9

10 **Abstract**

11 Biogeochemical hot spots are defined as areas where biogeochemical processes occur with
12 anomalously high reaction rates relative to their surroundings. Due to their importance in carbon
13 and nutrient cycling, characterization of hot spots is critical to accurately predict carbon budgets
14 in the context of climate change. However, biogeochemical hot spots are difficult to identify in
15 the environment, as sampling resolutions are often too coarse to find these areas in the
16 subsurface. Here, we present imaging results of a geophysical survey using the non-invasive
17 induced polarization (IP) method to identify biogeochemical hot spots of carbon turnover in a
18 minerotrophic wetland. To interpret the field-scale IP signatures, geochemical analyses were
19 performed on freeze-core samples obtained in areas characterized by anomalously high and low
20 IP responses. Our results reveal large variations in the electrical response, with the highest IP
21 phase values (> 20 mrad) corresponding with high concentrations of phosphates (>4000 μM),
22 an indicator of carbon turnover. Moreover, analysis of the freeze core reveal negligible
23 concentrations of iron sulfides. The extensive geochemical and geophysical data presented in
24 our study demonstrates that IP images can assess changes in the biogeochemical activity in
25 peat, and identify hot spots.

27 conductivity; induced polarization; microbiologically active zones

28

29 **1 Introduction**

30 In terrestrial and aquatic ecosystems ‘patches’ or areas that show disproportionately high
31 biogeochemical reaction rates relative to the surrounding matrix are referred to as
32 biogeochemical ‘hot spots’ (McClain et al., 2003). Hot spots for turnover of redox-sensitive
33 species (e.g. oxygen, nitrate or dissolved organic carbon) are often generated at interfaces
34 between oxic and anoxic environments, where the local presence/absence of oxygen either
35 favours or suppresses biogeochemical reactions such as aerobic respiration, denitrification or
36 oxidation/reduction of iron (McClain et al., 2003). Biogeochemical hot spots are important for
37 nutrient and carbon cycling in various systems such as wetlands (Frei et al., 2010; 2012), lake
38 sediments (Urban, 1994), the vadose zone (Hansen et al., 2014), hyporheic areas (Boano et al.,
39 2014) or aquifers (Gu et al., 1998). Wetlands are distinct elements in the landscape, which are
40 often located where various hydrological flow paths converge, such as at the bottoms of basin
41 shaped catchments, local depressions or around rivers and streams (Cirimo and McDonnell 1997).
42 Wetlands are attracting increasing interest because of their important contribution to water
43 supply, water quality, nutrient cycling, and biodiversity (Costanza et al., 1997; 2017).
44 Understanding microbial moderated cycling of nutrients and carbon in wetlands is critical, as
45 these systems store a significant part of the global carbon through the accumulation of
46 decomposed plant material (Kayranli et al., 2010). In wetlands, water table fluctuations as well
47 as plant roots determine the vertical and horizontal distribution of oxic and anoxic areas (Frei
48 et al., 2012; Gutknecht et al., 2006). Small scale subsurface flow processes in wetlands,
49 moderated by micro-topographical structures (hollow and hummocks) (Diamond et al., 2020),
50 can control the spatial presence of redox-sensitive solutes and formation of biogeochemical hot
51 spots (Frei et al., 2010; 2012). Despite their relevance for the carbon and nutrient cycles, the
52 field observations of the basic mechanisms controlling the formation and distribution of
53 biogeochemical hot spots in space is largely missing.

54 Biogeochemical active areas traditionally have been identified and localized through chemical
55 analyses of point samples from the subsurface and then subsequent interpolation of the data in
56 space (Morse et al., 2014; Capps and Flecker, 2013; Hartley and Schlesinger, 2000). However,
57 such point-based sampling methods may either miss hot spots due to the low spatial resolution
58 of sampling (McClain et al., 2003) or disturb the redox-sensitive conditions in the subsurface
59 by bringing oxygen into anoxic areas during sampling. Non-invasive methods, such as
60 geophysical techniques, have the potential to study biogeochemical hot spots in-situ without
61 interfering with the subsurface environment (e.g., Williams et al., 2005; 2009; Atekwana and
62 Slater 2009; Flores Orozco et al., 2015; 2019; 2020). Geophysical methods permit to map large

63 areas in 3D and still resolve subsurface physical properties with a high spatial resolution (Binley
64 et al., 2015).

65 In particular, the induced polarization (IP) technique has recently emerged as a useful tool to
66 delineate biogeochemical processes in the subsurface (e.g., Kemna et al., 2012; Kessouri et al.,
67 2019; Flores Orozco et al., 2020). The IP method provides information about the electrical
68 conductivity and the capacitive properties of the ground, which can be expressed, respectively,
69 in terms of the real and imaginary components of the complex resistivity (Binley and Kemna,
70 2005). The method is commonly used to explore metallic ores because of the strong polarization
71 response associated to metallic minerals (e.g., Marshall and Madden, 1959; Seigel et al., 2007).
72 Pelton et al. (1978) and Wong (1979) proposed the first models linking the IP response to the
73 size and content of metallic minerals. More recently, the role of chemical and textural properties
74 in the polarization of metallic minerals has been investigated in detail (Revil et al., 2012, 2015a;
75 2015b, Bückner et al., 2018; 2019). In porous media without a significant metallic content, the
76 IP response can be related to the polarization of the electrical double layer formed at the grain-
77 fluid interface (e.g., Waxman and Smits, 1968; Revil and Florsch, 2010; Revil, 2012). In
78 particular, Revil et al. (2017) carried out complex conductivity measurements on a large set of
79 soil samples, for which they report a linear relation between the magnitude of the polarization
80 response and the cation exchange capacity (CEC), which in turn is related to surface area and
81 surface charge density.

82 Since the early 2010s, various studies have explored the potential of IP measurement for the
83 investigation of biogeochemical processes (Slater and Atekwana, 2013). Laboratory studies on
84 sediment samples examined the correlation between the spectral induced polarization (SIP)
85 response and X iron sulfid precipitation caused by iron reducing bacteria (Williams et al., 2005;
86 Ntarlagiannis et al., 2005; 2010; Slater et al., 2007; Personna et al., 2008; Zhang et al., 2010;
87 Placencia Gomez et al., 2013; Abdel Aal et al., 2014). Further investigations in the laboratory
88 have also revealed an increase in the polarization response accompanying the accumulation of
89 microbial cells and biofilms (Davis et al., 2006; Abdel Aal et al., 2010a, 2010b; Albrecht et al.,
90 2011; Revil et al., 2012; Zhang et al., 2013; Mellage et al., 2018; Rosier et al., 2019; Kessouri
91 et al., 2019).

