**Abstract.** The complexity of organic matter (OM) degradation mechanisms represents a significant challenge for developing biogeochemical models to quantify the role of aquatic sediments in the climate system. The common representation of OM by carbohydrates formulated as CH<sub>2</sub>O in models comes with the assumption that its degradation by fermentation produces equimolar amounts of methane (CH<sub>4</sub>) and dissolved inorganic carbon (DIC). To test the validity of this assumption, we modeled using reaction-transport equations vertical profiles of the concentration and isotopic composition ( $\delta^{13}\text{C}$ ) of CH<sub>4</sub> and DIC in the top 25 cm of the sediment column from two lake basins, one whose hypolimnion is perennially oxygenated and one with seasonal anoxia. Furthermore, we modeled solute porewater profiles reported in the literature for four other seasonally anoxic lake basins. A total of seventeen independent porewater datasets are analysed. CH<sub>4</sub> and DIC production rates associated with methanogenesis at the five seasonally anoxic sites collectively show that the fermenting OM has a mean ( $\pm$ SD) carbon oxidation state (COS) value of  $-1.4 \pm 0.3$ . This value is much lower than the value of zero expected from carbohydrates fermentation. We conclude that carbohydrates do not adequately represent the fermenting OM in hypolimnetic sediments and propose to include the COS in the formulation of OM fermentation in models applied to lake sediments to better quantify sediment CH<sub>4</sub> outflux. This study highlights the potential of mass balancing the products of OM mineralization to characterize labile substrates undergoing fermentation in sediments.

## 25 1 Introduction

Significant proportions of atmospheric methane (CH<sub>4</sub>) and carbon dioxide (CO<sub>2</sub>), two powerful greenhouse gases, are thought to originate from freshwater lake sediments (Bastviken et al., 2004; Turner et al., 2015; Wuebbles and Hayhoe, 2002), but large uncertainties remain concerning their contribution to the global CO<sub>2</sub> and CH<sub>4</sub> budgets (Saunois et al., 2016). The role of these waterbodies in the global carbon (C) budget has been acknowledged for more than a decade (Cole et al., 2007). Especially in the lake-rich boreal region, lakes are hotspots of CO<sub>2</sub> and CH<sub>4</sub> release (Hastie et al., 2018; Wallin et al., 2018) and intensive sites of terrestrial C processing (Holgerson and Raymond, 2016; Staehr et al., 2012). Using high-resolution satellite imagery,

Verpoorter et al. (2014) estimated to about 27 million the number of lakes larger than 0.01 km<sup>2</sup> on Earth and reported that the highest lake concentration and surface area are found in boreal regions. Boreal lakes, which are typically small and shallow, are known to store large amounts of organic C, to warm up quickly, and to develop anoxic hypolimnia in the warm season (Sabrekov et al., 2017; Schindler et al., 1996). Owing to the great abundance of boreal lakes, their sensitivity to climate change and foreseen important role in the global C cycle, there is a need to further develop process-based models to better quantify C processing reactions in these lakes and their alteration under warming (Saunio et al., 2016).

In aquatic environments, CH<sub>4</sub> is mainly produced (methanogenesis) in the sediment along with CO<sub>2</sub> at depths where most electron acceptors (EAs) are depleted (Conrad, 1999; Corbett et al., 2013). During its upward migration to the atmosphere, CH<sub>4</sub> is partly aerobically or anaerobically oxidized to CO<sub>2</sub> (methanotrophy) in the upper strata of the sediments and in the water column (Bastviken et al., 2008; Beal et al., 2009; Egger et al., 2015; Ettwig et al., 2010; Raghoebarsing et al., 2006). The oxidation of organic matter (OM) by EAs such as O<sub>2</sub>, NO<sub>3</sub><sup>-</sup>, Fe(III), Mn(IV), SO<sub>4</sub><sup>2-</sup> and humic substances, as well as the partial fermentation of high molecular weight organic matter (HMW OM) into lower molecular weight organic matter (LMW OM) are also potential sources of CO<sub>2</sub> in the sedimentary environment (Corbett et al., 2015). Predicting fluxes of CH<sub>4</sub> and CO<sub>2</sub> from the aquatic sediments and water column to the atmosphere is challenging considering the various transport processes and chemical and microbially-mediated reactions implicated and the complexity of natural OM which serves as substrate (Natchimuthu et al., 2017).

Process-based geochemical models taking into account both the numerous biogeochemical reactions involving C and transport processes are powerful tools able to interpret present-day sediment, porewater and water-column profiles of C species and offer a great potential to forecast changes in cycling of this element under variable environmental scenarios (Arndt et al., 2013; Paraska et al., 2014; Saunio et al., 2016; Wang and Van Cappellen, 1996). Nonetheless, the performance of these models depends on the correct formulation of the complete OM mineralization reactions, e.g., OM decomposition to DIC, phosphate, ammonium and CH<sub>4</sub> through oxidation and fermentation reactions (Burdige 1991), particularly in terms of the metabolizable organic compounds involved. Up to now, carbohydrates, represented as the simple chemical formula CH<sub>2</sub>O (or C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>), whose average carbon oxidation state (COS) is zero, are commonly assumed to be representative of the bulk of metabolizable OM, including the substrates involved in fermentation reactions (e.g., Arndt et al., 2013; Arning et al., 2016; Paraska et al., 2014 and references therein). The capacity of CH<sub>2</sub>O to represent adequately the ensemble of labile organic compounds is, nevertheless, becoming increasingly questioned in the literature given the variety and complexity of organic molecules present in the environment (Alperin et al., 1994; Burdige and Komada, 2011; Clayer et al., 2016; Jørgensen and Parkes, 2010). Based on the observation that methanogenesis produced CH<sub>4</sub> three times faster than CO<sub>2</sub> in the sediments of a boreal, sporadically anoxic lake basin, Clayer et al. (2018) concluded that the fermenting OM had a markedly negative COS value of -1.9. This COS value corresponds more closely to a mixture of fatty acids and fatty alcohols than to carbohydrates (e.g., CH<sub>2</sub>O), which would have yielded equivalent CH<sub>4</sub> and CO<sub>2</sub> production rates. The low COS value of metabolizable OM in the sediment layer where methanogenesis occurred in this lake has been attributed to the nearly complete consumption of the most labile organic components (e.g., carbohydrates, proteins) during its downward transport through the water column and the upper sediment

layers, thus leaving only material of lower lability such as fatty acids and fatty alcohols available for methanogenesis. Such interpretation, however, must be validated by investigating other lakes before revising the formulation of the fermenting OM used in diagenetic models in order to improve model predictions of C cycling, including greenhouse gases production and emission from these environments.

70 In this study, the approach described in Clayer et al. (2018), combining concentration and  $\delta^{13}\text{C}$  inverse modeling, is applied to the two newly acquired datasets. These datasets include centimeter-scale vertical porewater profiles of the concentrations and of the stable carbon isotope ratios ( $\delta^{13}\text{C}$ ) of  $\text{CH}_4$  and dissolved inorganic carbon (DIC), as well as those of the concentrations of EAs from hypolimnetic sediments of two boreal lake basins showing contrasted  $\text{O}_2$  dynamics: one whose hypolimnion remains perennially oxygenated and the other whose hypolimnion becomes anoxic for several months annually. This procedure  
75 enables us to constrain the effective rates of OM mineralization reactions and calculate, using a mass balance equation, the COS of the substrates fermenting in the sediments in these two lake basins. In addition, we modelled solute porewater profiles gathered from the scientific literature or from our data repository for four other seasonally anoxic lake basins to estimate, using the mass balance equation, the COS of the substrates fermenting in these sediments. A total of seventeen independent datasets are analysed to provide additional insight into the COS of the fermenting OM in boreal lakes and the associated mineralization  
80 pathways.

## 2 Materials and Methods

### 2.1 Study sites

This study was carried out in two small, dimictic, oligotrophic and headwater lakes located within 50 km from Québec City, Eastern Canada and having fully forested and uninhabited watersheds (Fig. 1). Lake Tantaré ( $47^\circ 04' \text{N}$ ,  $71^\circ 32' \text{W}$ ) is part of  
85 the Tantaré Ecological Reserve and has four basins connected by shallow channels and a total surface area of  $1.1 \text{ km}^2$ . Lake Bédard ( $47^\circ 16' \text{N}$ ,  $71^\circ 07' \text{W}$ ), lying in the protected Montmorency Forest, comprises only one small ( $0.05 \text{ km}^2$ ) basin. The samples for this study were collected at the deepest sites of Lake Bédard (10 m) and of the westernmost basin of Lake Tantaré (15 m), thereafter referred to as Basin A of Lake Tantaré to remain consistent with our previous studies (e.g., Clayer et al., 2016; Couture et al., 2008). These two sampling sites were selected based on their contrasting  $\text{O}_2$  regimes (Fig. 1): Lake Bédard  
90 develops an anoxic hypolimnion early in the summer (D'arcy, 1993), whereas the hypolimnion of Lake Tantaré Basin A is perennially oxygenated (Couture et al., 2008). The  $\text{O}_2$  diffusion depth in the sediments of Lake Tantaré Basin A, as measured with a microelectrode, does not exceed 4 mm (Couture et al., 2016).

