Abstract. The hydro-biogeochemical model Catchment Nutrient Management Model - DeNitrification-DeComposition (CNMM-DNDC) was established to simultaneously quantify ecosystem productivity and losses of nitrogen and carbon at the site or catchment scale. As a process-oriented model, this model is expected to be universally applied to different climate zones, soils, land uses and field management practices. This study is one of many efforts to fulfil such an expectation, which was performed to improve the CNMM-DNDC by incorporating a physical-based soil thermal module to simulate the soil thermal regime in the presence of freeze-thaw cycles. The modified model was validated with simultaneous field observations in three typical alpine ecosystems (wetlands, meadows and forests) within a catchment located in the seasonally frozen region of the eastern Tibetan Plateau, including soil profile temperature, topsoil moisture and fluxes of methane (CH_4) and nitrous oxide (N_2O). The validation showed that the modified CNMM-DNDC was able to simulate the observed seasonal dynamics and magnitudes of above variables in the three typical alpine ecosystems, with index of agreement values of 0.91–1.00, 0.49–0.83, 0.57–0.88 and 0.26–0.47, respectively. Consistent with the emissions determined from the field observations, the simulated aggregate emissions of CH_4 and N_2O were highest for the wetland among three alpine ecosystems, which were dominated by the CH_4 emissions. This study indicates the possibility for utilizing the process-oriented model CNMM-DNDC to predict hydro-biogeochemical processes, as well as related gas emissions, in seasonally frozen regions. As the original CNMM-DNDC was previously validated in some unfrozen regions, the modified CNMM-DNDC could be potentially applied to estimate the emissions of CH_4 and N_2O from various ecosystems under different climate zones at the site or catchment scale.

1 Introduction

35

36   During the last 50 years, the extraordinary changes in the nitrogen and carbon cycles have occurred globally, which are

37   essential components of ecosystems (e.g., Galloway *et al.*, 2008; Canfield *et al.*, 2010). Climate changes due to warming and

38   human anthropogenic activities derived from food production have significantly altered the cycling of nitrogen and carbon

39   and led to increased reactive nitrogen availability and carbon losses, which result in a series of environmental problems at

40   the catchment, regional and even global scales (e.g., Galloway *et al.*, 2004; Galloway *et al.*, 2008; Ju *et al.*, 2009). Excessive

41   reactive nitrogen in soils can be lost in the forms of nitrogen gases, such as nitrous oxide (N_2O), nitric oxide (NO) and

42   ammonia (NH_3), and nitrogen pollution, such as nitrate (NO_3^-) and ammonium (NH_4^+), in water through leaching or surface

43   runoff (e.g., Seitzinger, 2008; Collins *et al.*, 2016). In the face of increased air temperatures and intensive land use changes,

44   especially in cold regions, the soil organic carbon stored since the Last Glacial Maximum has been lost to the atmosphere via

45   methane (CH_4) and carbon dioxide (CO_2) (e.g., Piao *et al.*, 2009; Fenner and Freeman, 2011; Schuur *et al.*, 2015). These

46   nitrogen and carbon losses contribute to potential global warming (CO_2, CH_4 and N_2O), air pollution (NO and NH_3) and

47   surface/groundwater pollution (NO_3^- and NH_4^+). Therefore, sustainable ecosystems urgently need to be established that not

48   only focus on net primary productivity but also are friendly to the environment with the minimal hazards, including

49   greenhouse gases, air pollution and water pollutants (e.g., Cui *et al.*, 2018; Zhang *et al.*, 2019).

50   The cycling of nitrogen and carbon is closely related to soil water processes (e.g., Breuer *et al.*, 2010; Vereecken *et al.*,

51   2016; Zhang *et al.*, 2018b). Thus, interactions among soil waters and the cycling of nitrogen and carbon govern biological

52   productivity and environmental outcomes (e.g., Zhu *et al.*, 2018). The interactions consist of the redox potential for different

53   transformation processes influenced by the spatiotemporal variation in soil water content and the lateral transport of water

54   and dissolved nitrogen or carbon controlled by surface and subsurface flow (e.g., McClain *et al.*, 2003; Castellano *et al.*,

55   2013; Bechmann, 2014). For example, the variation in soil water content can create hot spots or moments of nitrogen and

56   carbon losses by influencing plant nitrogen uptake, redox potential, and the transport of dissolved nitrogen and carbon (e.g.,

57   Zhu *et al.*, 2012; Keiluweit *et al.*, 2017). Therefore, a complete understanding of biogeochemical processes will inevitably

58   involve interactions among soil water and the cycling of nitrogen and carbon (e.g., Breuer *et al.*, 2010; Vereecken *et al.*,

59   2016; Zhu *et al.*, 2018).

60   Biogeochemical models, such as DNDC, LandscapeDNDC, WNMM, MOMOS, CENTURY and DayCent, are

61   effective tools for simulating the cycling of nitrogen and carbon and quantifying the effects of climate change and

62   anthropogenic activities on ecosystems (e.g., Foereid *et al.*, 2007; Haas *et al.*, 2012; Li, 2007; Li *et al.*, 2007; Pansu *et al.*,

63   2010; Cheng *et al.*, 2014; Pansu *et al.*, 2014). In recent years, some new conceptual approaches are applied in the

64   biogeochemical models, such as centering on the functional role of the soil microbial biomass (Pansu *et al.*, 2010; Pansu *et*

65   *al.*, 2014) and detailing the lateral transport of water and nutrients (Haas *et al.*, 2012; Zhang *et al.*, 2018b). Generally,

66   comprehensive hydrological processes, especially for the lateral transport of water and nutrients, are simplified or ignored in

67   most models due to specific questions that must be addressed (e.g., Li, 2007; Li *et al.*, 2007; Chen *et al.*, 2008; Deng *et al.*,

68   2014). For the land surface or hydrological models at large scales, they are designed with explicit mechanisms of hydrology

69   and generally focus on vertical and lateral nutrient transport, such as nitrate loads into rivers (e.g., Liu *et al.*, 2019). However,

70   the simulations of nitrogen and carbon processes are usually based on empirical functions even without predicting gas loss.

71   Due to the various purposes of different models, coupling soil hydrological models with biogeochemical models can be an

72   effective strategy for integrating soil water and cycling of nitrogen and carbon to improve model performance. Thus, the

73   coupled model with improved performance can be applied to simultaneously predict productivity and potential negative

74   environmental effects (e.g., Chen *et al.*, 2008; Zhu *et al.*, 2018).