92 Motivated by these successful laboratory measurements (i.e., Abdel Aal and Atekwana, 2014),
93 the IP method has also been used to characterize biogeochemical degradation of contaminants
94 at the field scale (Williams et al., 2009; Slater and Binley 2006; Flores Orozco et al., 2011;
95 2012b; 2013; 2015; Maurya et al., 2017). Natural accumulations of organic matter in areas with

96 indigenous iron-reducing bacteria might result in naturally reduced zones and the precipitation
97 of iron sulfide minerals. Wainwright et al. (2016) demonstrated the applicability of IP imaging
98 to identify naturally reduced zones, i.e., hot spots in floodplains. Moreover, in a recent study,
99 Flores Orozco et al. (2020) demonstrated the possibility to delineate biogeochemically active
100 zones in a municipal solid waste landfill even in the absence of iron sulfides. Flores Orozco et
101 al. (2020) argued that the high content of organic matter itself might explain both, the high
102 polarization response and high rates of microbial activity; thus, opening the possibility to
103 delineate biogeochemical hot spots that are not related to iron-reducing bacteria. This
104 conclusion is consistent with previous studies performed in marsh and peat soils, areas with a
105 high organic matter content and high microbial turnover rates (Mansoor and Slater, 2007;
106 McAnallen et al., 2018). Peat soils are characterized by a high surface charge and have been
107 suggested to enhance the IP response (Slater and Reeve, 2002). Mansoor and Slater (2007)
108 concluded that the IP method is a useful tool to map iron cycling and microbial activity in marsh
109 soils. Uhlemann et al. (2016) found differences in the electrical resistivity of peat according to
110 saturation, microbial activity, and pore water conductivity; however, their study was limited to
111 direct-current resistivity and did not investigate variations in the IP response. In contrast to
112 these observations, laboratory studies have shown a low polarization response in samples with
113 a high organic matter content, despite its high CEC (Schwartz and Furman, 2014). Based on
114 field measurements, McAnallen et al. (2018) found that active peat is less polarizable due to
115 variations in groundwater chemistry imposed by sphagnum mosses; while degrading peat
116 resulted in low resistivity values and a high polarization response. Based on measurements with
117 the Fourier Transform Infrared (FTIR) Spectroscopy in water samples, the authors concluded
118 that the carbon-oxygen (C=O) double-bond in degrading peat correlated with the polarization
119 magnitude of the peat material. Based on laboratory investigations, Ponziani et al. (2011) also
120 conclude that decomposition of peat occurs predominantly by aerobic respiration, i.e. using
121 molecular oxygen as the terminal electron acceptor to oxidize organic matter. Thus
122 decomposition rates are expected to be highest at the interface between the oxic and anoxic
123 zones.

124 Based on these promising previous results, we believe that the IP method is a potentially useful
125 tool for in-situ investigation of biogeochemical processes. However, different lab and field
126 investigations do not offer a clear interpretation scheme of general validity. This study presents
127 an extensive IP imaging dataset collected at a peatland site to investigate the controls on the IP
128 response in biogeochemically active areas. IP monitoring results are compared to geochemical
129 data obtained from freeze cores and pore water sample analysis. Our main objectives are (i) to

130 assess the applicability of the IP method to spatially delimit highly active biogeochemical areas
131 in the peat soil and (ii) to investigate whether the local IP response is related to the accumulation
132 of iron sulfides or high organic matter turnover.

133 **2 Material and methods**

134 2.1 Study site

135 The study site is part of the Lehstenbach catchment located in the Fichtelgebirge mountains
136 (Fig. 1a), a low mountain range in north-eastern Bavaria (Germany) close to the border to the
137 Czech Republic. Various soil types including Dystric Cambisols, Haplic Podisols, and Histosols
138 (i.e. peat soil) cover the catchment area of approximately 4.2 km², situated on-top of variscan
139 granite bedrock (Strohmeier et al., 2013). The catchment is bowl shaped (Fig. 1b), and
140 minerotrophic riparian peatlands have developed around the major streams. The plot scale study
141 site (Fig. 1c) is located in a riparian peatland draining into a nearby stream close to the
142 catchment's outlet (Fig. 1b).

143 The groundwater level in this area annually varies within the top 30 cm of the peat soil and was
144 5-10 cm below the surface during the measurement campaign. The local groundwater flow has
145 a S-SW orientation (Durejka et al., 2019) towards a nearby drainage ditch. Permanently high
146 water saturation of the peat soil favors the development of anoxic biogeochemical processes
147 close to the surface. Frei et al. (2012) demonstrated that hot spots, related to the stimulation of
148 iron reducing bacteria and accumulation of iron sulfides, are generated by small scale
149 subsurface flow processes and the spatial non uniform availability of electron acceptors and
150 donors induced by the peatland's typical micro topography. Transport limited and spatially non
151 uniform availability of electron acceptors and donors, which to a large extent is controlled by
152 subsurface flow patterns induced by the wetland's micro-topography (hummocks and hollows),
153 in combination with labile carbon stocks are the primary drivers in generating biogeochemical
154 hot spots in the peatland (Frei et al., 2012; Mishra and Riley, 2015).

155 2.2 Experimental plot and geochemical measurements

156 The experimental plot for the geophysical measurements covers approximately 160 m² (12.6 x
157 12.6 m, Fig. 1c) of the riparian peatland. Sphagnum Sp. (peat moss) and *Molinia caerulea*
158 (purple moor-grass) dominate the vegetation, with the sphagnum and purple moor-grass
159 abundance being higher in the Northern part of the plot (Fig. 2a and 2b). In the Southeastern
160 region, where the sphagnum is less abundant, permanent surface runoff was observed (Fig. 2d).
161 To measure the thickness of the peat, a stainless-steel rod (0.5 cm in diameter) was pushed into

162 the ground until it reached the granitic bedrock (similar to Parry et al., 2014). Peat thickness
163 was measured with a 1 m resolution in E-W direction and 0.5 m resolution in N-S direction.
164 During the experiments, the local groundwater level was measured in two piezometers.
165 Groundwater samples were collected at three different locations (S1, S2, and S3 indicated in
166 Fig. 3) using a bailer. Pore water profiles were taken at S1, S2, and S3 at 5 cm intervals to a
167 maximum depth of 50 cm below ground surface (bgs) using stainless steel mini-piezometers.
168 All water samples were filtered through 0.45 μm filters and analyzed for fluoride, chloride,
169 nitrite, bromide, nitrate, phosphate, and sulfate using an ion chromatograph (Compact IC plus
170 882, Metrohm GMBH). Dissolved organic carbon (DOC) was measured using a Shimadzu TOC
171 analyzer via thermal combustion. Dissolved iron species (Fe^{2+}) and total iron (Fe^{tot})
172 concentrations were measured photometrically using the 1,10-phenanthroline method on pore
173 water samples that had been stabilized with 1% vol/vol 1M HCl in the field (Tamura et al.,
174 1974). Two freeze cores (see Fig. 2d) were extracted at locations S1 and S2 (Fig. 3) by pushing
175 an 80-cm long stainless-steel tube into the peat. After the tube was installed, it was filled with
176 a mixture of dry ice and ethanol. After around 20 minutes, the pipe with the frozen peat sample
177 was extracted and stored on dry ice for transportation to the laboratory at the University of
178 Bayreuth. Both freeze cores were cut into 10 cm segments. Each segment was analyzed for
179 reactive iron (1M HCl extraction and measured for Fe^{tot} as described above) (Canfield, 1989),
180 reduced sulfur species using the total reduced inorganic sulfur (TRIS) method (Canfield et al.,
181 1986) and carbon and nitrogen concentrations after combustion using a thermal conductivity
182 detector. Peat samples were also analyzed by FTIR using a Vector 22 FTIR spectrometer
183 (Bruker, Germany) in absorption mode; with subsequent baseline subtraction on KBr pellets
184 (200 mg dried KBr and 2 mg sample). Thirty-two measurements were recorded per sample and
185 averaged from 4.500 to 600 cm^{-1} in a similar manner to Biester et al. (2014).

