trees; however, FATES-HYDRO treats all the aboveground xylem as a single pool and thus it should not affect our model simulation results.

Based on a hierarchical cluster analysis (Bridges 1966) of allometry and trait data, there are a clear separation among the shrub species. First, the dendrogram is built and every data point finally merges into a single cluster with the height shown on the y-axis. Then we cut the dendrogram in order to create the desired number of clusters determined by a pragmatic choice based on hydraulic traits of eleven chaparral shrub species (Fig. 1). R's rect.hclust function (https://www.rdocumentation.org/packages/stats/versions/3.6.2/topics/rect.hclust) was used to

see the clusters on the dendrogram. All parameters of allometry, leaf and wood traits, and hydraulic traits were collected from observations shown in the Table S2 and S3 of the supplementary. According to the principle of model parsimony, we do not want to classify the species into more than 3 PFTs. Meanwhile, we also want to differentiate the fundamental plant growth and water use strategies that will determine plant transpiration rate and the corresponding LFMC. If we choose to classify the species into two PFTs (based on the solid horizontal line in Fig. 1), then we will not be able to differentiate species with aggressive and conservative hydraulic strategies in the second group and not be able to test H4. Therefore, the chaparral shrub species were classified into three PFTs (based on the dotted horizontal line in Fig. 1 and Table S3), that are able to differentiate plant growth and hydraulic strategy. The three PFTs include a low productivity, aggressive drought tolerance hydraulic strategy PFT (PFT-LA) with a relative low $V_{c,max25}$ (the maximum carboxylation rate at 25 $^{o}$C) and a very negative $P_{50}$ (the leaf water potential leading to 50% loss of hydraulic conductivity); a medium productivity, conservative drought tolerance hydraulic strategy PFT (PFT-MC) represented by a medium $V_{c,max25}$ and a less negative $P_{50}$, turgor loss point and water potential at full turgor; and a high productivity, aggressive drought tolerance hydraulic strategy PFT (PFT-HA) with a relatively high $V_{c,max25}$ and a very negative $P_{50}$. The mean of species-level trait data weighted by species abundance at the site were used to parameterize FATES-HYDRO.

## 2.4 Model initialization

Our model simulation is transient in terms of soil water content, leaf water content, carbon and water fluxes. The forest structure (plant sizes and number density) is fixed and is parameterized based on a vegetation inventory from Venturas et al. (2016). The soil texture and depth information are parameterization based on a national soil survey database

(https://websoilsurvey.sc.egov.usda.gov/App/WebSoilSurvey.aspx; Table S1). The soil moisture is initialized with 50% of the saturation and the tissue plant water content is initialized so that it is in equilibrium with the soil water potential. We run the model for 10 years based on 1950-1960 climate so that the simulated soil moisture, leaf water content, carbon and water fluxes are not depending on their initial conditions.

### 2.5 Live Fuel Moisture Content for model validation

In this study, we used measured LFMC to validate simulated LFMC. FATES-HYDRO does not directly simulate the LFMC. Thus, we estimated the LFMC based on simulated LWC. The LWC in the model is calculated as follows,

$$\mathrm{LWC} = \frac{fw-dw}{dw} * 100, \quad (4)$$

where, *fw* is the fresh weight and *dw* is the dry weight, which are simulated within FATES-HYDRO. Then, we estimated the LFMC within leaves and shoots (< 6 mm diameter) using the empirical equation derived from shrub LFMC and LWC data including the three regenerative strategies [seeder (S), resprouter (R) and seeder–resprouter (SR)], in summer, autumn and winter from Fig. 4 and 5 in Saura-Mas and Lloret's study (2007) as follows (Fig. S4),

$$\mathrm{LFMC} = 31.091 + 0.491\mathrm{LWC}, \quad (5)$$

The climate in Saura-Mas and Lloret's study is Mediterranean (north-east Iberian Peninsula), which is consistent with the climate of our study area. LFMC was measured on our site approximately every three weeks, concurrently with plant water potentials in 2015 and 2016. LFMC measurement details can be found in Pivovaroff et al. (2019). For comparison with our model outputs, we calculated the mean LFMC within leaves and shoots for each PFT weighted

by the species abundance (Venturas et al. 2016). Species abundance was calculated by dividing mean density of a specific species by the mean density of all species.

### 2.6 Climate drivers

We forced the FATES-HYDRO model with 6-hourly temperature, precipitation, downward solar radiation, and wind components. Historical climate data during 2012-2019, which were used for FATES-HYDRO calibration, were extracted from a local weather station (https://stuntranch.ucnrs.org/weather-date/). Historical and future climate data during 1950-2099, which were used for simulations of LFMC by FATES-HYDRO model, were downloaded from the Multivariate Adaptive Constructed Analogs (MACA) datasets (Abatzoglou & Brown 2012; http://maca.northwestknowledge.net). The MACA datasets (1/24-degree or approximately 4-km; Abatzoglou & Brown 2012) include 20 ESMs with historical forcings during 1950-2005 and future Representative Concentration Pathways (RCPs) RCP 4.5 and RCP8.5 scenarios during 2006-2099 from the native resolution of the ESMs. The gridded surface meteorological dataset METDATA (Abatzoglou, 2013) were used with high spatial resolution (1/24-degree) and daily timescales for near-surface minimum/maximum temperature, precipitation, downward solar radiation, and wind components. Then we downscaled the MACA daily data to 6-hourly based on the temporal anomaly of the observed mean daily data to the hourly data for each day during 2012-2019. The model is driven by yearly $CO_2$ data obtained from Meinshausen et al (2011).