75   In recent years, efforts have been implemented to couple models, such as SWAT-N, LandscapeDNDC-CMF, APSIM,

76   SWAT-DayCent, and CNMM-DNDC (e.g., Pohlert *et al.*, 2007; Haas *et al.*, 2012; Holzworth *et al.*, 2014; Wu *et al.*, 2016;

77   Zhang *et al.*, 2016; Zhang *et al.*, 2018b). The models derived from SWAT were all based on semi-distributed hydrological

78   models using hydrologic response units and did not perform better in estimating non-point source pollution (e.g., Pohlert *et*

79   *al.*, 2007; Bosch *et al.*, 2011 ;Wu *et al.*, 2016). A coupler was used to couple two models for LandscapeDNDC-CMF, which

80   realized the simulation of horizontal movement of water and nutrients (e.g., Haas *et al.*, 2012; Klatt *et al.*, 2017; Schroeck *et*

81   *al.*, 2019). Compared with other models, the Catchment Nutrient Management Model - DeNitrification-DeComposition

82   (CNMM-DNDC), which was established by incorporating the core biogeochemical processes of DNDC into the

83   hydrological framework of the CNMM, was validated at a catchment with complex landscapes in the subtropical region and

84   showed good performance for simultaneously simulating various variables, including ecosystem productivity, hydrological

85   nitrogen losses and nitrate discharge in streams, and emissions of gaseous carbon and nitrogenous gases (Zhang *et al.*,

86   2018b). Therefore, the CNMM-DNDC has the capacity to simulate the various variables closely related to both productivity

87   and environmental hazards.

88   However, as a process-oriented hydro-biogeochemical model designed to be applicable to different climate zones, soils,

89   land uses and field management practices, CNMM-DNDC testing is still lacking due to limited observations for model

90   validation. In this study, the model was applied to a catchment in a seasonally frozen region located on the eastern Tibetan

91   Plateau with the land use types of alpine wetlands, meadows and forests to test its ability to simulate hydro-biogeochemical

92   processes. However, scientific descriptions of soil thermal dynamics due to freeze-thaw cycles are still lacking for the

93   CNMM-DNDC. This gap may hinder model application in seasonally frozen regions, which account for 56% of the exposed

94   land surface of the Northern Hemisphere (Jiang *et al.*, 2020). In addition, the soil freeze-thaw cycles that occur in these mid-

95   high latitude regions exert important influences on soil thermal dynamics, as well as on related hydrological processes, thus

96   increasing the availability of substrates and stimulating the processes of CH_4 and N_2O production and emissions in soils (e.g.,

97   Song *et al.*, 2019). Therefore, we hypothesize that adding the missing scientific processes of soil thermal dynamics into the

98   internal model program codes can improve the performance of the CNMM-DNDC in simulating the soil thermal dynamics,

99   hydrological processes and CH_4 and N_2O fluxes in seasonally frozen regions. Filling this gap is especially necessary to

100   broaden model applicability.

101   To test the above hypothesis, the catchment simulation in the Rierlangshan was conducted using a unique experimental
102   dataset, which was obtained by Zhang *et al.* (2018a, 2019) and Yao *et al.* (2019) for the catchment that involved three typical
103   alpine ecosystems, wetlands, meadows and forests, on the eastern Tibetan Plateau. The aims of this study were to (i) attempt
104   to address the gap in the CNMM-DNDC by improving the scientific processes of soil thermal dynamics for seasonally
105   frozen regions and (ii) compare the performances of the original and modified models in simulating the soil profile
106   temperature, topsoil moisture and CH_4 and N_2O fluxes in three typical alpine ecosystems in the Rierlangshan catchment with
107   field observations. Therefore, the validated model with modifications provides a mechanism for not only interpreting
108   observations but also predicting the CH_4 and N_2O fluxes in alpine ecosystems.

109   ## 2 Materials and methods

110   ### 2.1 Model description

111   ### 2.1.1 Overview of the CNMM-DNDC model

112   The CNMM-DNDC is a process-oriented model developed for simulating hydro-biogeochemical interactions at the
113   catchment or site scale, and this model is designed following the basic theories of physics, chemistry, and biogeochemistry
114   and has the capacity to simulate the complex transport and transformation of water, nitrogen and carbon in terrestrial
115   ecosystems under both aerobic and anaerobic conditions. The model can be applied to simultaneously quantify ecosystem
116   productivity, net emissions of nitrogen and carbon gases and hydrological nitrogen losses through soil leaching and
117   discharge in streams from an entire catchment or individual landscape unit (Zhang *et al.*, 2018b).The model was established
118   to address the bottleneck issue associated with most biogeochemical models, i.e., the inability to simulate the lateral flows of
119   water and nutrients, by incorporating the core biogeochemical processes of DNDC (including the processes of
120   decomposition, nitrification, denitrification and fermentation) into the hydrological framework of the CNMM, which is fully
121   distributed. For the new generation of biogeochemical models, the microbial ecology was integrated into the biogeochemical
122   models, which represents direct microbial control over decomposition, such as MOMOS (Pansu *et al.*, 2010; Treseder *et al.*,
123   2011; Todd-Brown *et al.*, 2012; Pansu *et al.*, 2014). The biogeochemical processes simulated by the DNDC were generally
124   based on first-order kinetics for decomposition and Michaelis-Menten kinetics of two substrates for nitrification and
125   denitrification, which only the parameterized growth and death of nitrifiers and denitrifiers were considered (Li, 2000).
126   However, due to the global application and validation of DNDC (e.g., Chen *et al*., 2008; Giltrap *et al*., 2010; Cui *et al*., 2014,
127   Zhang *et al*., 2015), the biogeochemical processes of DNDC were selected in the CNMM-DNDC despite some deficiencies
128   in simulating microbial biomass.
129   The simulated soil depth (including bedrock) is user-defined. The temporal and spatial resolutions are also user-
130   defined according to the driving data of climate (generally in 3 hours) and digital elevation model (DEM). The soil moisture
131   was calculated based on the mass balance of precipitation, irrigation, evapotranspiration, vertical flow, lateral flow and water

132 from a rising water table. The total water that can be infiltrated during each time step was determined by a defined maximum