186 2.3 Non-invasive techniques: induced polarization measurements

187 The induced polarization (IP) imaging method, also known as complex conductivity imaging
188 or electrical impedance tomography, is an extension of the electrical resistivity tomography
189 (ERT) method (e.g., Kemna et al., 2012). As such, it is based on four-electrode measurements,
190 where one pair of electrodes is used to inject a current (current dipole) and a second pair of
191 electrodes is used to measure the resulting electrical potential (potential dipole). Modern
192 devices can measure tens of potential dipoles simultaneously for a given current dipole,
193 permitting the collection of dense data sets within a reasonable measuring time. This provides
194 an imaging framework to gain information about lateral and vertical changes in the electrical
195 properties of the subsurface. IP data can be collected in the frequency domain (FD), where an

196 alternating current is injected into the ground where the polarization of the ground leads to a
197 measurable phase shift between the periodic current and voltage signals. FD measurements can
198 be conducted at different frequencies to gain information about the frequency dependence of
199 the electrical properties of the subsurface. This approach is known as spectral IP (SIP). From
200 the ratio of the magnitudes of the measured voltage and the injected current, as well as the phase
201 shift between the two signals, we can obtain the electrical transfer impedance. The inversion of
202 imaging data sets, i.e. a large set of such four-point transfer-impedance measurements collected
203 at different locations and with different spacing between electrodes along a profile, permits to
204 solve for the spatial distribution of the electrical properties in the subsurface (see deGroot-
205 Hedlin and Constable, 1990; Kemna et al., 2000; Binley and Kemna, 2005).

206 IP imaging results can be expressed in terms of the complex conductivity (σ^*), or its inverse
207 the complex resistivity ($\sigma^*=1/\rho^*$). The complex conductivity can either be denoted in terms of
208 its real (σ') and imaginary (σ'') components, or in terms of its magnitude ($|\sigma|$) and phase (φ):
209 $\sigma^*=\sigma'+i\sigma''=|\sigma|e^{i\varphi}$, (1)

210 where $i = \sqrt{-1}$ is the imaginary unit, $|\sigma| = \sqrt{\sigma'^2 + \sigma''^2}$ and $\varphi = \tan^{-1} \frac{\sigma''}{\sigma'}$.

211 The real part of the complex conductivity is mainly related to the Ohmic conduction, while the
212 imaginary part is mainly related to the polarization of the subsurface. For a more detailed
213 description of the IP method, the reader is referred to the work of Ward (1988), Binley, and
214 Kemna (2005).

215 In this study, we conducted FDIP measurements at 1 Hz along 65 lines during a period of four
216 days in July 2019. We used the DAS-1 instrument manufactured by Multi-Phase Technologies
217 (now MTP-IRIS Inc.). We collected 64 N-S oriented lines (referred to as By 1 to By 64) with
218 20 cm spacing between each line. One additional line (By 68) was collected with a W-E
219 orientation, which intersects the N-S oriented lines at 3 m, as presented in Fig. 3. Each profile
220 consisted of 64 stainless steel electrodes (3 mm diameter) with a separation of 20 cm between
221 each electrode (Fig. 2c). Besides the short electrode spacing, the use of a dipole-dipole
222 configuration with a unit dipole length of 20 cm warranted a high resolution within the upper
223 50 cm of the peat, where the biogeochemical hot spots were expected. We deployed a dipole-
224 dipole skip-0 (i.e., the dipole length for each measurement is equal to the unit spacing of 20
225 cm) configuration, voltage measurements were collected across eight adjacent potential dipoles
226 for each current dipole. The dipole-dipole configuration avoids the use of electrodes for
227 potential measurements previously used for current injections to avoid contamination of the
228 data caused by remnant polarization of electrodes. To evaluate data quality, reciprocal readings

229 were collected along one profile every day (see e.g., LaBrecque et al., 1996; Flores Orozco et
230 al., 2012a; 2019). Reciprocal readings refer to data collected after interchanging current and
231 potential dipoles. We used coaxial cables to connect the electrodes with the measuring device
232 to minimize the distortion of the data due to electromagnetic coupling and cross talking between
233 the cables (e.g., Zimmermann et al., 2008, 2019; Flores Orozco et al., 2013), with the shields
234 of all coaxial cable running together into one ground electrode (for further details see Flores
235 Orozco et al., 2020).

236 **3 Results**

237 3.1 Data quality and processing

238 In Fig. 4, we present a modified pseudosection showing both normal (negative pseudodepth)
239 and reciprocal (positive pseudodepth) readings in terms of apparent resistivity (ρ_a) and apparent
240 phase (ϕ_a) for the data collected along line By 25. Plots in Fig. 4 show consistency between the
241 normal and reciprocal readings of apparent resistivity (4a) and phase (4b). The principle of
242 reciprocity asserts that normal and reciprocal readings should be the same (e.g., Slater et al.,
243 2000). Hence, the misfit between them can be used to detect outliers, and to quantify data errors
244 (LaBrecque et al., 1996; Flores Orozco et al., 2012a; Slater and Binley, 2006; Slater et al.,
245 2000). Figures 4c and 4d show the histograms of the normal-reciprocal misfits along line By
246 25 for both the resistance and phase (ΔR and $\Delta\phi$ respectively), which exhibit near Gaussian
247 distributions with low standard deviations (as expected for random noise) for both the
248 normalized resistance ($S_R=0.027$) and the apparent phase ($S_\phi=1.1$ mrad). Readings exceeding
249 these standard deviation values were considered as outliers (between 16 and 33% of the data at
250 the different lines) and were removed from the data set prior to the inversion.