### 2.7 Hypothesis testing

To test $H_0$ (future climate change will decrease LFMC and consequently result in a longer fire season as determined by a critical threshold of LFMC), we compared the simulated mean LFMC, derived from modeled leaf water content, under the climate projections from 20 ESMs

316 under RCP 4.5 and 8.5. We then tested if the LFMC during the April-October dry season in the
317 historic period of 1960-1999 is significantly higher than that in the future period of 2080-2099.
318 For the fire season duration, we estimated the number of days per year below a critical threshold
319 of LFMC (79%). Similarly, we tested if the number of days per year below the critical threshold
320 of LFMC during the historical period are significantly different from that during the future
321 period. We used a bootstrapped approach (Jackson 1993) to test if the mean of LFMC or fire
322 season duration are significantly different between these two periods. Specifically, we randomly
323 draw 10000 samples from the simulated residuals of LFMCs or fire season durations estimated
324 by 20 ESMs for these two periods under the null hypothesis that there is no difference in the
325 mean. We then calculated p-values by comparing the simulated mean difference to the empirical
326 distribution of difference estimated from these 10000 samples. See Supplementary section 5.2
327 within Xu et al. (2019) for the details.

328 To test $H_1$ (warming has a stronger impact on LFMC than $CO_2$ fertilization), we
329 compared mean simulated LFMC and fire season length for three PFTs with/without $CO_2$
330 changes (fixed $CO_2$ at 367 ppm vs dynamic $CO_2$ concentrations from RCP 4.5 or RCP 8.5) and
331 warming. To remove the future warming trend, future temperature was replaced with historical
332 (1986-2005) temperature data for every 20 year period. Similarly, to test $H_2$ (the reductions in
333 spring and autumn precipitation lead to a longer fire season as determined by LFMC), we
334 compared the model outputs of LFMC and fire season length for three PFTs with/without
335 precipitation changes. To test $H_3$ (the combined impacts of warming and precipitation on fire
336 season length are equal to the additive impacts of warming and precipitation change
337 individually), we compared model outputs of LFMC and fire season length for three PFTs under
338 three scenarios: 1) without warming; 2) without precipitation changes; and 3) without warming

and precipitation changes. Finally, to test $H_4$ (LFMC for plants with more conservative hydraulic strategies will be more vulnerable to warming), we compared model outputs of LFMC and fire season length across the three different PFTs with different hydraulic strategies.

## 3. Results

### 3.1 Comparison between simulated and measured LFMC

Our results showed that FATES-HYDRO was able to capture variation in the LFMC for different PFTs and soil water content in 5-cm depth (Fig. 2 and S3), also for Chamise in 2018 (Fig. S5) although we had limited observed LFMC data. Specifically, the model was able to capture 96%, 86%, and 80% of the variance in observed LFMC for the period of 2015-2016 for three PFTs, respectively (Fig. 2 b, d, f). The model was also able to capture the seasonal dynamics of soil water content, LFMC, and LFMC below the threshold 79% in comparison to observed data (Fig. 2 a, c, e and S3). To validate that FATES-HYDRO is able to capture the interannual variability of LFMC, we compared the simulated LFMC for PFT-LA with the long-term observations of LFMC for the chamise species (*Adenostoma fasiculatum*; Fig. S5). Our results showed that the model is able to reasonably capture the seasonal and interannual variability for the period of 2006-2019 ($R^2$=0.7), although it underestimates peaks in LFMC in 4 of 14 years.

### 3.2 Changes in the LFMC and fire season length from historical to future periods

Using the validated model driven by climate projections from 20 ESMs under greenhouse gas emission scenarios RCP4.5 and RCP 8.5, we found that the daily mean LFMC during the future period of 2080-2099 was projected to become significantly lower than that during the historical period of 1960-1999 for all three PFTs (Fig 3, P<0.000001). Our results also showed

that the spread among models increase with time, suggesting a larger uncertainty in the projection into the future. Specifically, the histogram of daily mean LFMC during the April-October dry season showed that there was a higher probability of low LFMC under future climate conditions (Fig. S1). The daily mean LFMC decreased from 84.7%, 101.3%, and 78.4% during the historical period of 1960-1999 to 81.0-82.8%, 96.3-98.8%, and 74.8-76.6% during the future period of 2080-2099 under both climate scenarios for PFT-LA, PFT-MC, PFT-HA, respectively (Fig 3).