133 infiltration rate. Darcy's law was applied for predicting the vertical water flow in the soil profile. A cell-by-cell approach

134 using a kinematic approximation was applied to route the saturated overland and subsurface flow based on DEM. The stream

135 flow was estimated using a cascade of linear channel reservoirs (Wigmosta *et al.*, 1994). For plant growth, gross primary

136 production was simulated using Farquhar *et al.* (1980) for C_3 and Collatz *et al.* (1992) for C_4, with annual primary

137 productivity calculated as the residue of gross primary production and autotrophic respiration. The processes related to the

138 production of N_2O include nitrification and denitrification, which occur simultaneously at aerobic and anaerobic microsites,

139 respectively. The concept of an "anaerobic balloon" was adopted to determine the microsites and allocate substrates for

140 nitrification and denitrification. The sizes of the aerobic (nitrification) and anaerobic (denitrification) microsites were

141 determined by the soil redox potential (Eh) using the Nernst equation (Li, 2007). The "hole in the pipe" concept was applied

142 to calculate N_2O production during nitrification, which is influenced by the soil moisture, temperature and pH (Li, 2016).

143 The production of N_2O during denitrification was predicted with Michaelis-Menten kinetics and Pirt functions following the

144 reaction chain of denitrification. The predicted CH_4 flux was influenced by CH_4 production, oxidation and transportation

145 derived from the module of fermentation in the DNDC (Li, 2007). Methane production and oxidation occurred

146 simultaneously and were determined by the sizes of the aerobic (production) and anaerobic (oxidation) microsites, which

147 were defined by an Eh calculator in terms of an "anaerobic balloon" ("CH_4 balloon") (Li, 2007). The predicted CH_4

148 production was calculated from the carbon substrates resulting from decomposed soil organic carbon (SOC) and plant root

149 biomass with the effects of soil temperature (Li, 2000, 2016). For more details, please see Li. (2000, 2007) and Zhang *et al.*

150 (2018b).

151 **2.1.2 Modifications of the CNMM-DNDC model**

152   In the CNMM-DNDC, the soil temperature was predicted by solving the one-dimensional heat conduction equation

153 with the implicit method of Crank-Nicholson. However, despite the simple parameterization used for the calculation of soil

154 heat capacity and thermal conductivity, the variations of soil temperature induced by the freeze-thaw cycles were also not

155 considered (Table S1 of the online supplementary materials), which inevitably hindered its application in seasonally frozen

156 regions. In this study, the CNMM-DNDC was modified by replacing the above soil thermal module by a physical based

157 module of Northern Ecosystem Soil Temperature (Zhang *et al.*, 2003; Deng *et al.*, 2014), which can explicitly describe the

158 energy exchange within the soil, the active layer dynamics and the soil thermal regime in the presence of freeze-thaw cycles.

159 These modifications are indispensable for accurately simulating freeze-thaw cycles in seasonally frozen regions, which are

160 crucial for characterizing the active layer and soil thermal dynamics, soil hydrology and nitrogen or carbon cycling in these

161 regions. Therefore, the CNMM-DNDC with and without the above modifications are hereafter referred to as the original and

162 modified model, respectively.

163   The modified thermal dynamics of the soil are calculated by the one-dimensional heat conduction equation (Eq. 1).

164 The equation is solved numerically by converting to an explicit form (Eqs. 2–4), which is more efficient for considering the

165 freeze-thaw cycles (Zhang *et al.*, 2003). In the above equations, C (J m^{-3} ℃$^{-1}$), k (W m^{-1} ℃$^{-1}$), T (℃) and G (W m^{-2}) denote

166 the soil heat capacity, thermal conductivity, soil temperature and heat fluxes between layers, respectively. Both Z and D are

167 the thicknesses of the soil layer (m), Δt is the time step of the calculation, and l denotes the soil layer l. S is the internal heat

168 exchange due to freezing or thawing (W m^{-3}) when the soil temperature is around 0 ℃. The soil temperature changes

169 affected by freezing or thawing are determined on the basis of energy conservation, which indicate that the latent heat

170 released during freezing equalled the amount of heat required for the increased soil temperature and vice versa. The dynamic

171 soil heat capacity (C_l, J m^{-3} ℃$^{-1}$) is the weighted average of the heat capacity for five constituents, including organic matter

172 ($C_{l,\,OM}$), minerals ($C_{l,Min}$), water ($C_{l,\,Water}$), ice ($C_{l,\,Ice}$) and air ($C_{l,\,Air}$) (Eq. 5). The values of heat capacity for organic matter,

173 minerals, water, ice and air were 2.5×10^6, 2.0×10^6, 4.2×10^6, 2.1×10^6 and 1.2×10^3 J m^{-3} ℃$^{-1}$, respectively (Huang, 2000). The

174 weight is the relative volumetric fraction of each constituent ($\theta_{l,\,OM}$, $\theta_{l,\,Min}$, $\theta_{l,\,Water}$, $\theta_{l,\,Ice}$, $\theta_{l,\,Air}$) in the soil. The dynamic

175 thermal conductivity (k_l, W m^{-1} ℃$^{-1}$) is calculated using the thermal conductivities of above five constituents (Eq. 6–13),

176 with values of 0.25 ($k_{l,\,OM}$), 2.9 ($k_{l,\,Min}$), 0.57 ($k_{l,\,Water}$), 2.2 ($k_{l,\,Ice}$) and 0.025 ($k_{l,\,Air}$) W m^{-1} ℃$^{-1}$ for organic matter, minerals,

177 water, ice and air, respectively (Johansen, 1975). ST$_l$ denotes the soil temperature of layer l (℃). The upper and lower

178 boundary conditions of the thermal dynamics were determined by the surface energy balance and the defined geothermal

179 heat flux at a soil depth of 35 m.