The sediment accumulation rates are  $4.0\text{--}7.3$  and  $2.4\text{--}46.8 \text{ mg cm}^{-2} \text{ yr}^{-1}$  at the deepest sites of Lake Tantaré Basin A and Lake Bédard, respectively (Couture et al., 2010). The relatively constant organic C ( $\text{C}_{\text{org}}$ ) content ( $20 \pm 2\%$ ; Fig. 2b), the elevated  
95  $\{\text{C}_{\text{org}}\}:\{\text{N}\}$  molar ratio ( $17 \pm 2$ ; Fig. 2b), the  $\delta^{13}\text{C}$  ( $-29\text{‰}$ ; Joshani, 2015) and  $\delta^{15}\text{N}$  ( $+0.5\text{‰}$  to  $-2.5\text{‰}$ ; Joshani, 2015) values reported for the sediment OM over the top 30 cm in Lake Tantaré Basin A are typical of terrestrial humic substances (Botrel et al., 2014; Francioso et al., 2005). The  $\text{C}_{\text{org}}$  content ( $21 \pm 2.7\%$ ; Fig. 2a) and  $\{\text{C}_{\text{org}}\}:\{\text{N}\}$  molar ratio ( $14 \pm 1.9$ ; Fig. 2a)

reported over the top 30 cm of Lake Bédard sediments show slightly more variation with depth, but are also typical of terrestrial OM. In addition, the  $\{C_{org}\}:\{S\}$  ratios of both lake basin sediments (50–200) are typical of those reported for soil OM (~125; Buffle, 1988).

## 2.2 Sample collection

Sediment porewater samples were acquired by *in situ* dialysis in October 2015 with peepers (Carignan et al., 1985; Hesslein, 1976) deployed by divers within a 25-m<sup>2</sup> area at the deepest site of each lake basin. Bottom water O<sub>2</sub> concentrations were ~2.5 and < 0.1 mg L<sup>-1</sup> in Lake Tantaré Basin A and in Lake Bédard, respectively. The acrylic peepers comprised two columns of 4-mL cells, filled with ultrapure water, and covered by a 0.2- $\mu$ m Gelman HT-200 polysulfone membrane, which allowed porewater sampling from about 23–25 cm below the sediment-water interface (SWI) to 5 cm above this interface (thereafter referred to as overlying water) at a 1-cm depth resolution. Oxygen was removed from the peepers prior to their deployment, as described by Laforte et al. (2005). Four peepers were left in the sediments of each lake basin for at least 15 d, i.e., a longer time period than that required for solute concentrations in the peeper cells to reach equilibrium with those in the porewater (5–10 d; Carignan et al., 1985; Hesslein, 1976). At least three independent porewater profiles of pH, of the concentrations of CH<sub>4</sub>, DIC, acetate, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup>, Fe and Mn, and of the  $\delta^{13}C$  of CH<sub>4</sub> and DIC were generated for the two sampling sites. In Lake Bédard, samples were also collected to determine three porewater profiles of sulfide concentrations ( $\Sigma S(-II)$ ). After peeper retrieval, samples (0.9–1.9 mL) for CH<sub>4</sub> and DIC concentrations and  $\delta^{13}C$  measurements were collected within 5 minutes from the peeper cells with He-purged polypropylene syringes. They were injected through rubber septa into He-purged 3.85-mL exetainers (Labco Limited), after removal of a volume equivalent to that of the collected porewater. The exetainers were preacidified with 40–80  $\mu$ L of HCl 1N to reach a final pH  $\leq$  2. The protocols used to collect and preserve water samples for the other solutes are given by Laforte et al. (2005).

## 2.3 Analyses

Concentrations and carbon isotopic composition of CH<sub>4</sub> and DIC were measured as described by Clayer et al. (2018). Briefly, the concentrations were analyzed within 24 h of peeper retrieval by gas chromatography with a precision better than 4 % and detection limits (DL) of 2  $\mu$ M and 10  $\mu$ M for CH<sub>4</sub> and DIC, respectively. The <sup>13</sup>C/<sup>12</sup>C abundance ratios of CH<sub>4</sub> and CO<sub>2</sub> were determined by Mass Spectrometry with a precision of  $\pm$  0.2 ‰ when 25  $\mu$ mol of an equimolar mixture of CH<sub>4</sub> and CO<sub>2</sub> was injected, and results are reported as:

$$\delta^{13}C = 1000 \left( \frac{\left( \frac{{}^{13}C_{\text{solute}}}{{}^{12}C_{\text{solute}}} \right)_{\text{sample}}}{\left( \frac{{}^{13}C}{{}^{12}C} \right)_{\text{standard}}} - 1 \right) \quad (1)$$

where the subscript solute stands for CH<sub>4</sub> or DIC and the reference standard is Vienna Pee Dee Belemnite (VPDB). Acetate concentration was determined by ion chromatography (DL of 1.4 μM) and those of Fe, Mn, NO<sub>3</sub><sup>-</sup>, SO<sub>4</sub><sup>2-</sup> and ΣS(-II), as given by Laforte et al. (2005).

## 2.4 Inverse modeling of porewater solutes

The following one-dimensional mass-conservation equation (Boudreau, 1997):

$$\frac{\partial}{\partial x} \left( \varphi D_s \frac{\partial [\text{solute}]}{\partial x} \right) + \varphi \alpha_{\text{Irrigation}} ([\text{solute}]_{\text{tube}} - [\text{solute}]) + R_{\text{net}}^{\text{solute}} = 0 \quad (2)$$

was used to separately model the porewater profile of each relevant solute, i.e., CH<sub>4</sub>, DIC, O<sub>2</sub>, Fe and SO<sub>4</sub><sup>2-</sup>, considering steady state and negligible solute transport by bioturbation and advection. The validity of these assumptions has been previously demonstrated for the study sites (Couture et al., 2008; Couture et al., 2010; Clayer et al., 2016). In this equation, [solute] and [solute]<sub>tube</sub> denote a solute concentration in the porewater and in the animal tubes (assumed to be identical to that in the overlying water), respectively, x is depth (positive downward), φ is porosity, D<sub>s</sub> is the solute effective diffusion coefficient in sediments, α<sub>Irrigation</sub> is the bioirrigation coefficient, and R<sub>net</sub><sup>solute</sup> (in mol cm<sup>-3</sup> of wet sediment s<sup>-1</sup>) is the solute net production rate (or consumption rate if R<sub>net</sub><sup>solute</sup> is negative). D<sub>s</sub> was assumed to be φ<sup>2</sup>D<sub>w</sub> (Ullman and Aller, 1982), where D<sub>w</sub> is the solute tracer diffusion coefficient in water. The values of D<sub>w</sub>, corrected for in situ temperature (Clayer et al., 2018), were 9.5 × 10<sup>-6</sup>, 6.01 × 10<sup>-6</sup>, 1.12 × 10<sup>-5</sup>, 5.81 × 10<sup>-6</sup>, 3.19 × 10<sup>-6</sup>, 1.17 × 10<sup>-5</sup> cm<sup>2</sup> s<sup>-1</sup> for CH<sub>4</sub>, HCO<sub>3</sub><sup>-</sup>, CO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup>, Fe and O<sub>2</sub>, respectively. The values of α<sub>Irrigation</sub> in Lake Tantaré Basin A were calculated as in Clayer et al. (2016), considering that α<sub>Irrigation</sub> varies linearly from α<sub>0,Irrigation</sub> at the SWI (calculated according to Boudreau, 1984 based on an inventory of benthic animals Hare et al., 1994) to 0 at 10 cm depth (the maximum depth at which chironomids are found in lake sediments; Matisoff and Wang, 1998), and were assumed to be 0 in Lake Bédard since its bottom water was anoxic (Fig. 1).