251 For the inversion of the IP imaging data set, we used CRTomo, a smoothness-constrained least-
252 squares algorithm by Kemna (2000) that allows inversion of the data to a level of confidence
253 specified by an error model. We used the resistance and phase error models described by Kemna
254 (2000) and Flores Orozco et al. (2012a). The resistance (R) error model is expressed as
255 $s(R)=a+bR$, where a is the absolute error, which dominates at small resistances (i.e., $R < 0$),
256 and b is the relative error, which dominates at high resistance values (LaBrecque et al., 1996;
257 Slater et al., 2000). For the phase, the error model is also expressed as a function of the
258 resistance $s(\phi_a)=cR^d$, where $d < 0$ in our study due to the relative low range in the measured
259 resistances (see Flores Orozco et al., 2012a for further details). If $d \rightarrow 0$, the model reduces to

260 the constant-phase-error model (Flores Orozco et al., 2012a) with $s(\phi)=c$ described by Kemna
261 (2000) and Slater and Binley (2006). We quantified the error parameter for each line collected
262 as normal and reciprocal pairs (using the approach outlined by Flores Orozco et al., 2012a) and
263 computed the average value of the error parameters for the inversion of the entire data set. Here,
264 we present inversion results obtained using the error parameters, $a = 0.001 \Omega$, $b = 2.2 \%$, and c
265 $= 1$ mrad. For the imaging, we defined a cut-off value of the cumulated sensitivity of $10^{2.75}$,
266 with pixels related to a lower cumulated sensitivity blanked in the images. The cumulated
267 sensitivity values are a widely used parameter to assess the depth of investigation (Kemna et
268 al., 2002; Flores Orozco et al., 2013).

269 3.2 Complex conductivity imaging results and their link the peat thickness and land 270 cover

271 The thickness of the peat in the plot was found to vary between 40 and 160 cm (Fig. 5). The
272 thickness of the peat unit increased in the W-E direction, with much smaller variations in the
273 N-S direction. Variations in the vegetation cover (as indicated by the three vegetation classes,
274 abundant (*av*), moderate (*mv*) and sparse (*sv*)) do not seem to correspond with the variations in
275 the peat thickness. Note that the N-S orientation of the majority of IP lines is approximately
276 aligned with the direction of minimum changes in the peat thickness.

277 Figure 6 shows the imaging results of the N-S oriented profiles By 25, By 46, and the W-E
278 oriented profile By 68 expressed in terms of the real- (σ') and imaginary (σ'') part of the complex
279 conductivity. These images reveal three main electrical units: (i) a shallow unit with high σ'
280 ($>5 \text{ mSm}^{-1}$) and high σ'' ($>80 \text{ } \mu\text{Sm}^{-1}$) values in the top 10-20 cm bgs, (ii) an intermediate unit
281 with moderate to low σ' ($<5 \text{ mSm}^{-1}$) and moderate σ'' ($40\text{--}80 \text{ } \mu\text{Sm}^{-1}$) values, and (iii) a deep
282 unit characterized by moderate to low σ' ($<5 \text{ mSm}^{-1}$) values and the lowest σ'' ($<40 \text{ } \mu\text{Sm}^{-1}$)
283 values. The low complex conductivity (both σ' and σ'') in the third unit corresponds to the
284 granite bedrock. The compact structure of the granite, corresponding to low porosity, explains
285 the observed low conductivity values ($\sigma' <5 \text{ mSm}^{-1}$) due to low surface charge and surface area.
286 The second and third unit boundary corresponds to the contact between peat and granite
287 measured using the metal rod (represented by the dashed line in Fig. 5). This shows that the
288 electrical imaging can accurately resolve the contact with the bedrock - even in areas where it
289 is located deeper than 1 m bgs.

290 The shallow and intermediate electrical units are related to the relatively heterogeneous peat
291 (Fig. 6). In the first unit, the electrical images reveal lateral changes along the profiles oriented
292 N-S (By 25 and By 46), while we generally observe higher polarization values (σ'') in the

293 northern part of the profiles than in the southern part. This lateral change corresponds to the W-
294 E oriented profile By 68, where the polarization values are the highest around sampling point
295 S1.

296 The phase of the complex conductivity roughly represents the ratio of the polarization (σ'')
297 relative to the Ohmic conduction (σ'). Therefore, it has been argued that the phase represents
298 the polarization effect better than the imaginary conductivity itself as it removes effects
299 stemming from changes in fluid conductivity, saturation, and porosity (Kemna et al., 2004;
300 Ulrich and Slater 2004). Similar to the σ'' images, the phase images presented in Fig. 7 resolve
301 the three main units: (i) the shallow peat unit in the top 10-50 cm is characterized by the highest
302 values ($\phi > 22$ mrad), (ii) the intermediate unit still corresponding to peat, is characterized by
303 moderate ϕ values (between 13 and 22 mrad), and (3) the deep unit, associated to the granitic
304 bedrock, related to the lowest ϕ values (< 13 mrad). The polarization images expressed in terms
305 of ϕ solve the thickness of the peat with higher resolution than the σ' (or σ'') images. Moreover,
306 the shallow unit shows more pronounced lateral variations in the phase than in σ'' and patterns
307 within the peat unit are more clearly defined: Along line By 25, the thickness of the first unit
308 decreases from approx. 0.5 m at 2 m along the profile to 0 m around 10 m at the end of the
309 profile. Along line By 46, the first unit is slightly thicker than 50 cm and shows the highest
310 phase values (~ 25 mrad) between 0 and 6.5 m along the profile. Beyond 6.5 m, the polarizable
311 unit becomes discontinuous with isolated polarizable (~ 18 mrad) zones, which also extend to a
312 depth of 50 cm. The geometry of the polarizable shallow unit is consistent with the
313 corresponding results along line By 68, which crosses By 25 and By 46 at 3 m along these lines
314 (S1 and S3 are located at these intersections). In particular, it is clear that the highest phase
315 values were consistently found in the shallowest 50 cm in the peat unit, at the depth where the
316 presence of biogeochemical hot spots has been reported in previous studies (e.g., Frei et al.,
317 2012).

318 The histograms presented in the right column of Fig. 7 show the distribution of the phase values
319 in the images, with a different color for model parameters extracted above and below the contact
320 between the peat and the granite. The histograms highlight that the lowest phase values clearly
321 correspond to the granite bedrock (< 15 mrad), while higher phase values are characteristic for
322 the peat unit.

323 Fig. 8 presents maps of the electrical parameters at different depths aiming at the identification
324 of a possible link to the vegetation cover: abundant- (*av*), moderate- (*mv*) and sparse vegetation
325 (*sv*), observed at the field (Fig. 5). Such maps present the interpolation of values inverted in

326 each profile. Along each profile, a value is obtained through the average of model parameters
327 (conductivity magnitude and phase) within the surface and a depth of 20 cm (shallow maps)
328 and between 100 and 120 cm (for deep maps). The western part of the experimental plot
329 (between 0 and 4 m in X-direction and between 2 and 9 m in Y-direction) corresponds to a
330 shallow depth to the bedrock (a peat thickness of ~ 50-70 cm) and is associated with a high
331 electrical response in the shallow maps ($\phi > 17$ mrad, $\sigma' > 7$ mSm⁻¹ and $\sigma'' > 100$ μSm⁻¹). In the
332 Northern part of the experimental plot, in the area with abundant vegetation, we observe a
333 higher polarization response for the top 20 cm ($\phi > 20$ mrad and $\sigma'' > 80$ μSm⁻¹) than the one
334 corresponding to the moderate vegetation located at the southern part. In contrast, the lowest
335 polarization values ($\phi < 15$ mrad, and $\sigma'' < 80$ μSm⁻¹) values are related to the area with sparse
336 vegetation. Thus, maps in Fig. 8 suggest that the biogeochemical process controlling the
337 polarization response correlate to the vegetation. On the contrary, the electrical conductivity
338 (σ') reveals only a weak dependence on the vegetation.