$$C\frac{\partial T}{\partial t} = \frac{\partial}{\partial Z}\left(k\frac{\partial T}{\partial Z}\right) + S \tag{1}$$

$$C_l\frac{\Delta T_l}{\Delta t} = \frac{G_{l-1,\,l} - G_{l,\,l+1}}{D_l} + S_l \tag{2}$$

$$G_{l-1,\,l} = \frac{(0.5k_l + 0.5k_{l-1})(T_{l-1} - T_l)}{0.5D_{l-1} + 0.5D_l} \tag{3}$$

$$G_{l,\,l+1} = \frac{(0.5k_l + 0.5k_{l+1})(T_l - T_{l-1})}{0.5D_l + 0.5D_{l+1}} \tag{4}$$

$$C_l = C_{l,\,OM}\theta_{l,\,OM} + C_{l,\,Min}\theta_{l,\,Min} + C_{l,\,Water}\theta_{l,\,Water} + C_{l,\,Ice}\theta_{l,\,Ice} + C_{l,\,Air}\theta_{l,\,Air} \tag{5}$$

$$k_l = \frac{\theta_{l,\,Water}k_{l,\,Water} + F_{l,\,Air}\theta_{l,\,Air}k_{l,\,Air\_adj} + F_{l,\,OM+Min}\left(\theta_{l,\,OM} + \theta_{l,\,Min}\right)k_{l,\,OM+Min} + F_{l,\,Ice}\theta_{l,\,Ice}k_{l,\,Ice}}{\theta_{l,\,Water} + F_{l,\,Air}\theta_{l,\,Air} + F_{l,\,OM+Min}\left(\theta_{l,\,OM} + \theta_{l,\,Min}\right) + F_{l,\,Ice}\theta_{l,\,Ice}} \tag{6}$$

$$k_{l,\,Air\_adj} = \begin{cases} k_{l,\,Air} + 0.0238e^{0.0536ST_l} & (\theta_{l,\,Water}>0.09) \\ 0.418 \times \left(0.0615+1.96\theta_{l,\,Water}\right) & (\theta_{l,\,Water} \geq 0.09) \end{cases} \tag{7}$$

$$g\_a = \begin{cases} 0.333 - \dfrac{0.298\theta_{l,\,Air}}{1 - \theta_{l,\,OM} - \theta_{l,\,Min}} & (\theta_{l,\,Water}>0.09) \\ 0.013 + 0.944\theta_{l,\,Water} & (\theta_{l,\,Water} \geq 0.09) \end{cases} \tag{8}$$

$$g\_c = 1.0 - 2.0g\_a \tag{9}$$

$$k_{l,\,OM+Min} = k_{l,\,OM}^{\frac{\theta_{l,\,OM}}{\theta_{l,\,OM} + \theta_{l,\,Min}}} + k_{l,\,Min}^{\frac{\theta_{l,\,Min}}{\theta_{l,\,OM} + \theta_{l,\,Min}}} \tag{10}$$

$$F_{l, \text{Air}} = 0.333\left(\frac{2.0}{1.0 + g\_a\left(\frac{k_{l, \text{Air\_adj}}}{k_{l, \text{Water}}} - 1.0\right)} + \frac{1.0}{1.0 + g\_c\left(\frac{k_{l, \text{Air\_adj}}}{k_{l, \text{Water}}} - 1.0\right)}\right) \tag{11}$$

$$F_{l, \text{OM+Min}} = 0.333\left(\frac{2.0}{1.0 + 0.125\left(\frac{k_{l, \text{OM+Min}}}{k_{l, \text{Water}}} - 1.0\right)} + \frac{1.0}{1.0 + 0.75\left(\frac{k_{l, \text{OM+Min}}}{k_{l, \text{Water}}} - 1.0\right)}\right) \tag{12}$$

$$F_{l, \text{Ice}} = 0.333\left(\frac{2.0}{1.0 + 0.125\left(\frac{k_{l, \text{Ice}}}{k_{l, \text{Water}}} - 1.0\right)} + \frac{1.0}{1.0 + 0.75\left(\frac{k_{l, \text{Ice}}}{k_{l, \text{Water}}} - 1.0\right)}\right) \tag{13}$$

180

181   Compared to the original thermal module, the internal heat exchange due to freezing or thawing (S) was included with
182 improved algorithm for thermal conductivity (k). In addition, the one-dimensional heat conduction equation (Eq. 1) was
183 solved by converting it to an explicit form in the modified model (Eqs. 2–4), while was solved with the implicit method in
184 the original models (Table S1). The modified CNMM-DNDC was able to simulate the thermal dynamics in seasonally
185 frozen regions as well as their impacts on biogeochemical processes, such as the emissions of nitrogen and carbon gases.

2.2 Catchment and field descriptions

187   The study area is the Rierlangshan catchment (34°02′N, 102°43′E) on the eastern Tibetan Plateau with an area of 189
188 ha (Yao *et al.*, 2019). This catchment is located in the source region of the Pai-Lung River, which is a sub-branch of the
189 upper Yangtze River (Zhang *et al.*, 2018a; 2019). This region is subject to a cold humid continental monsoon climate, and it
190 had an annual mean air temperature of 1.6 ± 0.7 ℃ and average annual precipitation of 649 ± 94 mm in 1980–2012 as
191 observed at the Zoige Meteorological Station (~80 km south of the catchment) (Ma *et al.*, 2018). The catchment consists of
192 alpine wetlands, meadows and forests (Yao *et al.*, 2019). The alpine wetlands in the catchment are part of the Zoige wetland
193 and are degraded due to anthropogenic drainage and climate warming (Dong *et al.*, 2010; Li *et al.*, 2014). Degraded alpine
194 wetlands are commonly distributed throughout the Zoige wetland, and nearly 83% of the permanently inundated wetlands
195 have been converted into "wet grassland" (Xiang *et al.*, 2009; Li *et al.*, 2014).

196   CH_4 and N_2O fluxes were manually measured once or twice per week using the gas chromatograph-based static opaque
197 chamber method (Zhang *et al.*, 2018a) at three sites in alpine wetlands (34°02′6.53″N, 102°43′29.66″E, 3304 m a.s.l.),
198 meadows (34°02′01″N, 102°43′28″E, 3326 m a.s.l.) and forests (34°01′47.13″N, 102°44′0.87″E, 3415 m a.s.l.) in the
199 Rierlangshan catchment from 2013 to 2015 (Zhang *et al.*, 2018a; Yao *et al.*, 2019; Zhang *et al.*, 2019) (Fig. S1). Each
200 chamber was wrapped with a layer of styrofoam and aluminium foil to mitigate temperature increases inside the enclosures
201 due to the heating of solar radiation. The alpine wetland site is located at a slope base with a slope of 2°. The wetland has
202 suffered from anthropogenic drainage and climate warming, and thus degraded to be seasonally inundated. The alpine
203 meadow site neighbours the alpine wetland site, which is located on the north-facing slope with gradient of 11°. In addition,
204 soil temperatures at different depths and topsoil moisture in the alpine wetlands, meadows and forests were observed daily

205 and twice per week, respectively. The details regarding the available field observations of the CH_4 and N_2O fluxes and the
206 relevant auxiliary variables are described in Table S2.