The R<sub>net</sub><sup>solute</sup> values were determined from the average (n = 3 or 4) solute concentration profiles by numerically solving Eq. 2 with the computer code PROFILE (Berg et al., 1998). The boundary conditions were the solute concentrations at the top and at the base of the porewater profiles. In situ porewater O<sub>2</sub> profiles were not measured in Lake Tantaré Basin A. For modeling this solute with PROFILE, we assumed that the [O<sub>2</sub>] in the overlying water was identical to that measured in the lake bottom water and equal to 0 below 0.5 cm (based on O<sub>2</sub> penetration depth; Couture et al., 2016). This procedure provides a rough estimate of R<sub>net</sub><sup>O<sub>2</sub></sup> at the same vertical resolution as for the other solutes. The code PROFILE yields a discontinuous profile of discrete R<sub>net</sub><sup>solute</sup> values over depth intervals (zones) which are objectively selected by using the least square criterion and statistical F-testing (Berg et al., 1998). In order to estimate the variability in R<sub>net</sub><sup>solute</sup> related to heterogeneity within the 25-m<sup>2</sup> sampling area, additional R<sub>net</sub><sup>solute</sup> values were obtained by modeling the average profiles whose values were increased or decreased by one standard deviation. This variability generally ranges between 2 and 10 fmol cm<sup>-3</sup> s<sup>-1</sup>.

In addition, the computer program WHAM 6 (Tipping, 2002) was used, as described by Clayer et al. (2016), to calculate the speciation of porewater cations and anions. The solute activities thus obtained, together with solubility products ( $K_s$ ), were used to calculate saturation index values ( $SI = \log IAP/K_s$ , where IAP is the ion activity product).

## 155 2.5 Reaction network

The main reactions retained in this study to describe carbon cycling in the sediments of the two lake basins are shown in Table 1.  $R_i$  and  $\alpha_i$  denote, respectively, the effective (or gross) reaction rate and the carbon isotopic fractionation factor associated with each reaction  $r_i$  (Table 1). Once oxidants are depleted, fermentation of metabolizable OM of general formula  $C_xH_yO_z$  can yield acetate,  $CO_2$  and  $H_2$  ( $r_1$ ). The coefficient  $\nu_1$  in  $r_1$  constrains the relative contribution of acetoclasty and hydrogenotrophy. The partial degradation of high molecular weight OM (HMW OM) into lower molecular weight OM (LMW OM) can also produce  $CO_2$  ( $r_2$ , Corbett et al., 2013; Corbett et al., 2015). Acetoclasty ( $r_3$ ) and hydrogenotrophy ( $r_4$ ) yield  $CH_4$ . Moreover,  $CH_4$  ( $r_5$ ) and OM ( $r_6$ ) can be oxidized to  $CO_2$  when electron acceptors such as  $O_2$ , Fe(III) and  $SO_4^{2-}$  are present. Note that the electron acceptors (EAs)  $NO_3^-$  and Mn oxyhydroxides were shown to be negligible in these two lake basins (Clayer et al., 2016; Feyte et al., 2012) as well as the precipitation of carbonates whose saturation index values are negative ( $SI \leq -1.5$ ) except for siderite ( $r_7$ ) in Lake Bédard ( $SI = 0.0$  to  $0.7$  below 10 cm depth).

## 2.6 Determining realistic ranges for effective reaction rates

Considering the net reaction rates obtained by inverse modelling, a realistic range of values can be given for each of the effective reaction rates  $R_i$  in each depth interval using the general equations described below. The detailed calculations for each  $R_i$  at both study sites are described in section S2.

170 From Table 1, the net rate of  $CH_4$  production,  $R_{net}^{CH_4}$ , in the sediments is:

$$R_{net}^{CH_4} = R_3 + R_4 - R_5 \quad (3)$$

where  $R_3$  and  $R_4$  are the rates of acetoclastic ( $r_3$ ) and hydrogenotrophic ( $r_4$ ) production of  $CH_4$ , respectively, and  $R_5$  is the rate of DIC production due to  $CH_4$  oxidation ( $r_5$ ). The net rate of DIC production,  $R_{net}^{DIC}$ , can be expressed as:

$$R_{net}^{DIC} = R_1 + R_2 + R_3 - R_4 + R_5 + R_6 - R_7 \quad (4)$$

175 where  $R_1$ ,  $R_2$  and  $R_6$  are the rates of DIC production due to complete fermentation of labile OM ( $r_1$ ), partial fermentation of HMW OM ( $r_2$ ) and OM oxidation ( $r_6$ ), respectively, and  $R_7$  is the rate of DIC removal by siderite precipitation ( $r_7$ ). It can also be written that:

$$R_{net}^{Ox} = -2R_5 - R_6 \quad (5)$$

where  $R_{net}^{Ox}$  is the net reaction rate of all relevant oxidants consumption, i.e.,  $O_2$ , Fe(III) and  $SO_4^{2-}$  only because  $NO_3^-$  and Mn(IV) are negligible (see above). For simplicity,  $R_{net}^{Ox}$  is expressed in equivalent moles of  $O_2$  consumption rate, taking into account that  $SO_4^{2-}$  and Fe(III) have twice and one quarter the oxidizing capacity of  $O_2$ , respectively. In practice, the value of

180  $R_{\text{net}}^{\text{Ox}}$  was calculated by adding those of  $R_{\text{net}}^{\text{O}_2}$ ,  $\frac{1}{4}R_{\text{net}}^{\text{Fe(III)}}$  and  $2R_{\text{net}}^{\text{SO}_4^{2-}}$  where  $R_{\text{net}}^{\text{O}_2}$ ,  $R_{\text{net}}^{\text{Fe(III)}}$  and  $R_{\text{net}}^{\text{SO}_4^{2-}}$  were estimated with PROFILE. In this calculation, we assumed that all dissolved Fe is in the form of Fe(II), and that the rate of Fe(II) consumption through reactions r7 is negligible compared to those associated with reactions r5 and r6. Under these conditions,  $R_{\text{net}}^{\text{Fe(III)}} = -R_{\text{net}}^{\text{Fe}}$ . It should be noted that using  $R_{\text{net}}^{\text{O}_2}$ ,  $-R_{\text{net}}^{\text{Fe}}$  and  $R_{\text{net}}^{\text{SO}_4^{2-}}$  to calculate  $R_{\text{net}}^{\text{Ox}}$ , we indirectly take into account the re-oxidation of reduced S and Fe(II), respectively, to  $\text{SO}_4^{2-}$  and Fe(III) by  $\text{O}_2$ . Indeed, with this procedure, we underestimate the terms  $\frac{1}{4}R_{\text{net}}^{\text{Fe(III)}}$  and  $2R_{\text{net}}^{\text{SO}_4^{2-}}$  because re-oxidation reactions are ignored, but we overestimate by the same amount the term  $R_{\text{net}}^{\text{O}_2}$ . In 185 other words, omission of these re-oxidation reactions affects only the relative consumption rates of individual oxidants and not the value of  $R_{\text{net}}^{\text{Ox}}$ , which is of interest here.

## 2.7 Constraining effective reaction rates with $\delta^{13}\text{C}$ modeling

Once the range of values have been determined for each of the effective rates  $R_i$  (see Table S2), they can be used in another reaction-transport equation to model the  $\delta^{13}\text{C}$  profiles of  $\text{CH}_4$  and DIC. Only sets of  $R_i$  values that yield acceptable modeled 190  $\delta^{13}\text{C}$  profiles, i.e., which fall within one standard deviation of the measured  $\delta^{13}\text{C}$  profiles (grey area fills in Fig. 4), were kept for COS calculation below (section 2.8). The  $\delta^{13}\text{C}$  modeling procedure is summarized below and described in detail in Section S.2. This procedure takes into account the effect of diffusion, bioirrigation (in Lake Tantaré Basin A) and the isotopic fractionation effect of each reaction  $r_i$ .

Briefly, the  $\delta^{13}\text{C}$  profiles of  $\text{CH}_4$  ( $\delta^{13}\text{C}\text{-CH}_4$ ) and DIC ( $\delta^{13}\text{C}\text{-DIC}$ ) were simulated with a modified version of Eq. 1 (Clayer et al., 2018): 195

$$\delta^{13}\text{C} = 1000 \left( \frac{\left( \frac{[^{13}\text{C}]}{[\text{C}]} \right)_{\text{sample}}}{\left( \frac{[^{13}\text{C}]}{[^{12}\text{C}]} \right)_{\text{standard}}} - 1 \right) \quad (6)$$

where  $[\text{C}]$  is the total  $\text{CH}_4$  or DIC concentration ( $[^{12}\text{C}]$  can be replaced by  $[\text{C}]$  since  $\sim 99\%$  of C is  $^{12}\text{C}$ ), and  $[^{13}\text{C}]$  is the isotopically heavy  $\text{CH}_4$  or DIC concentration. Equation 6 allows calculating a  $\delta^{13}\text{C}$  profile once the depth distributions of  $[^{13}\text{C}]$  and  $[\text{C}]$  are known. This information is obtained by solving the mass-conservation equations of C and  $^{13}\text{C}$  for  $\text{CH}_4$  and DIC. The one-dimensional mass-conservation of  $[\text{C}]$  is given by Eq. 2 where [solute] is replaced by  $[\text{C}]$ , whereas that for  $[^{13}\text{C}]$  is 200 the following modified version of Eq. 2 (Clayer et al., 2018):

$$\frac{\partial}{\partial x} \left( \varphi \frac{D_s}{f} \frac{\partial [^{13}\text{C}]}{\partial x} \right) + \varphi \alpha_{\text{Irrigation}} ([^{13}\text{C}]_{\text{tube}} - [^{13}\text{C}]) + \sum_{i=1}^5 \frac{R_i}{\alpha_i} \left( \frac{\delta^{13}\text{C}_i^{\text{reactant}}}{1000} + 1 \right) \left( \frac{[^{13}\text{C}]}{[^{12}\text{C}]} \right)_{\text{standard}} = 0 \quad (7)$$

where  $f$ , the molecular diffusivity ratio, is the diffusion coefficient of the regular solute divided by that of the isotopically heavy solute,  $\alpha_i$  is the isotope fractionation factor in reaction  $r_i$ , and  $\delta^{13}\text{C}_i^{\text{reactant}}$  is the  $\delta^{13}\text{C}$  of the reactant leading to the formation of the solute ( $\text{CH}_4$  or DIC) in reaction  $r_i$ . Input and boundary conditions used to numerically solve Eqs 2 and 7 for

[C] and [<sup>13</sup>C], respectively, via the `bvp5c` function of MATLAB® are described in section 3.4 and in section S2 of the Supporting Information (SI).