339 To support our observation regarding the electrical response and the vegetation, we present in
340 Fig. 8j to 8l the histograms of the electrical parameters extracted at each one of the three
341 vegetation features (abundant, moderate and sparse vegetation). These histograms show, in
342 general, that the location with sparse vegetation, where the water can be seen on the surface,
343 presents the lowest phase values (histogram peak at 13 mrad). Moderate vegetation corresponds
344 with moderate phase values (histogram highest peak at 17 mrad), while the abundant vegetation
345 corresponds with the highest phase values (histogram peak at 20 mrad) in the top 20 cm. The
346 histogram of the three vegetation features in terms of σ' values overlap each other. However,
347 we observe a strong correlation between σ'' and the vegetation, with variations in σ'' permitting
348 to discriminate between areas with a surface cover with abundant and moderate sphagnum and
349 purple moor-grass.

350 3.3 Comparison of electrical and geochemical data

351 The pore-fluid conductivity measured in water samples retrieved from the piezometers show
352 little variations with values ranging between 6.7 and 10.4 mSm⁻¹. The evaluation of the imaging
353 results measured along profiles By 25, By 46, and By 68 were used to guide the selection of
354 locations for the freeze core and sampling of pore water and groundwater. Sampling points S1
355 and S3 were found in the highly polarizable parts of the uppermost peat unit (high σ' and σ''
356 values). In contrast, sampling point S2 is located in an area characterized by particularly low
357 polarization values. Figures 9a-e show the chemical parameters measured in the water samples,
358 specifically chloride (Cl⁻), phosphate (PO₄³⁻), dissolved organic carbon (DOC), total iron (Fe_{tot})

359 = $\text{Fe}^{2+} + \text{Fe}^{3+}$), and pH; whereas Fig. 9f-j show the chemical parameters measured in the peat
360 samples extracted from the freeze cores, namely, cation exchange capacity (CEC),
361 concentrations of iron sulfid (FeS or FeS_2), total reactive iron (Fe_{tot}), potassium (K^+), and
362 sodium (Na^+). To facilitate the comparison of electrical parameters and geochemical data, Fig.
363 9k-m show the complex conductivity values (σ' , σ'' and ϕ) at the sampling points S1, S2 and
364 S3, which were extracted as vertical 1D profiles from the corresponding imaging results.

365 As observed in Fig. 6 and 7, the complex conductivity values (σ' , σ'') were highest within the
366 uppermost 10-20 cm and rapidly decreased with depth. Furthermore, the values of ϕ and σ'' in
367 the top 20 cm at S1 and S3 are significantly higher than those at the location S2. High values
368 of ϕ and σ'' at S1 and S3 correspond with high concentrations of DOC, phosphate⁻, Fe_{tot} in water
369 samples, as well as with high K^+ , and Na^+ contents measured in soil materials extracted from
370 the freeze cores. Fig. 9 reveals consistent patterns between geochemical and geophysical
371 parameters: in the first 10 cm bgs close to the sampling points S1 and S3, we observe complex
372 conductivity values (σ' and σ'') as well as chemical parameters, such as DOC, phosphate, Fe_{tot}
373 at least two times higher than those in S2.

374 Figure 10 shows the actual correlations between complex conductivity and Cl^- , DOC and Fe_{tot}
375 concentrations measured in groundwater samples. In Fig. 10, we also provide a simple linear
376 regression analysis to quantify possible correlations. Figure 10 reveals that the phase has a weak
377 to moderate correlation with DOC, Cl^- and Fe_{tot} . The conductivity (σ') shows a slightly stronger
378 correlation with the DOC, the Cl^- and total iron concentration than the polarization (σ''). The
379 highest σ'' values ($>100 \mu\text{Sm}^{-1}$) are related to the highest DOC and total iron concentration.
380 Hence, it is possible to interpret the high phase values as those related to biogeochemical hot
381 spots.

382 Figure 11 shows the FTIR spectroscopy analysis of the freeze core samples. The spectra show
383 the absorbance intensity at different wavenumbers, C-O bond ($\sim 1050 \text{ cm}^{-1}$), C=O double-bond
384 ($\sim 1640 \text{ cm}^{-1}$), carboxyl ($\sim 1720 \text{ cm}^{-1}$) and O-H bonds ($\sim 3400 \text{ cm}^{-1}$). The peaks are also indicated
385 in Fig. 11 with the interpretation based on the typical values reported in peatlands, for instance
386 McAnallen et al. (2018) or Artz et al. (2008).

387 4 DISCUSSION

388 4.1 Biogeochemical interpretation

389 The geochemical and geoelectrical parameters presented in Fig. 6-7 and 9 displayed consistent
390 patterns, with the highest values within the uppermost 20 cm around S1 and S3. The high DOC,

391 K^+ and phosphate concentrations in the uppermost peat layers and especially in the areas found
392 to be biogeochemically active, strongly suggest that there is rapid decomposition of dead plant
393 material in these areas (Bragazza et al., 2009). Ions such as K^+ and phosphate are essential plant
394 nutrients, and phosphate species especially are often the primary limiting nutrient in peatlands
395 (Hayati and Proctor, 1991). The presence of dissolved phosphate in pore waters suggests that
396 (i) the plant uptake rate of this essential nutrient is exceeded by its production through the
397 decomposition of plant material; and (ii) that organic matter turnover must be rapid indeed to
398 deliver this amount of phosphate to the pore water. This is supported by the DOC concentrations
399 in pore waters exceeding 10 mM. DOC is produced as a decomposition product during
400 microbial hydrolysis and oxidation of solid phase organic carbon via enzymes such as phenol
401 oxidase (Kang et al., 2018). Enzymatic oxidation processes are enhanced by oxygen ingress via
402 diffusion and more importantly by water table fluctuations that work as an ‘oxygen pump’ to
403 the shallow subsurface (Estop-Aragonés et al., 2012). Thus, an increased DOC concentration
404 in the pore water can be used as an indicator for microbial activity (Elifantz et al., 2011; Liu,
405 2013). The small amount of phosphate measured in the less active area S3 can be explained by
406 advective transport from the active area S1, which is directly ‘up-stream’ of S2. In this case,
407 advective water flow through the uppermost peat layers along the hydrological head gradient
408 may have transported a small amount of reaction products from the biogeochemical source
409 areas to the ‘non-active’ area. The high DOC, Fe, K^+ and phosphate levels confirm our initial
410 interpretation of the highly conductive and polarizable geophysical units within the first 20 - 50
411 cm bgs in the surroundings of S1 and S3 as biogeochemically active areas.