2.3 Model simulation

208   The modified CNMM-DNDC was applied in the Rierlangshan catchment with the three alpine ecosystems: wetlands,
209 meadows and forests. The dataset required for the catchment simulation included (1) a digital elevation model (DEM) with a
210 resolution of 30×30 m^2 from the geospatial data cloud (Fig. S1; http://www.gscloud.cn/); (2) a map of alpine ecosystems,
211 including wetlands, meadows and forests; (3) a climate dataset of 3-hour weather data (air temperature, precipitation, wind
212 speed, solar radiation, longwave radiation, and humidity), which were obtained from the meteorological station in the target
213 catchment for the years with field observations (2013.11–2015.10) and were adapted from the daily data at the Zoige
214 Meteorological Station (provided by the National Meteorological Information Center: http://data.cma.cn/; last access: 10th
215 June, 2020) for other years; (4) a soil properties dataset of the observed clay fraction, organic matter content, total nitrogen,
216 pH and bulk density of the three alpine ecosystems in 1 m soil profile (Ma *et al.*, 2018; Zhang *et al.*, 2018a; Yao *et al.*, 2019;
217 Zhang *et al.*, 2019; Table S3); and (5) a management practices dataset including grazing time and intensity for the alpine
218 wetlands and meadows (Table S3). In addition, other required soil inputs of field capacity, wilting point and saturated
219 hydrological conductivity were calculated by pedo-transfer functions (Li *et al.*, 2019; Table S4). The simulated soil depth
220 was defined as 35 m due to the lower boundary conditions of the thermal dynamics, which was set as the geothermal heat
221 flux at a soil depth of 35 m. The simulated soil profile (0−35 m depth) was divided into 23 layers, including the soil (0−1.5
222 m) and bedrock (1.5−35 m). The layer thicknesses of the soil (0−1.5 m) were 1, 5 10 and 50 cm for the depth of 0–10, 10–20,
223 20–100 and 100–150 cm, respectively. The layer thicknesses of the bedrock (1.5−35 m) were 3.5 and 31m for the depth of
224 1.5−4.0 and 4.0−35 m, respectively. The geothermal heat flux in the catchment was estimated at 0.053 W m^{-2} (Pollack and
225 Chapman, 1977). For the target catchment, the soil water dynamics of the alpine ecosystems were determined by the
226 precipitation, evapotranspiration, infiltration, penetration and lateral flow. Using the database, a catchment simulation of
227 hydro-biogeochemical processes was performed with spatial and temporal resolutions of 30×30 m^2 and 3 hours, respectively,
228 by the modified CNMM-DNDC from 2012 to 2015, which could reflect the influences of hydrological processes on soil
229 water dynamics. Thus, the soil water dynamics of the seasonally inundated wetlands were determined by the hydrological
230 processes without any artificial disturbances in the catchment simulation.

2.4 Statistics and analysis

232   The statistical criteria applied for evaluating the model performance in this study included (i) the index of agreement
233 (IA), (ii) the Nash–Sutcliffe efficiency (NSE), and (iii) the determination coefficient (R^2) and slope of the zero-intercept
234 univariate linear regression (ZIR) of the observations against the simulations (e.g., Nash and Sutcliffe, 1970; Willmott and
235 Matsuura, 2005; Moriasi *et al.*, 2007; Congreves *et al.*, 2016; Jiang, 2010; Dubache *et al.*, 2019). A value of IA (0–1) closer
236 to 1 showed a better simulation. An NSE value (ranging from minus infinity to 1) closer to 1 was better. Better model

237 performance was indicated by a slope and an R^2 value that were both closer to 1 in a significant ZIR. For more details on

238 these criteria, refer to the Eqs. S1−4 in Table S5. In addition, the SPSS Statistics Client 19.0 (SPSS Inc., Chicago, USA) and

239 Origin 8.0 (OriginLab, Northampton, MA, USA) software packages were applied for the statistical analysis and graphical

240 comparison.

241 **3 Results**

242 **3.1 Model validation**

243 **3.1.1 Soil temperature and moisture**

244 The profile soil temperatures were observed for alpine wetland and meadow, but only topsoil temperature was

245 observed for the alpine forest, which could be used for model validation. The simulated soil temperatures of the three typical

246 alpine ecosystems were significantly improved by including the scientific processes of soil thermal dynamics suitable for

247 seasonally frozen regions (Figs. 1 and S2). The simulated seasonal dynamics and magnitudes were consistent with those

248 from the field observations for various soil depths, with IA, NSE, and ZIR slopes and R^2 values of 0.91−1.00, 0.68−0.99,

249 0.83−1.09 and 0.73−1.00 for the three alpine ecosystems, respectively (Table 1). For the observed alpine wetlands and

250 meadows, the simulation showed that the freezing of soil started in early November and continued to the end of April in the

251 next year. The frozen depth reached a maximum in the middle of February. However, the simulated maximum frozen depths

252 for the observed alpine meadows (0.69−0.74 m) were approximately double those for the alpine wetlands (0.30−0.39 m) (Fig.

253 S3).

254 For the soil moisture, only topsoil moisture was observed in the three alpine ecosystems, which could be applied for

255 model validation. The simulated topsoil moisture dynamics were comparable to those from the field observations, with IA

256 and NSE values of 0.49−0.83 and -0.80−0.32 for the three alpine ecosystems, respectively (Fig. 2 and Table 1). In

257 comparison to the other alpine ecosystems, the alpine wetlands had higher soil moisture, which ranged from 0.41 to 0.98 and

258 from 0.38 to 0.93 for the observations and simulations in the water-filled pore space (WFPS), respectively. The soil moisture

259 values of the alpine meadows and forests were highly variable and depended on the variation trend in precipitation for both

260 observations and simulations. However, an underestimation of soil moisture in the winter period occurred for both alpine

261 meadows and forests due to a possible overestimation of evapotranspiration. The performances of the modified model in

262 simulating the soil profile temperature and topsoil moisture indicate that the modified CNMM-DNDC can generally predict

263 the soil thermal and topsoil moisture dynamics in the three alpine ecosystems, which is crucial for correctly simulating soil

264 hydrology, plant growth and biogeochemical processes.