The goodness of fit of the model was assessed with the norm of residuals ( $N_{res}$ ):

$$N_{res} = \sqrt{\sum_{x=0.5}^{22.5} (\delta^{13}C_m - \delta^{13}C_s)^2} \quad (8)$$

where  $\delta^{13}C_m$  and  $\delta^{13}C_s$  are the measured and simulated  $\delta^{13}C$  values, respectively. The norm of residuals ( $N_{res}$ ) varies between 0 and infinity with smaller numbers indicating better fits.

## 2.8 COS calculation

210 Considering the complete fermentation of metabolizable OM of general formula  $C_xH_yO_z$ , and making two assumptions, described below for clarity, the COS of the fermenting molecule is given by (combining Eq. S8 and S15; see Section S2 for details):

$$COS = -4 \left( \frac{R_{net}^{CH_4} - R_{net}^{DIC} - R_{net}^{Ox} + R_2}{R_{net}^{CH_4} + R_{net}^{DIC} + (1 - \chi_M)R_{net}^{Ox} - R_2} \right) \quad (9)$$

where  $\chi_M$  is the fraction of oxidants consumed by methanotrophy. Equation 9 is only valid if i)  $r_1$  is the only source of substrates for hydrogenotrophy and acetoclasty (this assumption is discussed in Section 4.2 below); and that ii) siderite precipitation ( $r_7$ ) is negligible (Saturation Index for siderite are negative except below 10 cm depth in the sediment of Lake Bédard, this case is considered in Section S2.1.2.2). With values of  $R_{net}^{CH_4}$  and  $R_{net}^{Ox}$  obtained from PROFILE (section 2.4), values of  $R_2$  and  $\chi_M$  constrained by  $\delta^{13}C$  modeling (section 2.7), Eq. 9 can be used to calculate the COS of the fermenting molecule.

## 2.9 Data treatment of other data sets

220 To better assess the COS of the fermenting OM in lakes, relevant sets of porewater concentration profiles ( $CH_4$ , DIC, EAs, Ca) available from the literature or from our data repository have been modeled with the code PROFILE, as described in section 2.3, to extract their  $R_{net}^{CH_4}$ ,  $R_{net}^{DIC}$  and  $R_{net}^{Ox}$  profiles. These porewater datasets, described in section S3 of the SI, had been generated by sampling porewater in the hypolimnetic sediments of: i) Lake Bédard and Basin A of Lake Tantaré, at other dates than for this study (Clayer et al, 2016); ii) Basin B of Lake Tantaré (adjacent to Basin A; Fig 1), on four occasions (Clayer et al., 2016; 2018); iii) Williams Bay of Jacks Lake (44°41' N, 78°02' W), located in Ontario, Canada, on the edge of the Canadian Shield (Carignan and Lean, 1991); iv) the southern basin of the alpine Lake Lugano (46°00'N, 3°30'E) located in Switzerland, on two occasions (Lazzaretti-Ulmer and Hanselmann, 1999). All lake basins, except Basin A of Lake Tantaré develop an anoxic hypolimnion.

### 3 Results

#### 230 3.1 Solute concentration profiles

Differences among the replicate profiles of CH<sub>4</sub>, DIC, SO<sub>4</sub><sup>2-</sup>, ΣS(-II) and Fe (Fig. 3) at the two sampling sites are generally small (except perhaps those of SO<sub>4</sub><sup>2-</sup> in Lake Bédard) and should be mainly ascribed to spatial variability within the 25-m<sup>2</sup> sampling area. Indeed, the main vertical variations in the profiles are defined by several data points without the sharp discontinuities expected from sampling and handling artifacts. Note that the acetate concentrations, which were consistently  
235 low (< 2 μM), are not shown.

The low Fe (< 5 μM; Fig. 3f) and CH<sub>4</sub> (< 2 μM; Fig. 3a) concentrations as well as the relatively high SO<sub>4</sub><sup>2-</sup> concentrations (36 ± 2.1 μM; Fig. 3e) in the sediment overlying water of Lake Tantaré Basin A are all consistent with the [O<sub>2</sub>] (~2.5 mg L<sup>-1</sup>) measured in the bottom water and are indicative of oxic conditions at the sediment surface. The sharp Fe gradients near the SWI indicate an intense recycling of Fe oxyhydroxides (Fig. 3f; Clayer et al., 2016) and the concave-down curvatures in the  
240 SO<sub>4</sub><sup>2-</sup> profiles (Fig. 3e) reveal SO<sub>4</sub><sup>2-</sup> reduction near the SWI. In contrast to Lake Tantaré Basin A, high Fe (> 200 μM), measurable CH<sub>4</sub> (> 200 μM) low SO<sub>4</sub><sup>2-</sup> (2.7 ± 1.4 μM) and detectable ΣS(-II) concentrations in the overlying waters of Lake Bédard (Fig. 3i, m and n) are consistent with anoxic conditions at the sediment surface. The absence of a sharp Fe gradient at the SWI in Lake Bédard suggests that Fe oxyhydroxides were not recycled in these sediments when porewater sampling occurred.

245 In the two lake basins, SO<sub>4</sub><sup>2-</sup> concentrations reach a minimum between the SWI and 5 cm depth (Fig. 3e and m) and increase below these depths. While increasing SO<sub>4</sub><sup>2-</sup> concentrations with sediment depth are unusual in lake sediments, the mineralization of sulfur-containing OM in the sediment can be a source of SO<sub>4</sub><sup>2-</sup> in low SO<sub>4</sub><sup>2-</sup> environments (Fakhraee et al., 2017). Although, unraveling the sediment sulfur cycling is out of the scope of this study, we note that SO<sub>4</sub><sup>2-</sup> generation through OM mineralization would be consistent with the fact that the dominant sulfur pool in Lake Tantaré Basin A is bound to  
250 sediment OM (Couture et al., 2016).

The concentrations of CH<sub>4</sub> (< 1.5 mM; Fig. 3a and i) are well below saturation at 4°C and *in situ* pressure (4.4–5.5 mM; Duan and Mao, 2006), implying that CH<sub>4</sub> ebullition is a negligible CH<sub>4</sub> transport process. The CH<sub>4</sub> values increases from < 2 μM in the overlying water to 0.18–0.20 mM at the base of the Lake Tantaré Basin A profiles (Fig. 3a), and from 0.2–0.5 mM to 1.0–1.4 mM in those of Lake Bédard (Fig. 3i). The three CH<sub>4</sub> profiles from Lake Tantaré Basin A (Fig. 3a) show a modest concave-up curvature in their upper part, close to the SWI, indicative of a net CH<sub>4</sub> consumption, and a convex-up curvature in their  
255 lower part, typical of a net CH<sub>4</sub> production. Such trends, however, are not observed in Lake Bédard sediments. The CH<sub>4</sub> profiles from this lake exhibit a convex-up curvature over the whole sediment column, although more pronounced in its upper part (Fig. 3i).

The DIC concentrations consistently increase from 0.27–0.32 mM and 1.2–1.5 mM in the sediment overlying water to 0.76–  
260 0.83 mM and 3.5–4.3 mM at the bottom of the profiles in Lake Tantaré Basin A and Lake Bédard, respectively (Fig. 3c and

k). All DIC profiles show a similar shape with a slight concave-up curvature in their lower segment and a convex-up curvature in their upper portions.