412 The high DOC concentrations are also likely to be directly or indirectly responsible for the Fe
413 maximum in the upper layers. Dissolved Fe was predominantly found as Fe^{2+} (reducing
414 conditions) suggesting either that high labile DOC levels maintain a low redox potential, or that
415 the dissolved Fe^{2+} was complexed with the DOC limiting the oxidation kinetics enough so that
416 Fe^{2+} can accumulate in peat pore waters. The TRIS analysis clearly showed very low levels of
417 sulfide minerals in both freeze cores, especially in the uppermost peat layers. This was
418 unexpected considering the reducing conditions implied by the dominance of pore water Fe^{2+} .
419 We argue that the lack of sulfide minerals is due to insufficient H_2S or HS^- needed to form FeS
420 or FeS_2 , or that the redox potential was not low enough to reduce sulfate to H_2S or HS^- . Both
421 mechanisms are possible, as groundwater in the catchment has generally low sulfate
422 concentrations and sulfate was detected in peat pore water samples, which would not be
423 expected if redox potentials were low enough to reduce sulfate to sulfide. The chemical analyses
424 do not reveal any significant or systemic vertical gradient in mineral sulfide concentrations, as

425 expected for the site (Frei et al., 2012). The maximum in extractable (reactive) solid phase Fe
426 was also located in the upper most peat layer at the ‘hot spot’ S1. This Fe was likely in the form
427 of iron oxides or bound to/in the plant organic matter. Such iron rich layers typically form at
428 the redox boundary between oxic and anoxic zones and can be quite dynamic depending on
429 variations in the peatland water levels and oxygen ingress (Wang et al., 2017; Estop-Aragonés,
430 2013).

431 Similar to other peatlands, the FTIR spectra show the presence of carbon-oxygen bonds such
432 as C-O, C=O and COOH booth at S1 and S2, furthermore, the peak intensities at S1 tend to
433 decrease with the depth, while the peak intensities at S2 samples tend to increase correlated to
434 the IP response. The phosphate and Fe could potentially form complexes with the O-H groups
435 that show an absorbance peak at 1050 cm^{-1} (Arai and Sparks, 2001; Parikh and Chorover, 2006).
436 Furthermore, the iron can also form complexes with the carboxyl groups (absorbance at ~ 1720
437 cm^{-1}).

438 4.2 Correlation between the peat and the electrical signatures

439 The two electrical units observed within the peat indicate variations in the biogeochemical
440 activity with depth. Thus, it is likely that the uppermost unit characterized by the highest σ' , σ'' ,
441 and ϕ values corresponds with an active biogeochemical zone, i.e., a hot spot. Consequently,
442 the second electrical unit associated with moderate σ , σ'' , and ϕ values is probably related to a
443 less biogeochemical active or even inactive zone in the peat. The third unit represents the
444 granitic bedrock. The low metal content and the well crystalized form of the granite leads to
445 low σ'' values (here, $< 40\ \mu\text{Sm}^{-1}$), as suggested by Marshall and Madden (1959).

446 The high polarization response of the peat is consistent with the measurements of McAnallen
447 et al. (2018), who performed time-domain IP measurements in different peatlands. They suggest
448 that the active peat is less polarizable due to the presence of the abundant sphagnum cover.
449 They found that in the areas where the peat is actively accumulating, the ratio of the vascular
450 plants and the non-vascular sphagnum is low, and therefore, the oxygen availability is low.
451 However, the sphagnum is expected to exude a small amount of carbon into the peat. Fenner et
452 al. (2004) found that the sphagnum contributes to the DOC leachate to the pore water, which is
453 contradictory to the model of McAnallen et al. (2018). Our observations also show that the high
454 DOC content correlates to an abundant sphagnum cover, in agreement with the observations by
455 Fenner et al. (2004), but we cannot clearly tie this to exudates from roots or decomposition of
456 decaying organic matter. Moreover, at our study site the abundant sphagnum grows in
457 conjunction with abundant purple moor-grass. Figures 8-9 reveal an increase in the polarization

458 response (σ'' , ϕ) with both the abundant vegetation as well as with DOC concentrations
459 measured in pore water. Thus, supporting our interpretation that high polarization values ($\sigma'' >$
460 $100 \mu\text{Sm}^{-1}$ and $\phi > 20 \text{ mrad}$) correspond to biogeochemical hot spots rather than vegetation type.
461 Recent studies have demonstrated an increase in the polarization response due to the
462 accumulation of biomass and activity in the root system (e.g., Weigand and Kemna 2017;
463 Tsukanov and Schwartz, 2020). However, the sphagnum does not have roots; on the other hand,
464 the vascular purple moor-grass can contribute to the high IP, as the roots transport oxygen into
465 the deeper area which contributes to the increase in the polarity and normalized chargeability
466 of the peat (McAnallen et al., 2018).

467 4.3 Possible polarization mechanisms

468 The low-frequency polarization response of subsurface materials is usually attributed to either
469 electrode polarization of highly conductive metallic minerals (e.g., Pelton et al., 1978; Wong,
470 1979) or the polarization of the electrical double layer (EDL) covering charged surfaces of
471 electrically non-conducting solid matter (e.g., Waxman and Smits, 1968; Revil and Florsch,
472 2010; Revil, 2012).

473 Electrode polarization arises from the conductivity contrast between the high electronic (or
474 semi-conductor) conductivity of the metallic mineral and the much lower electrolytic
475 conductivity of the surrounding pore fluid (Wong, 1979). This so-called charge polarization has
476 its maximum at relatively high frequencies ($\gg 1 \text{ kHz}$) unless the conducting minerals are large
477 (Bücker et al., 2018). If charge-transfer reactions take place at the mineral-electrolyte interface,
478 e.g., due to the presence of metallic ions in the electrolyte, the charge polarization is
479 accompanied by a concentration polarization, which potentially shifts the maximum of the
480 electrode-polarization response into the low-frequency range (Bücker et al., 2018). The
481 magnitude of electrode polarization is proportional to the volume content of the conductive
482 minerals (Wong, 1979).

483 In this study, we have found a strong correlation between the polarization response (ϕ and σ'')
484 and Fe_{tot} in the solid phase and a less pronounced correlation between the polarization response
485 and the concentration of dissolved iron in the liquid phase (see Fig. 10). If the iron in the solid
486 phase occurred in the form of highly conductive minerals, the two above correlations would
487 clearly point to an electrode-polarization mechanism as a possible explanation for the observed
488 response. Previous studies (e.g., Flores Orozco et al., 2011; 2013) imply that iron sulfides (FeS
489 or FeS_2) in sediments polarize as long as sufficient Fe^{2+} cations are available in the pore water.
490 However, in the case of the present study, the lack of sulfide, and the rather high Eh (inferred

491 from presence of sulfate) in the pore water, do not favor the precipitation of conductive sulfides
492 such as pyrite. Under these conditions, iron would rather precipitate as iron oxide or form iron-
493 organic matter complexes. The electrical conductivity of most iron oxides is orders of
494 magnitude smaller than the conductivity of sulfides (e.g., Cornell and Schwertmann, 1996), and
495 is thus too low to explain an increased electrode polarization. The only highly conductive iron
496 oxide is magnetite, with a conductivity similar to pyrite (Atekwana et al., 2016). Consequently,
497 the presence of magnetite could explain the electrode polarization. However, the low pH (~5)
498 typical for peat systems does not favor the precipitation of magnetite, but rather less
499 conducting, and thus, less polarizable iron (oxy)hydroxides such as ferrihydrite (Andrade et al.,
500 2010; Linke and Gislason, 2018). As indicated by the FTIR analysis, the iron might furthermore
501 have built complexes with the carboxyl (absorbance at $\sim 1720\text{ cm}^{-1}$). However, it is not clear if
502 these iron complexes might have a sufficiently high electrical conductivity and - in the fashion
503 of conductive iron minerals - permit electrode polarization mechanism.