3.1.2 Methane fluxes

The daily observed CH_4 emissions from the alpine wetlands were highly variable and showed a clear seasonal cycle, with intensive CH_4 emissions from May to November and weak emissions in other periods (Fig. 3a). The observed alpine meadows and forests functioned exclusively as sinks of atmospheric CH_4 with higher rates of uptake during the growing season and lower uptake rates in the dormant season (Figs. 3b−c). The original model significantly overestimated CH_4 emissions from the alpine wetlands. The modified CNMM-DNDC accurately identified the functions of the sources or sinks in the three alpine ecosystems and generally captured the magnitude and seasonal characteristics of the daily CH_4 fluxes, with an IA of 0.57−0.88 for the three alpine ecosystems (Figs. 3a−c and Table 1). However, the CH_4 uptake rates during the dormant season were obviously underestimated by the modified model at both sites, especially at the alpine forest site, which was responsible for the underestimation of cumulative CH_4 uptake. The observed cumulative CH_4 emissions ranged from -2.60 to 33.5 kg C ha^{-1} yr^{-1} and the modelled values ranged from -1.90 to 31.0 kg C ha^{-1} yr^{-1} (Fig. 4a). For the catchment simulation, the simulated annual CH_4 emissions ranged from -2.35 to 73.0 kg C ha^{-1} yr^{-1} from November 2013 to November 2014 (Fig. S4a). These results indicate that the modified CNMM-DNDC well simulated the CH_4 fluxes of the three typical alpine ecosystems.

3.1.3 Nitrous oxide fluxes

The daily observed N_2O emissions from the alpine wetlands were higher than those from the alpine meadows but lower than those from the alpine forests (Figs. 3d−f). Similar seasonal patterns of N_2O fluxes were observed for the three alpine ecosystems with intensive emissions in the growing season. The N_2O emission peak during the dormant season was observed in the alpine meadows, which was the major contributor to annual emissions. The modified CNMM-DNDC generally captured the seasonal dynamics of daily N_2O fluxes with an IA of 0.26−0.47 for the three alpine ecosystems (Figs. 3d−f and Table 1), but the N_2O emissions from the alpine wetlands were significantly overestimated by the original model. For the modified model, the simulated N_2O emissions from the alpine wetlands and forests showed obvious seasonal patterns with higher emissions during the growing season, but no abrupt emission peak was captured at the end of the growing season for the alpine wetlands. In addition, compared with the original model, the modified model captured the peak emissions that occurred during the freeze-thaw period from the alpine meadows due to the death of microbes, but the dynamics of the peak emissions were not well simulated. The observed cumulative N_2O emissions ranged from 0.14 to 0.58 kg N ha^{-1} yr^{-1} and the modelled values ranged from 0.12 to 0.32 kg N ha^{-1} yr^{-1} (Fig. 4b). For the catchment simulation, the simulated annual N_2O emissions ranged from 0.01 to 0.74 kg N ha^{-1} yr^{-1} from November 2013 to November 2014 (Fig. S4b). These results indicate that the modified CNMM-DNDC has the potential to estimate N_2O emissions in seasonally frozen regions.

3.2 Annual aggregate emissions of CH₄ and N₂O

Annual aggregate emissions of CH_4 and N_2O in carbon dioxide (CO_2) equivalents were calculated for the three alpine ecosystems from November 2013 to November 2014 for alpine wetlands and meadow and from April 2014 to April 2015 for alpine forests, and the global warming potentials were 34 for CH_4 and 298 for N_2O on a 100-year time horizon (IPCC, 2013). The simulated aggregate emissions by the modified model were 1.5, 0.015, and 0.061 Mg CO_2eq ha^{-1} yr^{-1} for the observed alpine wetlands, meadows and forests, respectively, which were consistent with those from the field observations (1.6, 0.014, and 0.15 Mg CO_2eq ha^{-1} yr^{-1} for the alpine wetlands, meadows and forests, respectively) (Fig. 4c). However, the original model significantly overestimated the aggregate emissions due to the high predicted CH_4 and N_2O emissions. In comparison, the observed seasonally inundated wetlands functioned as the sources of aggregate emissions of CH_4 and N_2O, but the aggregate emissions from adjacent wet alpine meadows were much lower.

4 Discussions

4.1 Model performance in simulating thermal dynamics

The soil freeze-thaw cycles in seasonally frozen regions determine the soil profile temperature and hydrological processes, which are key factors that regulate the cycling of nitrogen and carbon (e.g., Zhang *et al.*, 2015; Hugelius *et al.*, 2020). Therefore, improving the scientific processes of soil thermal dynamics in the presence of active layer dynamics is essential for applying the CNMM-DNDC to simulate the biogeochemical processes in seasonally frozen regions, which are sensitive and vulnerable to climate change and human activities (Hatano, 2019; Hugelius *et al.*, 2020; Jiang *et al.*, 2020). The original model adopted a relatively simple module to calculate thermal transportation within the soil profile and did not consider the effects of freeze-thaw cycles on soil temperature and moisture. The newly incorporated module was based on explicit energy conservation and exchange in the soil profile and successfully captured the variations in soil temperature and topsoil moisture for the three alpine ecosystems during the freeze-thaw period. The simulated lower soil frozen depth for the observed alpine wetland was primarily attributed to the higher soil profile moisture level, as the thermal conductivity and heat capacity for water-filled pores were higher than those for air-filled pores. In order to quantify the impacts of climate change on the cycling of carbon and water on the regional and global scales, several large scale ecosystem models or macroscale hydrological models, such as Terrestrial Ecosystem Model, Lund-Potsdam-Jena dynamic global vegetation model and Variable Infiltration Capacity model, have been enhanced to simulate the soil thermal dynamics at northern high latitude (e.g., Wania *et al.*, 2009; Zhuang *et al.*, 2001; Cuo *et al.*, 2015; Jiang *et al.*, 2020). In addition, the soil thermal modules were also improved in some biogeochemical models, such as DNDC and Mobile-DNDC, to evaluate the influences of climate warming on the biogeochemical processes in high latitude regions (e.g., Zhang *et al.*, 2003; de Bruijn *et al.*, 2009; Wolf *et al.*, 2011; Zhang *et al.*, 2012; Deng *et al.*, 2014). Compared with the simulated soil profile temperatures by above models at different scales, the simulations in this study by the modified CNMM-DNDC were equally well, especially for

deeper soil layers (e.g., Wania *et al.*, 2009). For the validated topsoil moisture in this study, the modified model generally captured the variation trends, which were comparable with the performances of other models (e.g., de Bruijn *et al.*, 2009; Wolf *et al.*, 2011; Cuo *et al.*, 2015). However, compared with the studies focused on simulating soil moisture (e.g., Ford *et al.*, 2014), further improvements are still required to improve the model performance in simulating the soil moisture. These results indicate the efficiency of the incorporated module in simulating soil thermal and topsoil moisture dynamics in seasonally frozen regions.