### 3.2 Modeled CH<sub>4</sub> and DIC concentration profiles

The modeled [CH<sub>4</sub>] and DIC profiles accurately fit the average (n = 3 or 4) data points ( $r^2 > 0.996$  and  $r^2 > 0.998$  for CH<sub>4</sub> and  
265 DIC, respectively; Fig. 3g,h,o and p). The  $R_{\text{net}}^{\text{CH}_4}$  profiles reveal three zones in each lake basin numbered Z<sub>1</sub>, Z<sub>2</sub> and Z<sub>3</sub> from the  
sediment surface whose boundaries match those defined by the  $R_{\text{net}}^{\text{DIC}}$  profiles. For Lake Tantaré Basin A, Z<sub>1</sub> corresponds to a  
net CH<sub>4</sub> consumption and Z<sub>2</sub> and Z<sub>3</sub> to net CH<sub>4</sub> production, with the highest rate in Z<sub>2</sub> (Fig. 3g). In contrast, the three zones in  
Lake Bédard show net CH<sub>4</sub> production with the highest rate in Z<sub>1</sub> and the lowest in Z<sub>3</sub> (Fig. 3o). The  $R_{\text{net}}^{\text{DIC}}$  profiles in both lake  
basins show a zone of net DIC consumption below two zones of net DIC production with the highest rate values in the Z<sub>1</sub> and  
270 Z<sub>2</sub> for Lake Tantaré Basin A and Lake Bédard, respectively.

The  $R_{\text{net}}^{\text{CH}_4}$  and  $R_{\text{net}}^{\text{DIC}}$  profiles displayed in Figure 3 are, among all the possible solutions, the ones that give the simplest rate  
profile while providing a satisfying explanation of the averaged solute concentration profile as determined by statistical F-  
testing implemented in the code PROFILE (P value  $\leq 0.001$  except for the  $R_{\text{net}}^{\text{DIC}}$  profile in Lake Bédard whose P value is  $\leq$   
0.005). As an additional check of the robustness of the depth distribution of  $R_{\text{net}}^{\text{CH}_4}$  and  $R_{\text{net}}^{\text{DIC}}$  provided by PROFILE, we used  
275 another inverse model, i.e., Rate Estimation from Concentrations (REC; Lettmann et al., 2012) to model the average CH<sub>4</sub> and  
DIC profiles. Note that the statistical method, implemented in REC to objectively select the depth distribution of the net  
reaction rates, i.e., the Tikhonov regularization technique, differs from that of PROFILE. Figure S1 (SI) shows that the two  
codes predicted mutually consistent  $R_{\text{net}}^{\text{CH}_4}$  and  $R_{\text{net}}^{\text{DIC}}$  profiles, with rate values of similar magnitude. PROFILE was also used to  
estimate  $R_{\text{net}}^{\text{SO}_4^{2-}}$ ,  $R_{\text{net}}^{\text{Fe}}$  and  $R_{\text{net}}^{\text{O}_2}$  in order to calculate the value of  $R_{\text{net}}^{\text{Ox}}$  in each zone at both sampling sites (see section 2.3 for  
280 details). The modeled [SO<sub>4</sub><sup>2-</sup>] and [Fe] profiles accurately fit the data points ( $r^2 > 0.983$ ; Fig. S3). As expected from the  
contrasting O<sub>2</sub> regimes of the two lake basins,  $R_{\text{net}}^{\text{Ox}}$  values for Lake Tantaré Basin A were one to two orders of magnitude  
higher than those for Lake Bédard. The values of  $R_{\text{net}}^{\text{CH}_4}$ ,  $R_{\text{net}}^{\text{DIC}}$  and  $R_{\text{net}}^{\text{Ox}}$  estimated in each zone of each lake basins are reported  
in Table 2.

### 3.3 Measured $\delta^{13}\text{C}$ profiles

285 The  $\delta^{13}\text{C}$ -DIC values increase from  $-28.2 \pm 0.4$  ‰ and  $-17.2 \pm 0.7$  ‰ in the overlying water to  $-5.1 \pm 1.0$  ‰ and  $3.6 \pm 1.7$  ‰  
at the base of the profiles in Lake Tantaré Basin A and Lake Bédard, respectively (Fig. 3d and l). Similarly, the  $\delta^{13}\text{C}$ -CH<sub>4</sub>  
values in Lake Bédard increase steadily from  $-82.5 \pm 3.3$  ‰ in the overlying water to  $-74.0 \pm 1.5$  ‰ at 24.5 cm depth (Fig.  
3j). Regarding Lake Tantaré Basin A, the CH<sub>4</sub> concentrations above 1.5 cm depth were too low for their <sup>13</sup>C/<sup>12</sup>C ratio to be  
determined. Starting at 1.5 cm depth, the  $\delta^{13}\text{C}$ -CH<sub>4</sub> values first decrease from  $-91.1 \pm 11.1$  ‰ to  $-107.0 \pm 6.8$  ‰ at 2.5 cm  
290 depth and then increase progressively to  $-83.5 \pm 1.6$  ‰ at the base of the profiles (Fig. 3b). Note that a shift toward more

positive  $\delta^{13}\text{C-CH}_4$  values upward, generally attributed to the oxidation of  $\text{CH}_4$  (Chanton et al., 1997; Norđi et al., 2013), is only observed in the profiles of Lake Tantaré Basin A (Fig. 3b).

As shown in Fig. S2 (SI), the isotopic signatures of nearly all samples from the two lake basins fall within the ranges reported for hydrogenotrophic methanogenesis, i.e.,  $\text{CO}_2$  reduction, in a  $\delta^{13}\text{C-CO}_2$  vs  $\delta^{13}\text{C-CH}_4$  graph similar to that proposed by Whiticar (1999). Indeed, the values of  $\delta^{13}\text{C-CH}_4$  which are lower than -70 ‰ over the whole profiles in the two lake basins, and the large difference (67 to 92 ‰) between the  $\delta^{13}\text{C}$  of gaseous  $\text{CO}_2$  ( $\delta^{13}\text{C-CO}_2$ ) and  $\delta^{13}\text{C-CH}_4$ , strongly contrast with the typical  $\delta^{13}\text{C-CH}_4$  values (-68 to -50 ‰) and with the difference between  $\delta^{13}\text{C-CO}_2$  and  $\delta^{13}\text{C-CH}_4$  (39 to 58 ‰) reported for acetoclasty (Whiticar, 1999). The  $\delta^{13}\text{C}$  results reported previously for another basin of Lake Tantaré (Basin B; Clayer et al., 2018) show also in the hydrogenotrophy domain in Fig. S2.

### 300 3.4 Modeled $\delta^{13}\text{C}$ profiles

In order to model the  $\delta^{13}\text{C}$  profiles with Eq. 6, accurate profiles of  $[\text{C}]$  and  $[\text{C}^{13}]$  need first to be determined by numerically solving Eqs. 2 and 7, respectively. The modeled profiles of  $[\text{CH}_4]$  and DIC obtained with Eq. 2 replicated perfectly the measured profiles of these two solutes. Getting a truthful profile of  $[\text{C}^{13}]$  with Eq. 7 requires accurate values of  $\delta^{13}\text{C}_i^{\text{reactant}}$ ,  $\alpha_i$ , and  $R_i$  for each of the reactions given in Table 1, and of  $f$  for both  $\text{CH}_4$  ( $f\text{-CH}_4$ ) and DIC ( $f\text{-DIC}$ ). The multi-step procedure to obtain the best  $[\text{C}^{13}]$  profiles for  $\text{CH}_4$  and DIC is described in section S2 (SI) and allowed us to constrain the  $f$ ,  $\chi_M$ ,  $\alpha_i$  and  $R_i$  values.

The best fits between the simulated and measured  $\delta^{13}\text{C}$  profiles of  $\text{CH}_4$  and DIC for Lake Tantaré Basin A and Lake Bédard (red lines in Fig. 4) were obtained with the  $f$ ,  $\alpha_i$  and  $R_i$  values displayed in Table 3. The optimal  $\alpha_i$  and  $f$  values were within the ranges reported in the literature for both lake basins and similar to those reported in our previous study on Lake Tantaré Basin B (Clayer et al., 2018), except for the lower-than-expected value of  $\alpha_2$  (0.984) in the  $Z_2$  of Lake Bédard. Modeled  $\delta^{13}\text{C}$  profiles were considered acceptable only when they fell within one standard deviation of the measured  $\delta^{13}\text{C}$  profiles (grey area fills in Fig. 4). Acceptable modeled  $\delta^{13}\text{C}$  profiles were obtained only when methanogenesis was 100% hydrogenotrophic, i.e., when  $R_3 = 0$  (see section S2.2.2.1).