504 In addition to the polarization of conductive minerals, the polarization response can also be
505 caused by the polarization of the electrical double layer (EDL). The EDL consists of an inner
506 Stern layer of cations adsorbed to the charged solid surface and an outer diffuse layer. Together,
507 these two layers screen the (usually) negative charge of the solid surface and represent a highly
508 conductive and, thus, polarizable surface layer. Depending on the specific geometry of solid
509 and liquid phases, EDL polarization can be understood in terms of the polarization of isolated
510 EDL-covered grains (e.g., Schwarz, Schurr, Leroy et al., 2008) or in terms of membrane
511 polarization linked to EDL-covered pore constrictions (e.g., Marshall and Madden, 1959;
512 Bückner and Hördt, 2013; Bückner et al., 2019). Regardless of the specific mechanism, all EDL
513 polarization mechanisms strongly depend on the specific surface area of the material and the
514 charge density at the surface (Revil, 2012; Waxman and Smits, 1968).

515 The product of both surface charge density and surface area can be quantified by the Cation
516 Exchange Capacity (CEC) of a material. As peat mainly consists of organic matter known to
517 have a high CEC (even compared to most clay minerals; e.g., Schwartz and Furman, 2014; and
518 references therein), EDL polarization of charged organic surfaces may explain the observed IP
519 response. However, in this case, we would expect an increase of the polarization magnitude
520 with the CEC, which we did not observe in our data. The CEC values of the freeze core samples
521 all vary within a narrow range of 5 to 25 meq/kg and we did not observe any correlation between
522 CEC and changes in the polarization magnitude (σ'' , ϕ). Ponziani et al. (2011), who conducted
523 SIP measurements on a set of peat samples, have reported a similar observation previously. In
524 summary, the measured CEC is high enough to explain a rise in EDL-polarization; however,

525 the (small) variation in CEC does not explain the observed variation in the polarization
526 magnitude.

527 The pH of the pore fluid is also known to control the magnitude of EDL polarization; an increase
528 of pH usually corresponds with an increase of the polarization magnitude (e.g., Skold et al.,
529 2011). At low pH values, H⁺ ions occupy (negative) surface sites and thus reduce the net surface
530 charge of the EDL (e.g., Hördt et al., 2016; and references therein). Our data seems to show the
531 opposite behavior: we found a lower pH in the highly polarizable anomalies at S1 and S3
532 compared to site S2 (the inactive and less polarizable location); while the pH increases at depth
533 for decreasing values in the polarization (both σ'' and ϕ). At the same time, variations in pH are
534 within the range 4.45 and 5.77 and thus might not be sufficiently large to cause the observed
535 variation in the polarization response.

536 Besides pH, pore fluid salinity plays a major role in the control of EDL polarization. Laboratory
537 measurements on sand and sandstone samples indicated that an increase in salinity leads to an
538 early increase of the imaginary conductivity, which is eventually followed by a peak and a
539 decrease at very high salinities during later stages of the experiments (e.g., Revil and Skold,
540 2011; Weller et al., 2015). Hördt et al. (2016) provided a possible theoretical explanation of
541 this behavior: In their membrane-polarization model, salinity controls the thickness of the
542 (diffuse layer) of the EDL and depending on the specific geometry of the pores; there is an
543 optimum thickness, which maximizes the magnitude of the polarization response. In the present
544 study, we observed that an increase in salinity (as indicated by the high Cl⁻ concentrations
545 within the uppermost 10 cm at all sampling locations) is associated with an increase in the
546 polarization magnitude response (e.g., Revil and Skold, 2011; Weller et al., 2015; Hördt et al.,
547 2016). However, the highest Cl⁻ concentrations were observed for the shallow layers at location
548 S2, where we measured lower polarization magnitudes (in terms of σ'' , ϕ) compared to S1 and
549 S3.

550 The strong correlation between the polarization response and the DOC suggest an, as yet not
551 fully understood, causal relationship. A similar observation has recently been reported by Flores
552 Orozco et al. (2020), who found a strong correlation between DOC as a proxy of microbial
553 activity and both σ' and σ'' in a municipal waste landfill in Austria. McAnallen et al. (2018)
554 reported a strong correlation between the occurrence of long-chained C=O double bonds and
555 the total chargeability of peat material. The upper peat layers are exposed to oxygen leading to
556 oxidation of the peat and formation of C=O double bonds at solid phase surfaces and in the pore
557 water DOC. Such long-chained organic molecules have an increased polarity and thus more

558 readily attach (or even form at organic matter surfaces) to the surface of solid organic and
559 mineral particles (Alonso et al., 2009). Based on a membrane-polarization model, Bücken et al.
560 (2017) predict an increase of the polarization magnitude in the presence of wetting (i.e., long-
561 chained) hydrocarbon in the free phase. The long-chained polar DOC attaches to the peat
562 surface, similar to polar hydrocarbon, and so it might provide extra surface charge, thus
563 reducing the pore space and causing membrane polarization (Marshall and Madden, 1959).

564 **5 Conclusions**

565 We investigated the applicability of induced polarization (IP) as a tool to identify and localize
566 biogeochemically active areas or “hot spots” in peatlands. IP imaging results revealed a high
567 polarization response for areas that based on the solid and solution phase chemistry can be
568 interpreted as biogeochemically active. The chemical analysis of the groundwater samples and
569 the freeze core indicate that the top 10-20 cm correspond to the highest geochemical activity,
570 whereas the deeper areas of the peat are less active. Accordingly, only the upper 10-20 cm can
571 be defined as biogeochemical hot spots. Moreover, our geophysical survey shows that IP
572 imaging can delineate the geometry of the hot spot with high spatial resolution. In this regard,
573 indicators for increased biogeochemical activity (DOC, phosphate) correspond to a high IP
574 response (σ'' and phase values).

575 Although the exact polarization mechanism is not fully understood, our results reveal that the
576 IP response of the peat changes with the level of biogeochemical activity. Thus, the IP method
577 is capable of distinguishing between biogeochemical active and inactive zones within the peat.
578 The phase values show a contrast between these active and inactive zones and characterize the
579 geometry of the hot spots even if iron sulfides are not present. Previous studies have only
580 investigated the conductive properties of the peat; however, biogeochemical activity within the
581 peat has not been investigated. In this regard, our study shows a new alternative method to
582 characterize biogeochemical changes and their geometry within the peat with high resolution.