Based on the projected LFMC, there was a significant increase in the fire season length with the critical threshold of LFMC from the historical period of 1960-1999 to the future period of 2080-2099 for three PFTs. With the critical threshold of 79% LFMC, the fire season length was projected to increase by 20, 22, 19 days under RCP 8.5 (Fig. 4 and Table S4), and to increase by 9, 11, 8 days under RCP 4.5 (Fig. 4 and Table S4). Our results also showed that the spread among models increase with time, suggesting a larger uncertainty in the projection into the future. The above results for mean LFMC and fire season length support hypothesis $H_0$ that future climate change will decrease LFMC and consequently result in a longer fire season, as determined by critical thresholds for LFMC, for all three PFTs.

### 3.3 Relative effects of individual climate changes on the length of the fire season

In order to better understand the relative contribution to fire season length of different climate variables, we ran FATES-HYDRO for three PFTs using meteorological forcings that isolated and removed changes in individual specific variables. Our results showed that the increase in fire season length mainly resulted from warming, which led to 16-23 days (9.1-18.6%) per year increase in fire season length for the critical threshold of 79% LFMC under RCP 8.5 (Fig. 5). This is because warming is pushing Vapor Pressure Deficit (VPD) higher, resulting

in increased fire season length. For RCP 4.5, the warming contributed to 5-6 days (3.8-4.3%) per year increase in fire season length (Fig. 5). We also found that elevated $CO_2$ concentrations decreased fire season length with 6-7 days (3.5-4.8%) per year decrease in fire season length under RCP 8.5 (Fig. 5). Under RCP 4.5, $CO_2$ increases led to 2-3 days (1.5-2.2%) per year decrease in fire season length (Fig. 5). Because the impact of warming on fire season length was stronger than the mitigation from $CO_2$ enrichment, our results support hypothesis $H_1$ (warming has a stronger impact on LFMC than $CO_2$ fertilization).

Even though total precipitation was projected to increase in the future, lower precipitation in the spring and autumn (Fig. S2 a, b) led to 8-10 days (6.3-8.1%) per year increase in fire season length with the critical threshold of 79% LFMC under RCP 8.5 (Fig. 5). Under RCP 4.5, the precipitation changes contributed to 1-3 days (0.8-1.6%) increase in fire season length (Fig. 5). This result supported hypothesis $H_2$ that the reductions in spring and autumn precipitation lead to a longer fire season as determined by LFMC.

Our results showed that the combined impacts of warming and precipitation on fire season length were equal to the additive impacts of warming and precipitation change individually. This supported hypothesis $H_3$. Specifically, the combined changes in temperature and precipitation caused 24-33 days per year (15.6-26.8%) increase in fire season length with the critical threshold of 79% LFMC under RCP 8.5 (Fig. 5). Under RCP 4.5, the combined changes in temperature and precipitation caused a 6-9 days per year (4.8-6.1%) change in fire season length.

### 3.4 Comparison of changes in fire season length among three PFTs under climate change

Regarding three PFTs under both climate scenarios, fire season length of PFT-HA was the longest (167-176 days per year), while fire season length of PFT-MC was the shortest (114-124 per year) during 2080-2099 (Fig. 4). However, the response of fire season length to warming was strongest for PFT-MC. Specifically, for PFT-MC, warming under RCP 8.5 led to an increase of 21.6% (22 days) in fire season length (Fig. 5 b) and warming under RCP 4.5 led to an increase of 10.8% (11 days) in fire season length. For PFT-LA, warming under RCP 8.5 led to an increase of 14.7% (19 days) in fire season length (Fig. 5 a) while warming under RCP 4.5 led to an increase of 7.4% (9 days) in fire season length. Finally, for PFT-HA, warming under RCP 8.5 led to an increase of 10.2% (18 days) in fire season length (Fig. 5 c) and 5.3% (8 days) in fire season length with under RCP 4.5. Because PFT-MC has a more conservative hydraulic strategy with less negative $P_{50}$, turgor loss point and water potential at full turgor, this result supported hypothesis $H_4$ that the LFMC for plants with more conservative hydraulic strategy will be more vulnerable to warming.

To validate our classification scheme, we compared these PFT-level results to those obtained with single-PFT and 2-PFT simulations finding that using the three PFTs defined by our cluster analysis gives a qualitatively different view of LFMC change than a single- or 2-PFT simulation. We found significant differences in the percentage changes of LFMC and fire season length between future period (2080-2099) and historical period (1960-1999) using three distinct PFTs, but no significant differences between PFTs in 2-PFT simulations under the different climate scenarios (Fig. S6).

## 4. Discussion

Low LFMC within shrub leaves and shoots increases the flammability and likelihood of combustion, making it vitally important to monitor temporal variations in LFMC, especially

during the dry season (Dennison et al, 2008). The strong relationships between observed and simulated LFMC of all PFTs (Fig. 2) suggested that the plant hydrodynamic model, FATES-HYDRO, could accurately estimate LFMC seasonal dynamics as a function of modeled leaf water content, and consequently be useful to predict fire risks in Mediterranean-type climate regions, although only small amount of validation data were used and the underlying assumption that a shrub was analogous to a small tree. Based on the simulated monthly mean LFMC during 2006-2019 for PFT-LA, which includes the chamise species, we found that our model can capture the seasonal variation and interannual variability, but underestimates the highest wet season peaks in LFMC in 4 of 14 years (Fig. S5). This may cause biases for future projections while it would not highly affect the long-term trend of LFMC and fire season length. During the future period (2080-2099) and the historical period (1960-1999), both periods displayed lower values in the dry season (April - October), which is consistent with lower LFMC during the summer-fall dry season, rather than the winter-spring wet season (Chuvieco et al, 2004; Pellizzaro et al, 2007; Pivovaroff et al. 2019). Extremely low daily LFMC was more likely to occur during the future period, which had higher temperature than the historical period. From the historical to the future period, fire season length could increase by 5.2-14.8% under climate change for chaparral shrub ecosystems ($H_0$). The fire season length was not validated, rather it was defined as number of days with LFMC below 79%.