The sharp upward depletion in  $^{13}\text{C-CH}_4$  leading to a minimum  $\delta^{13}\text{C-CH}_4$  value at 2.5 cm depth in Lake Tantaré Basin A sediments (Fig. 4a) was unanticipated since it occurs in the methanotrophic zone, i.e., where the remaining  $\text{CH}_4$  is expected to be  $^{13}\text{C}$ -enriched as a result of  $\text{CH}_4$  oxidation. Marked  $^{13}\text{C-CH}_4$  depletions at the base of the sulfate-methane transition zone, where  $\text{CH}_4$  is consumed via  $\text{SO}_4^{2-}$  reduction, have often been observed in marine sediments (Burdige et al., 2017 and references therein). Such features are generally attributed to the production of  $\text{CH}_4$  by hydrogenotrophy from the  $^{13}\text{C}$ -depleted DIC resulting from the anaerobic  $\text{CH}_4$  oxidation, a process referred to as intertwined methanotrophy and hydrogenotrophy (e.g., Borowski et al., 1997; Burdige et al., 2017; Pohlman et al., 2008). Here the modelled  $\delta^{13}\text{C-CH}_4$  profile captured the minimum in  $\delta^{13}\text{C-CH}_4$  in the  $Z_1$  by simply assuming concomitant hydrogenotrophy and methanotrophy in this zone and an upward-increasing  $\alpha_4$  value from 1.085 in the  $Z_3$  to 1.094 in the  $Z_1$  (section S2.2.1 of the SI). A small variation with sediment depth in

the fractionation factor  $\alpha_4$  is arguably possible since its value depends on the types of microorganisms producing  $\text{CH}_4$  (Conrad, 2005).

## 325 4 Discussion

### 4.1 Organic matter mineralization pathways at the sampling sites

The porewater data as well as the combined modeling of carbon isotopes and concentration profiles, allows to highlight key OM mineralization mechanisms and to quantify the relative contribution of methanogenesis and fermentation to OM degradation at both sampling sites. The  $^{13}\text{C}$  isotopic signatures, i.e., highly negative values of  $\delta^{13}\text{C}\text{-CH}_4$  and large differences  
330 between  $\delta^{13}\text{C}\text{-CO}_2$  and  $\delta^{13}\text{C}\text{-CH}_4$  (section 3.3 and Fig. S2 in the SI), as well as the modeling of the  $\delta^{13}\text{C}\text{-CO}_2$  and  $\delta^{13}\text{C}\text{-CH}_4$  profiles (section S2.2.2.1 and Fig S4a and b in the SI) all point to hydrogenotrophy as being the only pathway for methanogenesis in the two lake basins. The dominance of hydrogenotrophy is consistent also with the finding that acetate concentrations were close to or below DL in the porewater samples. Under the condition that acetoclasty is negligible (i.e.,  $x = \nu_1$ ), reaction r1 from Table 1 becomes:

335 Methanogenesis was also reported to be essentially hydrogenotrophic in the sediments of Basin B of Lake Tantaré (Clayer et al 2018). The absence of acetoclasty in the sediments of the oligotrophic lakes Bédard and Tantaré is consistent with the consensus that hydrogenotrophy becomes an increasingly important  $\text{CH}_4$  production pathway: i) when labile OM is depleted (Chasar et al., 2000; Hornibrook et al., 2000; Whiticar et al., 1986), ii) with increasing sediment/soil depth (Conrad et al., 2009; Hornibrook et al., 1997), or iii) with decreasing rates of primary production in aquatic environments (Galand et al., 2010;  
340 Wand et al., 2006).

The modelling of concentrations and  $\delta^{13}\text{C}$  profiles revealed that oxidative processes occurred essentially in the upper 7 cm of the sediments of the perennially oxygenated Lake Tantaré Basin A, i.e., mainly in the  $Z_1$  and, to a lesser extent, in the  $Z_2$  (Table 3 and sections S2.1.2.1 and S2.1.2.2 of the SI). Moreover, it showed that methanotrophy was the dominant oxidative reaction in these sediment layers since 75% of the oxidants were consumed through r5 (section S2.2.2.2 of the SI). This outcome is  
345 consistent with several studies showing that methanotrophy occurs at higher rates than OM oxidation at low EA concentrations (Kankaala et al., 2013; Pohlman et al., 2013; Sivan et al., 2007; Thottathil et al., 2019). Methanotrophy is also evidenced in the  $Z_1$  of this lake basin by the negative  $R_{\text{net}}^{\text{CH}_4}$  value and by a shift of the  $\delta^{13}\text{C}\text{-CH}_4$  profiles to more positive values in their upper part (Fig. 3b and g). Use of Eq. 2 to model the EAs profiles with the code PROFILE predicts that  $\text{O}_2$  was by far the main EA involved either directly, or indirectly via the coupling with the Fe or S cycles, in the oxidative processes. Indeed, comparing  
350 the values of  $R_{\text{net}}^{\text{O}_2}$  and  $R_{\text{net}}^{\text{Ox}}$  (see Section 3.2 and Table 2) shows that  $\text{O}_2$  accounts for 87% and 70% of the oxidants consumed in the  $Z_1$  and  $Z_2$  of Lake Tantaré Basin A, respectively. Since  $\text{O}_2$  penetration in the sediment by molecular diffusion is limited to ~4-mm, a significant amount of  $\text{O}_2$  is predicted by Eq. 2 to be transported deeper in the sediment through bioirrigation. The

predominance of O<sub>2</sub> among the EAs consumed in the sediments is consistent with our previous study in this basin of Lake Tantaré (Clayer et al., 2016). Given that methanotrophy is the dominant oxidative process and that O<sub>2</sub> is the main oxidant consumed, it is probable that aerobic oxidation of methane prevails over its anaerobic counterpart in this lake basin. This is in line with the common thinking that CH<sub>4</sub> oxidation in freshwater lake sediments is carried out by methanotrophs essentially in the uppermost oxic sediment layer (Bastviken et al., 2008 and references therein).

In the Z<sub>2</sub> of Lake Bédard, the net rate of DIC production (i.e., 167 fmol cm<sup>-3</sup> s<sup>-1</sup>) was more than 3 times that of CH<sub>4</sub> production (50 fmol cm<sup>-3</sup> s<sup>-1</sup>; Table 2). Given that the R<sub>net</sub><sup>Ox</sup> was negligible in this zone (i.e., R<sub>5</sub> = R<sub>6</sub> = 0), we obtain from Eqs 3 and 4 and Table 2 that R<sub>net</sub><sup>CH<sub>4</sub></sup> = R<sub>4</sub> = 50 fmol cm<sup>-3</sup> s<sup>-1</sup> and R<sub>net</sub><sup>DIC</sup> = R<sub>1</sub> + R<sub>2</sub> - R<sub>4</sub> = 167 fmol cm<sup>-3</sup> s<sup>-1</sup> (see section S2.1.2.2 of the SI). Should we assume that DIC production by r2 is negligible, i.e., R<sub>2</sub> = 0, a R<sub>1</sub>/R<sub>4</sub> ratio of 4.3 would be obtained. This high ratio indicates that DIC was not produced by fermentation (r1) alone in the Z<sub>2</sub> of this lake. Indeed, methanogenesis through the coupling of r1 and r4 yields a R<sub>1</sub>/R<sub>4</sub> ratio of 2 if the fermenting substrate is carbohydrates (COS of 0) and lower than 2 if the fermenting substrate has a negative COS value. We thus attributed the production of the additional DIC to the partial fermentation of HMW OM, an assumed non-fractionating process reported to occur in wetlands (Corbett et al., 2015). The better fitting of the δ<sup>13</sup>C-DIC profile when α<sub>2</sub> is set to 0.980–0.984 rather than to 1.000 in the Z<sub>2</sub> (compare the blue and red lines in Fig. 4b) suggests that C fractionates during this partial fermentation process.

Table 3 displays the depth-integrated reaction rates (ΣR<sub>i</sub>) over the top 21cm of the sediment column which are given by:

$$\Sigma R_i = \sum_{j=1}^3 \Delta x_j R_i \quad (11)$$

where Δx<sub>j</sub> (cm) is the thickness of the zone Z<sub>j</sub>. In this calculation, we assume that other zones of CH<sub>4</sub> or DIC production are absent below 21 cm. Values of ΣR<sub>i</sub> clearly show that anaerobic carbon mineralization reactions (fermentation and methanogenesis) are important contributors to the overall OM mineralization in the two studied lake basins. Indeed, the sum of the rates of CH<sub>4</sub> production (ΣR<sub>4</sub>), DIC production due to fermentation associated with CH<sub>4</sub> formation (ΣR<sub>1</sub> - ΣR<sub>4</sub>) and HMW OM partial fermentation (ΣR<sub>2</sub>) represents 54% and 100% of the total OM degradation rate (ΣR<sub>1</sub> + ΣR<sub>2</sub> + ΣR<sub>6</sub>) in the sediment of lakes Tantaré Basin A and Bédard, respectively. Considering the sediment accumulation rate and sediment C<sub>org</sub> content given in section 2.1, we calculate an average accumulation rate of C<sub>org</sub> of 4.7×10<sup>-11</sup> to 1.0×10<sup>-10</sup> and 2.9×10<sup>-11</sup> to 7.6×10<sup>-10</sup> mol C cm<sup>-2</sup> s<sup>-1</sup> for lakes Tantaré Basin A and Bédard, respectively. Hence, the total sediment OM degradation rate (ΣR<sub>1</sub> + ΣR<sub>2</sub> + ΣR<sub>6</sub>) of 1.3×10<sup>-12</sup> and 1.4×10<sup>-12</sup> reported in this study for lakes Tantaré Basin A and Bédard, respectively, would involve only 1.2–2.8% and 0.2–4.8% of the total C<sub>org</sub> deposited. Given that the remaining 95.2–99.8% of the deposited C<sub>org</sub> is preserved in the sediment, it is not surprising that the sediment C<sub>org</sub> concentration is constant with depth (Fig. 2).