4.2 Model performance in simulating CH$_4$ fluxes

Compared with the annually inundated wetlands, the seasonally inundated wetlands had relatively low observed and simulated CH$_4$ emissions due to the significant influences of the water table level on CH$_4$ emissions (e.g., Hatano, 2019; Zhang *et al.*, 2019). The CH$_4$ emissions simulated by the CNMM-DNDC were determined by the processes of production, oxidation and transpiration. The unsaturated soil with moisture levels ranging from 0.41 to 0.98 WFPS resulted in a small CH$_4$ balloon and thus reduced CH$_4$ production. At the same time, relatively dry conditions caused the upper soil layer to act as an efficient oxidative methanotrophic barrier for the diffusion of CH$_4$ from the subsoil and thus decreased CH$_4$ emissions (Kandel *et al.*, 2018; Tan *et al.*, 2020). In addition, the highly fluctuating CH$_4$ emissions simulated by the modified model were also attributed to the high dependency of CH$_4$ production on soil moisture, which controlled the size of the CH$_4$ balloon. Theoretically, the CH$_4$ emissions simulated by the original model should not be higher than those simulated by the modified model due to the lower predicted soil moisture level. The overestimated CH$_4$ emissions simulated by the original model were mainly attributed to the overestimated soil temperature due to their influences on mineralized substrates for CH$_4$ production, as well as the processes of CH$_4$ production. This result implies that global warming may trigger intensive CH$_4$ emissions from degraded wetlands, which could partly serve as a trade-off for the decreased CH$_4$ emissions due to the lower water table level in degraded wetlands (e.g., Gong *et al.*, 2020). For the studies focused on simulating CH$_4$ emissions from wetlands by the large-scale ecosystem models, the model validation with field observation is difficult due to coarse spatial resolution (e.g., Zhuang *et al.*, 2004). For the biogeochemical model, such as DNDC, the dynamics of CH$_4$ emissions from wetland and peatland in the northern permafrost regions were well simulated (Zhang *et al.*, 2012; Deng *et al.*, 2014), which showed consistent seasonal variations and magnitudes as those in this study. Both observations and simulations showed that the CH$_4$ uptake in alpine forests was higher than that in alpine meadows, which was mainly attributed to the high SOC content of the alpine forests in the simulation. Methane uptake by upland soils is a biological process governed by the availability of CH$_4$ and oxygen as well as the activity and quantity of methanotrophic bacteria in soils (e.g., Liu *et al.*, 2007; Zhang *et al.*, 2014). In the model, the simulated CH$_4$ uptake was positively related to the SOC content, which is closely related to the population size of methanotrophic bacteria. Thus, the SOC content primarily contributed to the differences in CH$_4$ uptake from alpine meadows and forests, as the values for forests were more than twice of those for meadows (Table S3). As the simulated dynamic characteristics of CH$_4$ uptake were primarily regulated by soil temperature and moisture, the inhibitory effects of low soil temperature (< 0.0 ℃) on CH$_4$ uptake rates resulted in obvious underestimations in the dormant season for both

358 alpine meadows and forests. Therefore, an improved parameterization for simulating CH$_4$ uptake under low soil temperatures
359 is required for the model to better capture the dynamics of CH$_4$ uptake in the dormant season.

4.3 Model performance in simulating N$_2$O fluxes

361　　In comparison, the N$_2$O emissions from the alpine wetlands and forests were higher than those from the alpine
362 meadows for both the observations and simulations due to the high SOC content and nitrogen availability. Natural wetlands
363 are large carbon reserves and play a crucial role in mitigating global warming (e.g., Deng *et al.*, 2014; Kang *et al.*, 2020; Tan
364 *et al.*, 2020). The intentional drainage of annually inundated wetlands alters not only the water regime but also nutrient
365 availability (e.g., Hoffmann *et al.*, 2016). The simulated relatively low soil moisture for the alpine wetlands stimulated the
366 decomposition of SOC and nitrogen (or peat oxidation) under aerobic conditions, thus improving nitrogen mineralization for
367 nitrification and denitrification and enhancing N$_2$O emissions (e.g., Tan *et al.*, 2020; Zhang *et al.*, 2020). The intensive N$_2$O
368 emissions simulated by the original model resulted from the overestimated soil temperature for the alpine wetlands. Firstly,
369 as the presence of ice could impede the water movement, the water lateral flows were promoted by the original model due to
370 the neglecting of freeze-thaw cycles. These further resulted in the lower simulated soil moisture as compared with the
371 modified model (Fig. S5), which provided favorable oxygen conditions for N$_2$O production. Meanwhile, the simulated high
372 soil moisture by the modified model provided feasible anaerobic conditions for thoroughly denitrification. Secondly, higher
373 simulated soil temperature by the original model also facilitated the mineralization, which provided more available mineral
374 nitrogen. Field studies showed that high SOC concentrations could stimulate the processes of mineralization and nitrification
375 in the forests (e.g., Li *et al.*, 2005; Yao *et al.*, 2019). The model input of soil organic matter measured in the observed alpine
376 forests was more than twice that in the observed alpine meadows (Table S3). Thus, the high SOC content at the alpine forest
377 site provided more available nitrogen through mineralization and thus stimulated the nitrification processes in the simulation.
378 Furthermore, the seasonal grazing that occurred in the alpine meadows resulted in constant loss of available nitrogen and
379 thus hindered the N$_2$O emissions from the biological processes in the simulation. Field observations showed that the soil
380 freeze-thaw cycles occurred in seasonally frozen regions not only increased the availability of nitrogen and carbon substrates
381 by disrupting of soil aggregates but also affected the structure, population and activity of the microbes, and thus influencing
382 the emissions of N$_2$O (e.g., Song *et al.*, 2019). de Bruijn *et al.* (2009) have explored the combined mechanisms for
383 simulating freeze–thaw related N$_2$O emissions, which were the promoted anaerobiosis and denitrification due to reduced gas
384 diffusion derived from soil frost and snow cover, and the stimulated microbial growth due to easy decomposable organic
385 carbon and nitrogen derived from the dead microbes during freeze-thaw cycles. Wolf *et al.* (2011) introduced an impedance
386 factor to parameterize the reduced water flow between layers in the presence of ice, which could captured the freeze–thaw
387 related N$_2$O emissions for ungrazed steppe. In the CNMM-DNDC, threshold values of soil temperature were set to trigger
388 the death of microbes during the freezing period and stimulate the production of NO, N$_2$O and N$_2$ using substrates derived
389 from the dead microbes during the thawing period, which was similar to one of the mechanisms explored by de Bruijn *et al.*
390 (2009). However, compared with the simulated freeze–thaw related N$_2$O emissions by other studies, the simulated dynamics