Quantifying influences of climatic variables on LFMC is crucial to predicting future fire risks (Dennison & Moritz, 2009). Our results showed that future warming was the most important driver of LFMC. This finding suggested that warming would substantially push Vapor Pressure Deficit (VPD) higher and decrease LFMC and strongly increase the fire season length, which may greatly increase fire risks in the future (e.g. Dennison et al, 2008; Chuvieco et al,

2009; Pimont et al, 2019). $CO_2$ fertilization is expected to reduce stomatal conductance (Pataki et al. 2000; Tognetti et al. 2000) and thus could mitigate the impacts of warming on LFMC. Our results illustrated that, even though the $CO_2$ impact did cause a 3.5-4.8% reduction in fire season length, the impact of warming on fire season length is about 5.6-13.8% larger than the $CO_2$ effect ($H_1$, warming has a stronger impact on LFMC than $CO_2$ fertilization). This result suggests that $CO_2$ fertilization cannot offset the LFMC impacts from warming. The FATES-HYDRO model assumes a consistent stomatal sensitivity to $CO_2$ concentration across Mediterranean shrub species. While Mediterranean shrub functional types in arid and semi-arid systems would vary in their stomatal response in the real world (Pataki et al. 2000). Therefore, our model may overestimate/underestimate the $CO_2$ effect on stomatal conductance and its mitigating influence might be smaller in reality for some species.

Previous studies implied that the timing of precipitation may have a strong impact on subsequent LFMC (e.g. Veblen et al. 2000; Westerling et al. 2006; Dennison & Moritz 2009). In this study, precipitation was also a key driver of LFMC under future climate conditions. Our results showed that, even though total precipitation was projected to increase, the reduction in spring and autumn precipitation (Fig. S2) was projected to cause a longer fire season length ($H_2$, the reductions in spring and autumn precipitation lead to a longer fire season as determined by LFMC; Fig. 5). This result was in agreement with a prior study indicating that spring precipitation, particularly in the month of March, was found to be the primary driver of timing of LFMC changes (Dennison & Moritz 2009). We also found that the combined impacts of warming and precipitation on fire season length were equal to the linearly additive impacts of warming and precipitation change individually ($H_3$). Our results suggested that, when evaluating

future fire risks, it is critical that we considered the seasonal changes in precipitation and its interaction with the warming impact.

Modeled vegetation responses to environmental changes is a function of variation in plant functional traits (Koven et al, 2020). The three PFTs represented in this study have similar patterns in LFMC in response to climate change during 1960-2099, but we did see some critical differences. Specifically, the plant functional type PFT-MC with more conservative hydraulic strategy had the strongest responses to climate change (Fig. 5). This could be related to the fact that the PFT-MC is a more conservative drought tolerant PFT in terms of hydraulic strategy with less negative $P_{50}$, turgor loss point, and water potential at full turgor. The PFT-MC plants had a relatively high saturated water content based on observed data (Fig 2) and the water within plant tissues thus changes more quickly in response to the environmental condition changes ($H_4$, LFMC for plants with more conservative hydraulic strategies will be more vulnerable to warming). However, the three different PFTs were coexisting at the same location in model simulations, coexistence and heterogeneity in LFMC might impact fire behavior and fire season length.

Because the moisture content of live fuels (~50–200%) are much higher than that of dead fuels (~7–30%), leaf senescence induced by drought stress and subsequent mortality are potentially vital factors to cause large wildfires (Nolan et al. 2016, 2020). Thus drought-induced canopy die-back and mortality could largely increase surface fine fuel loads and vegetation flammability, which can increase the probability of wildfire (Ruthrof et al. 2016). Since growth and mortality are turned off in model runs by using a reduced-complexity configuration, it is possible that vegetation density might decrease and LFMC could be conserved under future scenarios. In addition, potential vegetation transitions (e.g., shrubs to grassland and species

composition changes) might substantially affect flammability and thus fire intensity and frequency. In this study, we used the static mode of FATES-HYDRO to simulate LWC dynamics under climate change. If we need to assess how the leaf senescence and vegetation dynamics will impact the fire behavior, we can use the same model with dynamic mode to assess their impacts on fire behaviors under future drought and warming conditions.