The contribution of anaerobic mineralization for Lake Tantaré Basin A is about 1.8 times higher than the average of 30% reported for this lake basin in a previous study (Clayer et al., 2016). This significant discrepancy arises because these authors, in the absence of isotopic data to adequately constrain the R<sub>i</sub> values, assumed that R<sub>4</sub> = 0 in the net methanotrophic zone Z<sub>1</sub>. Should we make the same assumption in the present study, we would also estimate that fermentation and methanogenesis

represent only 30% of the total rate of OM degradation in the oxygenated Lake Tantaré Basin A and we would thus  
385 underestimate the importance of methanogenesis. The inclusion of  $\delta^{13}\text{C}$  data in the present modeling study thus allowed to  
better constrain the effective rates of  $\text{CH}_4$  production ( $R_4$ ). Indeed, a value of  $R_4 = 119 \text{ fmol cm}^{-3}\text{s}^{-1}$  was required in Eq. 7  
to produce an acceptable  $\delta^{13}\text{C}$ - $\text{CH}_4$  profile (Table 3 and Fig. S3).

#### 4.2 Organic substrates for methanogenesis at the sampling sites

Table 3 indicates that hydrogenotrophy ( $r_4$ ) coupled to the complete fermentation of OM ( $r_1$ ) produces  $\text{CH}_4$  at higher rates  
390 ( $R_4$ ) than DIC ( $R_1 - R_4$ ) in the  $Z_1$  and  $Z_2$  of both lake basins. This outcome is inconsistent with the equimolar production of  
 $\text{CH}_4$  and DIC expected from the fermentation of glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ ), the model molecule used to represent labile OM in  
diagenetic models (Paraska et al., 2014), thus suggesting that the fermentation of this compound is not the exclusive source of  
the  $\text{H}_2$  required for hydrogenotrophy. Had OM been represented by  $\text{C}_6\text{H}_{12}\text{O}_6$  in  $r_1$ , the rate of  $\text{H}_2$  production by this reaction  
would have been twice that of  $\text{CO}_2$ , i.e.,  $2R_1$ . For its part, the rate of  $\text{H}_2$  consumption through hydrogenotrophy is four times  
395 that of the  $\text{CH}_4$  production, i.e.,  $4R_4$ . Hence, an additional  $\text{H}_2$  production at rates of up to 212 and 70  $\text{fmol cm}^{-3}\text{s}^{-1}$ , i.e.,  $4R_4 -$   
 $2R_1$ , is needed to balance the  $\text{H}_2$  production rate expected from the fermentation of  $\text{C}_6\text{H}_{12}\text{O}_6$  and the  $\text{H}_2$  consumption rate by  
hydrogenotrophy observed in the sediments of Lake Tantaré Basin A and Lake Bédard, respectively. As discussed by Clayer  
et al. (2018), this additional production rate of  $\text{H}_2$  is likely provided by the fermentation of organic substrates that are more  
reduced than glucose.

400 Introducing the values of  $R_{\text{net}}^{\text{CH}_4}$ ,  $R_{\text{net}}^{\text{DIC}}$ ,  $R_{\text{net}}^{\text{Ox}}$ ,  $\chi_M$  and  $R_2$  (Table 2 and 3) into Eq. 9, we calculate COS values of  $-3.2$  and  $-0.9$   
for the  $Z_1$  and  $Z_2$  of Lake Tantaré Basin A, respectively, and of  $-1.0$  to  $-1.1$  for the  $Z_1$  of Lake Bédard, respectively. Note that  
we were unable to constrain with Eq. 9 the COS for the  $Z_2$  of Lake Bédard since we had to assume a COS value to estimate  
the  $R_i$  and the COS has no influence of the modelled  $\delta^{13}\text{C}$  profiles (section S2.2.2.3 of the SI). Negative COS values between  
 $-0.9$  and  $-1.1$  suggest that fermenting OM in the sediments of the two lake basins would be better represented by a mixture of  
405 fatty acids and fatty alcohols than by carbohydrates, as suggested by Clayer et al. (2018) for the sporadically anoxic Lake  
Tantaré Basin B. For its part, the highly negative COS value of  $-3.2$  calculated for the  $Z_1$  of Lake Tantaré Basin A is  
unreasonable, and the inaccuracy of the COS determination in this lake basin is discussed in section 4.3.

#### 4.3 Reduced organic compounds as methanogenic substrates in lake sediments

In order to better appraise the COS of the fermenting OM in lakes, relevant datasets of porewater solute concentration profiles  
410 were gathered from our data repository and from a thorough literature search. To be able to obtain by reactive-transport  
modeling the  $R_{\text{net}}^{\text{solute}}$  required to calculate the COS with Eq. 9, the datasets had to: (i) comprise porewater concentration profiles  
of  $\text{CH}_4$  and DIC and, ideally, those of the EAs; (ii) reveal a net methanogenesis zone, and (iii) enable the estimation of the  
carbonate precipitation/dissolution contribution to  $R_{\text{net}}^{\text{DIC}}$ . Detailed information on the origin and processing of the 17 selected  
datasets, acquired in 6 different lake basins from one sub-alpine and three boreal lakes sampled at various dates and/or depths,

415 is given in section S3 of the SI. The CH<sub>4</sub> and DIC porewater profiles determined at hypolimnetic sites of these lake basins and their modeling with the code PROFILE are shown in Fig. 5, whereas the  $R_{\text{net}}^{\text{CH}_4}$ ,  $R_{\text{net}}^{\text{DIC}}$  and  $R_{\text{net}}^{\text{Ox}}$  values determined from this modeling are regrouped in Table 4. The COS values displayed in Table 4 for all lake basins and dates were calculated by substituting the appropriate  $R_{\text{net}}^{\text{CH}_4}$ ,  $R_{\text{net}}^{\text{DIC}}$ ,  $R_{\text{net}}^{\text{Ox}}$  and  $R_2$  values in Eq. 9 and varying  $\chi_M$  between 0 and 1, except for Lake Tantaré Basin A for which  $\chi_M = 0.75$  (Table 3). When the value for  $R_2$  was not available, we assumed that  $R_2 = 0$ . Equation 9 indicates  
420 that  $R_2 > 0$ , would yield lower COS values than those reported in Table 4.

According to Table 4 the COS values are systematically negative at all dates for Lake Tantaré Basin B, Lake Bédard, Jacks Lake and the two sites of Lake Lugano, and they vary generally between  $-0.9$  and  $-1.9$ , with the exception of a value of  $-2.5$  obtained for Lake Tantaré Basin B in July 2007. This latter value is likely too low to be representative of fermenting material and should be rejected. The mean ( $\pm$  SD) COS values are  $-1.7 \pm 0.4$  for Lake Tantaré Basin B,  $-1.4 \pm 0.4$  for Lake Bédard,  
425  $-1.4 \pm 0.2$  for Jacks Lake and  $-1.4 \pm 0.3$  for Lake Lugano. These COS values, representative of a mixture of fatty acids (COS of  $-1.0$  for C4-fatty acids to about  $-1.87$  for C32-fatty acids) and of fatty alcohols (COS =  $-2.00$ ), strongly supports the idea that methanogenesis in oligotrophic boreal lakes sediments, and possibly other lake types, is fueled by more reduced organic compounds than glucose. Lipids such as fatty acids and fatty alcohols with similar COS are naturally abundant in sediments to sustain the estimated rates of CH<sub>4</sub> and DIC production during fermentation (Burdige, 2007; Cranwell, 1981; Hedges and  
430 Oades, 1997; Matsumoto, 1989). As discussed by Clayer et al. (2018) the most labile organic compounds (i.e., proteins and carbohydrates) can be rapidly degraded during their transport through the water column and in the uppermost sediment layer, leaving mainly lipids as metabolizable substrates at depths where fermentation and methanogenesis occurs. This interpretation is consistent with thermodynamic and kinetic evidences that proteins and carbohydrates are more labile and are degraded faster than lipids (LaRowe and Van Cappellen, 2011).