13

of peak emissions due to freeze-thaw cycles in this study were inconsistent with those from the field observations. Thus, improvements are required to incorporate some other effective mechanisms to better capture the dynamic characteristics. The peak emissions during the freeze-thaw period were not captured by the original model due to the significantly overestimated soil temperature. The low evaluation statistics for the daily fluxes, especially for the alpine forests, were also attributed to the underestimation of background emissions, which resulted from both measurement errors due to low fluxes around detection limits (± 0.41 g N ha^{-1} d^{-1}) and model deficiencies in the simulation of tight nitrogen cycling in natural ecosystems.

Compared with the empirical model, one key advantage of the process-oriented models is that the models are independent of the local parameterization (Zhang *et al.*, 2015). In this study, default internal parameter combinations of biogeochemical processes were used for the original and modified models, which have been applied in the catchment simulation in the subtropical region (Zhang *et al.*, 2018b), due to the limited field observations (only one year) for both calibration and validation. The biogeochemical processes were predicted by the first-order and Michaelis-Menten kinetics in the CNMM-DNDC based on some defined parameters of flow fractionation. For instance, there are 17 parameters related with N$_2$O emission in the module of denitrification (Table S6), which would inevitably increase the uncertainty of simulation. Houska *et al.* (2017) found that hydro-biogeochemical models can be right for the wrong reasons, such as matching greenhouse gas emissions while failing to simulate soil moisture, which emphasized the importance for simultaneous validations of multi-variables. Thus, simultaneous validations of CH$_4$ and N$_2$O fluxes, as well as soil environment variables, were necessary for comprehensive evaluation of the model performance. In addition, the microbial ecology was recently recommended to be integrated into the biogeochemical model using a smaller number of well-defined kinetic parameters, such as MOMOS (Pansu *et al.*, 2010; Treseder *et al.*, 2011). Therefore, direct control of microbial on biogeochemical processes, such as the stoichiometry of decomposer, is required to be included in the CNMM-DNDC in near future. The model performances of simulating various variables for three typical alpine ecosystems in the Rierlangshan catchment imply that the modified CNMM-DNDC can be applied to predict the thermal dynamics and fluxes of CH$_4$ and N$_2$O from alpine ecosystems in seasonally frozen regions.

5 Conclusions

To apply the process-oriented hydro-biogeochemical model Catchment Nutrient Management Model - DeNitrification-DeComposition (CNMM-DNDC) in seasonally frozen regions, an improved module of soil thermal dynamics for describing the soil thermal regime in the presence of freeze-thaw cycles was incorporated in this study. Using the unique experimental dataset obtained in the Rierlangshan catchment with the typical alpine wetland, meadow and forest ecosystems, the modified model was evaluated for simulating soil thermal dynamics (soil profile temperature), topsoil moisture and fluxes of methane (CH$_4$) and nitrous oxide (N$_2$O) in seasonally frozen regions of the Tibetan Plateau. The modified CNMM-DNDC could generally capture the seasonal dynamics and magnitudes of profile soil temperature, topsoil moisture and fluxes of CH$_4$ and N$_2$O in seasonally frozen regions. Both the observed and simulated CH$_4$ and N$_2$O fluxes from three alpine ecosystems

indice that the aggregate emissions of CH_4 and N_2O were highest for the wetland among three alpine ecosystems. The intensive aggregate emissions of CH_4 and N_2O were regulated by the high soil moisture, which was primarily determined by the CH_4 emissions. This study implies that a hydro-biogeochemical model, such as the modified CNMM-DNDC, are able to predict soil thermal dynamics, topsoil moisture and fluxes of CH_4 and N_2O in seasonally frozen regions with an improved physical-based soil thermal module.

Data availability

The model, input and output databases can be obtained from the first author and all the observed data sets used in this study can be available from the co-authors.

Author contribution

Zheng, X. and Zhang, W. contributed to developing the idea and enhancing the science of this study. Zhang, W. improved the scientific processes of the model, implemented the model simulations and prepared the manuscript with contributions from all co-authors. Li, S. improved the model structure for standard input. Yao, Z., Zhang, H., Ma, L., Wang, K., Wang, R. and Liu, C. designed and carried out the field experiments. Han, S. collected and established the input database for modelling. Deng, J and Li, Y contributed to the modification of the model and the improvement of the manuscript.

Competing interests

The authors declare that they have no conflict of interest.

	Forest	58	Daily	0.47	0.47	-1.85	-1.64	0.44	0.47	–	–	–	–

[a] n indicates the number of the observations. [b] DR denotes the time resolution of the observed data. [c] O indicates the simulations by the original model. [d] M indicates the simulations by the modified model. [e] "–" indicated no value due to the sum of regression square are larger than the sum of the total square for the regression). IA, NSE, ZIR-slope, ZIR-R^2 and ZIR-P indicate the index of agreement, Nash–Sutcliffe efficiency, determination coefficient and slope of the zero-intercept univariate linear regression (ZIR) of the observations against the simulations, as well as the significance level of the ZIR.