Application of a hydrodynamic vegetation model to estimate LFMC dynamics could potentially benefit wildfire modeling at the fine-scale, landscape-scale, and global-scale. This is because LFMC is one of the most critical factors influencing combustion, fire spread, and fire consumption while previous wildfire models mainly focus on impacts of dead fuel moisture, weather conditions on wildfire, fuel loads, and representation of live fuel moisture (Anderson & Anderson 2010; Keeley et al. 2011; Jolly & Johnson 2018). The implications of this are that fire potential will vary with plant water potential and uptake from soils, photosynthetic and respiratory activity, carbon allocation and phenology with variability across species and over time (Jolly & Johnson 2018). Therefore, future work to incorporate LFMC dynamics in wildfire models could potentially play a vitally important role in the future studies of wildfire modeling under climate change.

## 5. Conclusions

A hydrodynamic vegetation model, FATES-HYDRO, was used to estimate leaf water status and thus LFMC dynamics of chaparral shrub species in southern California under historical and future conditions. FATES-HYDRO model was validated using monthly mean LFMC for three PFTs. The fire season length was projected to substantially increase under both climate scenarios from 1960-1999 to 2080-2099. This could increase wildlife risk over time for chaparral shrubs in southern California. Our results showed that temperature was the most

important driver of LFMC among all climatic variables. The LFMC estimated by the FATES-HYDRO model offered a baseline of predicting plant hydraulic dynamics subjected to climate change and provided a critical foundation that reductions in LFMC from climate warming may exacerbate future wildfire risk. Longer fire season might have a significant impact on overall public health and quality of life in the future.

*Data availability.* LFMC measurement data can be found in Pivovaroff et al. (2019). Species abundance data can be found in Venturas et al. (2016). All other data are available within this paper and in the Supplement.

*Supplement.* The supplement related to this article is available online at

*Author contributions.* WM, LZ, and CX were involved in designing the study. WM and CX conducted the data analysis and ran model simulations. All authors contributed to writing, reviewing, and improving the manuscript.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* We thank the editor Martin De Kauwe, the referee Douglas Kelley, and the two anonymous referees for the improvement of this paper.

*Financial support.* This project is supported by the University of California Office of the President Lab Fees Research Program and the Next Generation Ecosystem Experiment (NGEE) Tropics, which is supported by the U.S. DOE Office of Science. CDK and JD are supported by the DOE Office of Science, Regional and Global Model Analysis Program, Early Career Research Program.

*Review statement.* This paper was edited by Martin De Kauwe, reviewed by the referee Douglas Kelley, and the two anonymous referees.

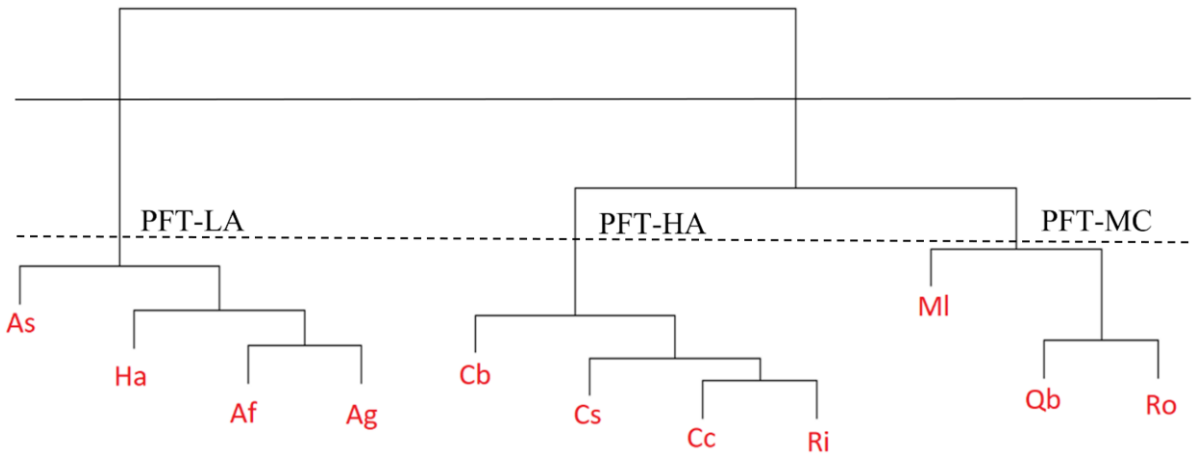

**Fig 1**. Hierarchical cluster analysis of allometry and hydraulic traits for eleven chaparral shrub species used to define three plant functional types at Stunt Ranch. The plant functional types with a low productivity and an aggressive drought tolerance hydraulic strategy (PFT-LA) was defined based on traits of red shank (Adenostoma sparsifolium - As), toyon (Heteromeles arbutifolia - Ha), chamise (Adenostoma fasciculatum - Af), big berry manzanita (Arctostaphylos glauca - Ag); the plant functional types with a high productivity and an aggressive drought tolerance hydraulic strategy (PFT-HA) was defined based on traits of mountain mahogany (Cercocarpus betuloides - Cb), greenbark ceanothus (Ceanothus spinosus - Cs), buck brush (Ceanothus cuneatus - Cc), hollyleaf redberry (Rhamnus ilicifolia - Ri); the plant functional types with a medium productivity and an conservative drought tolerance hydraulic strategy (PFT-MC) was defined based on traits of laurel sumac (Malosma laurina - Ml), scrub oak (Quercus berberidifolia - Qb), sugar bush (Rhus ovata - Ro).