583 For further improvement and understanding of the effect of the organic matter such as DOC or
584 phosphate on the polarization response, further laboratory studies on peat samples with different
585 concentration and mixture of DOC, phosphate and iron in the pore fluid are required.

The dashed lines represent the contact between peat and granite; the black dots show the electrode positions at the surface. The vertical lines represent the location of the fluid (S1, S2, S3) and freeze core (S1, S2) samples. The histograms represent the phase values of the granite and peat extracted from the imaging results in (6b, 6d, 6f) according to the geometry of the dashed lines.

611

Figure 8: Maps of the complex conductivity at different depths. The black lines indicate the profiles By 25, By 46, and By 68. The dots represent the locations of the vertical sampling profiles S1, S2, and S3. The white lines outline areas classified as (av) abundant vegetation, (mv) moderate vegetation, (sv) sparse vegetation, and histograms of the complex-conductivity imaging results of the masked areas, the abundant vegetation (red bins), the moderate vegetation (green bins) and the sparse vegetation (blue bins).

612

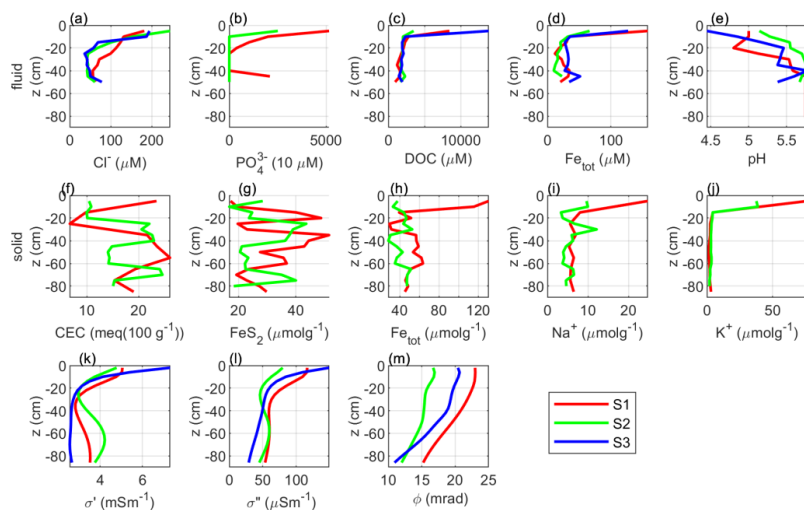

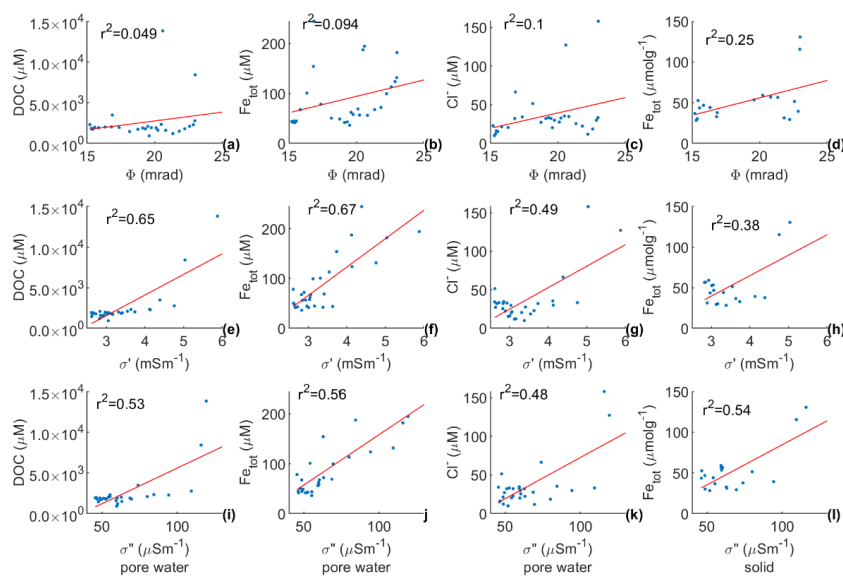

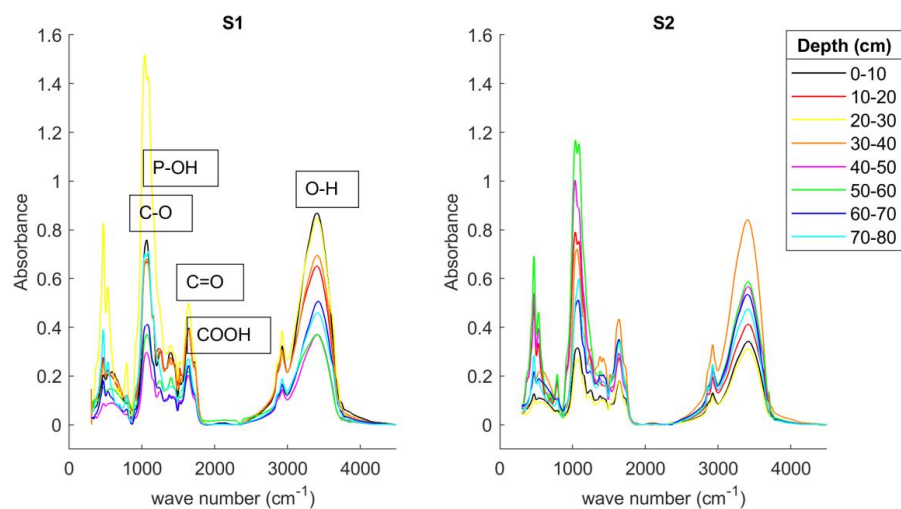

Figure 9: Results of geochemical analyses of water and soil samples. Fluid-sample analysis of the (a) chloride Cl^- , (b) phosphate PO_4^{3-} , (c) dissolved organic carbon, (d) total iron Fe_{tot} , and (e) pH. Freeze-core sample analysis of the (f) cation exchange capacity CEC, (g) iron sulfide FeS_2 , (h) total iron Fe_{tot} , (i) sodium Na^+ , and (j) potassium K^+ . Imaging results at the three sampling locations in terms of (k) real component σ' , (l) imaginary component σ'' , and (m) phase ϕ of the complex conductivity.

614

Figure 10: Correlations between the geophysical and geochemical parameters, phase (ϕ), the real (σ') and imaginary (σ'') component of the complex conductivity (retrieved from the imaging results) and the biogeochemical analysis, expressed in terms of the dissolved organic carbon (DOC), and chloride (Cl⁻) content from the pore fluid samples and total iron (Fe_{tot}) content from pore fluid in μmol^{-1} and solid samples in μmolg^{-1} . The correlation coefficients of least square regressions analysis are shown in the top left corners of the subplots.

615

616

Figure 11: Fourier transform infrared (FTIR) spectroscopy of the freeze core samples collected at S1 (left panel) and S2 (right panel). Each sample was extracted from the 10 cm segments. The lines represent the depth at every 10 cm between 0 and 80 cm below ground surface. The relevant peaks show the absorbance intensity, the interpretation is based on Artz et al. (2008), Arai and Sparks (2001), Parikh and Chorover (2006).