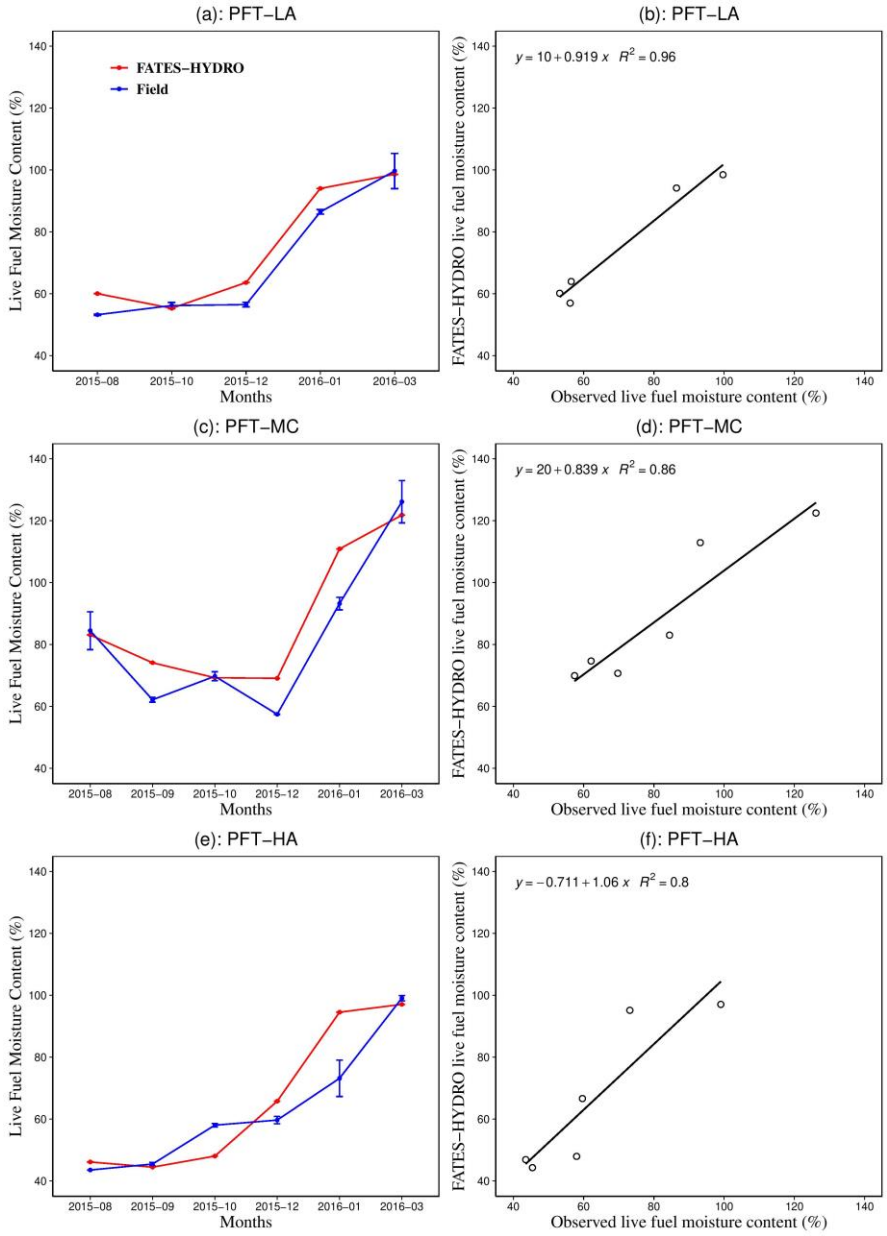

886

887 **Fig.2** Simulated and observed monthly live fuel moisture content and related $R^2$ values for three
888 PFTs (refer to Figure 1 for explanation of the PFTs).

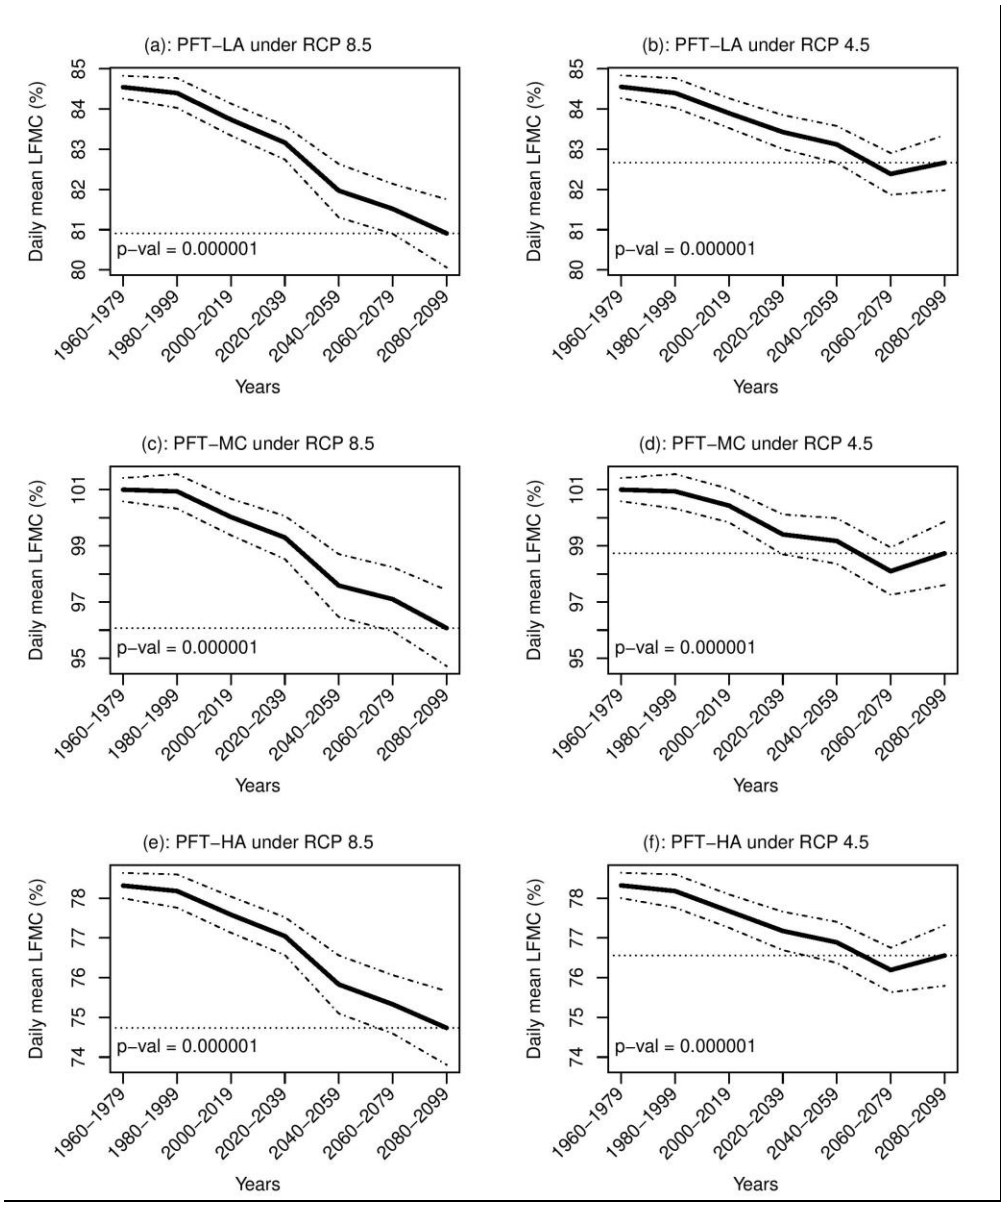

**Fig.3** Temporal changes in daily mean live fuel moisture content (black solid line) and 95% confidence interval (black dash-dot line) from 1960 to 2099 for three PFTs (refer to Figure 1 for explanation of the PFTs) under climate scenario RCP 4.5 and 8.5 with 20 Earth System Models considering all climatic variables changes. The P values were calculated using bootstrap sampling to test whether the daily mean live fuel moisture content across different models during the future period (2080–2099) was significantly lower than that during the historical period (1960-1999). The grey horizontal dotted line represents the ensemble mean for 2080–2099.

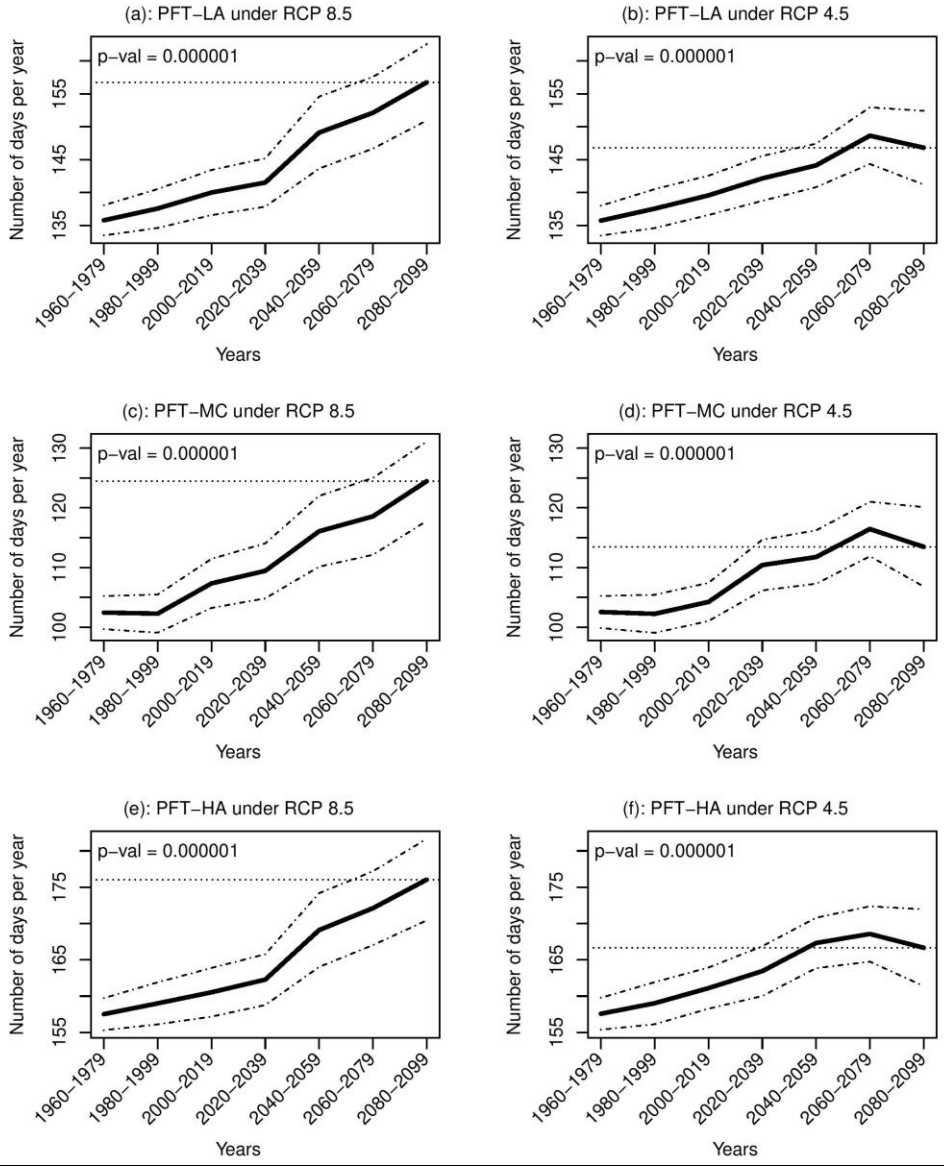

**Fig.4** Temporal changes in average number of days per year of live fuel moisture content below 79% (black solid line) and 95% confidence interval (black dash-dot line) from 1960 to 2099 for three PFTs (refer to Figure 1 for explanation of the PFTs) under climate scenario RCP 4.5 and 8.5 with 20 Earth System Models considering all climatic variables changes. The P values were calculated using bootstrap sampling to test whether the number of days across different models during the future period (2080–2099) was significantly higher than that during the historical period (1960-1999). The grey horizontal dotted line represents the ensemble mean for 2080–2099.

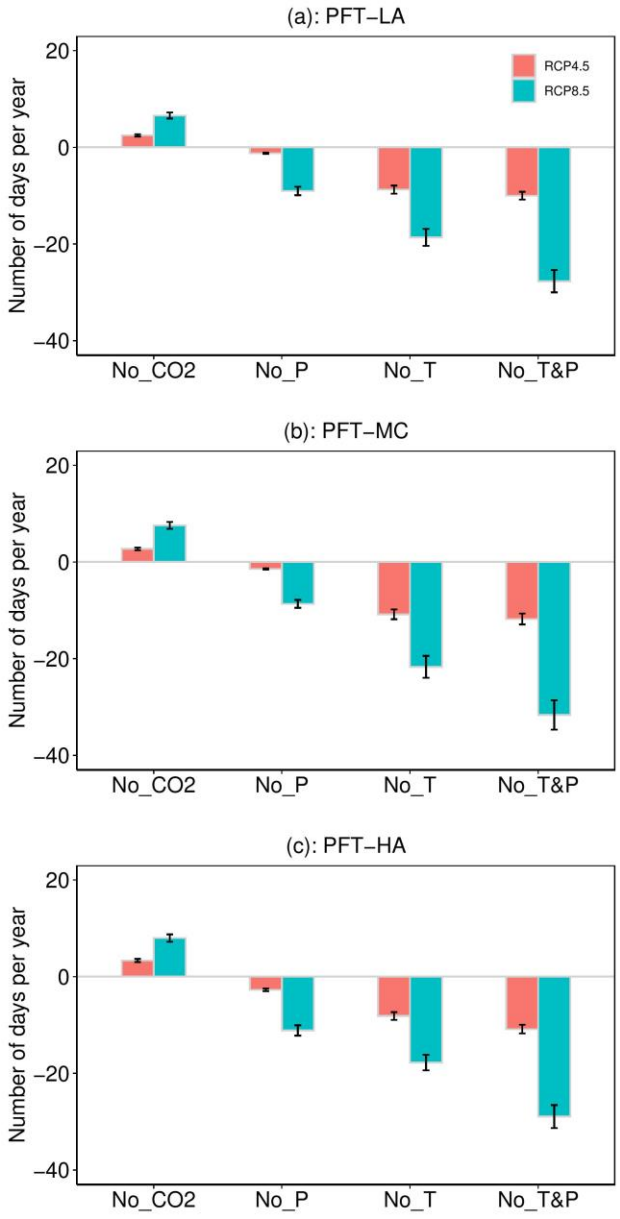

908

909 **Fig.5** Differences on number of days per year of live fuel moisture content below 79% from
910 2080 to 2099 for three PFTs (refer to Figure 1 for explanation of the PFTs) under climate
911 scenario RCP 4.5 and 8.5 between considering all climatic variables changes and without
912 considering $CO_2$, precipitation, temperature, and precipitation & temperature changes.