435 The COS values determined for the perennially oxygenated Basin A of Lake Tantaré (mean of  $-0.6 \pm 1.1$ ; range of  $-3.2$  to  $2.1$ ; Table 4) are much more variable than for the five other seasonally anoxic lake basins including unrealistic values for October 2015 in the Z<sub>1</sub> ( $-3.2$ ), September 2016 ( $0.4$ – $0.6$ ) and October 2005 ( $1.8$ – $2.1$ ). Indeed, the very negative value of  $-3.2$  does not correspond to any degradable compound under anoxic conditions, whereas the positive values of  $0.4$ – $0.6$  and  $1.8$ – $2.1$  would involve either amino acids and nucleotides which are very labile (Larowe and Van Cappellen 2011) and tend to be degraded  
440 in the water column (Burdige 2007), or oxidized compounds, such as ketones, aldehydes and esters, known to be quickly reduced to alcohols. Possible sources of uncertainty in the COS estimation include mis-quantification of bioirrigation and DIC production through HMW OM fermentation (reaction r2; Corbett et al. 2013). Clayer et al. (2016) provided evidences that sediment irrigation by benthic animals is effective in Lake Tantaré Basin A and that reaction rates are sensitive to the bioirrigation coefficient. Nevertheless, additional simulations show that changing the bioirrigation coefficient by a factor of 2  
445 (increased and decreased) did not result in significant changes in COS values ( $<0.2$ ). Bioirrigation might also be misrepresented. Indeed, the term used in Eq. 2 to calculate this contribution, i.e.,  $\phi_{\alpha_{\text{irrigation}}} ([\text{solute}]_{\text{tube}} - [\text{solute}])$ , is indeed an approximation of intricate 3-D processes variable in space and time (Meile et al., 2005; Boudreau and Marinelli, 1994; Forster

and Graf, 1995; Gallon et al., 2008; Riisgård and Larsen, 2005). On the other hand, DIC production through HMW OM fermentation (reaction r2; Corbett et al. 2013) was constrained by default in Lake Tantaré Basin A (Table 4). Indeed, fitting with Eq. 7 the experimental  $\delta^{13}\text{C}$  data does not allow partitioning the production of DIC between r1 and r2 given that both processes share the same fractionation factor ( $\alpha_1 = \alpha_2 = 1.000$ ). Equation 9 indicates that to obtain negative COS values for Lake Tantaré Basin A in September 2006 and October 2005,  $R_2$  should be  $>11 \text{ fmol cm}^{-2} \text{ s}^{-1}$  and  $>110 \text{ fmol cm}^{-2} \text{ s}^{-1}$ , respectively. These  $R_2$  values correspond to transferring  $>9\%$  and  $>44\%$  of the rate of DIC production from  $R_1$  to  $R_2$  for September 2006 and October 2005, respectively. Hence, owing to the imperfection in the COS estimations for Lake Tantaré Basin A, COS values estimated for this site should be treated with caution. Note that the sediment surface was also oxic at the sites Melide and Figino of Lake Lugano in March 1989 (Table 4) as revealed by detectable bottom water  $[\text{O}_2]$  (Table 4), and by low  $[\text{Fe}]$ , undetectable  $\Sigma\text{S}(-\text{II})$  and  $[\text{CH}_4]$  and relatively high  $[\text{SO}_4^{2-}]$  in overlying water (Lazzaretti et al., 1992; Lazzaretti-Ulmer and Hanselmann, 1999). Despite this, the COS values determined for the two sites of Lake Lugano appear realistic and consistent with those calculated for Lakes Tantaré Basin B, Bédard and Jacks. This disparity between Lake Tantaré Basin A and Lake Lugano could be explained by the presence of benthic organisms in the former (Hare et al., 1994) but their absence in the latter, as shown by the presence of varves (Lazzaretti et al., 1992) and the absence of benthos remains in the recent sediments of Lake Lugano (Niessen et al., 1992).

## 5 Conclusions

Our results show that fermentation and methanogenesis represent about 50% and 100% of OM mineralization in the top 25 cm of the sediments at the hypolimnetic sites in Lake Tantaré Basin A and Bédard, respectively, that methane is produced only by hydrogenotrophy and fermentation substrates have a negative COS at these two sites. The association of hydrogenotrophy with the fermentation of reduced OM (COS  $< -0.9$ ; implying that labile compounds are depleted) in the studied lake sediments is consistent with the fact that hydrogenotrophy becomes increasingly important when labile OM is depleted (Chasar et al., 2000; Hornibrook et al., 2000; Whiticar et al., 1986).

Reactive-transport modelling of twelve datasets of porewater profiles from three boreal lakes, i.e., Bédard, Tantaré (Basin B) and Jacks, as well as of the sub-alpine Lake Lugano (Melide and Figino sites) consistently showed that the main substrates for sediment methanogenesis at deep seasonally anoxic hypolimnetic sites have a mean COS value of  $-1.4 \pm 0.3$ . The OM in the sediment of the three boreal lakes, as well as their  $\text{O}_2$  seasonal dynamics, are typical of boreal forest lakes. While Lake Bédard experiences prolonged episodes of extended hypolimnetic anoxia, Lake Tantaré Basin B and Jacks Lake show more moderate seasonal anoxia, where some years the hypolimnion of Lake Tantaré Basin B is only hypoxic (Clayer et al., 2016; Carignan et al., 1991). Hence, the selective mineralization of OM described by Clayer et al. (2018), involving that the most labile compounds are mineralized during OM downward migration in the water column and at the sediment surface leaving mainly reduced organic compounds to fuel methanogenesis in the sediments, likely applies to a large portion of boreal lakes.

Hence, the current representation of the fermenting OM, i.e., CH<sub>2</sub>O, in process-based biogeochemical models entails a significant risk of underestimating sedimentary CH<sub>4</sub> production and release to the bottom water and, to a certain extent, of its evasion to the atmosphere under transient environmental scenarios. To better constrain CH<sub>4</sub> and CO<sub>2</sub> production within sediments, we suggest taking specifically into account the COS of the fermenting OM in formulating the reactions of methanogenesis associated with fermentation in these models. For example, the rates of CH<sub>4</sub> (R<sup>CH<sub>4</sub></sup>) and DIC (R<sup>DIC</sup>) production during fermentation coupled to hydrogenotrophy can be expressed as:

$$R^{\text{CH}_4} = R_4 = \frac{4 - \text{COS}}{8} R_1 \quad (12)$$

$$R^{\text{DIC}} = R_1 - R_4 = R_1 \left( 1 - \frac{4 - \text{COS}}{8} \right) \quad (13)$$

Given these rate expressions, the stoichiometric formulation of a typical fermentation reaction producing CH<sub>4</sub> becomes:

where  $a = 2 - \frac{\text{COS}}{2}$ ,  $b = 1 + \frac{\text{COS}}{4}$ . Introducing the average COS values reported in this study ( $-1.4 \pm 0.3$ ) into Eq. 14, the coefficients  $a$  and  $b$  would take values of  $2.7 \pm 0.15$  and  $0.65 \pm 0.125$ , respectively, and the CH<sub>4</sub> and CO<sub>2</sub> stoichiometric coefficients would be  $0.68 \pm 0.04$  and  $0.32 \pm 0.04$ , respectively. Note that the same stoichiometric formulation would be obtained with any possible combination of acetoclasty and hydrogenotrophy. Under these conditions, fermentation (r1) coupled to methanogenesis (r4) yields 2.2±0.4 times more CH<sub>4</sub> than DIC for the studied lake sediments. Ignoring the implications of the present study regarding the COS of the fermenting OM could lead to the underestimation of CH<sub>4</sub> sediment outflux or of the rate of oxidant consumption required to mitigate this efflux by a factor of up to 2.6.

The approach used to estimate the COS of the fermenting OM, although successful for the seasonally anoxic basins, failed to produce reliable COS values when applied to the perennially oxygenated Basin A of Lake Tantaré. We attribute this peculiarity to a misestimation and/or misrepresentation of the benthic irrigation and to the impossibility to partition the DIC production between reactions r1 and r2 which share the same fractionation factor value. Similar problems would likely be encountered also in other lake ecosystems such as epilimnetic sediments and wetlands where solute transport processes remain ill-known. Indeed, these shallow aquatic environments are subject to enhanced benthic activity (Hare, 1995), to plant-mediated transport of CH<sub>4</sub> and O<sub>2</sub> (Chanton et al., 1989; Wand et al., 2006), as well as to turbulence (Poindexter et al., 2016) which complicates the estimation of CH<sub>4</sub> and CO<sub>2</sub> production and consumption rates. Hence, the remaining challenge resides in the robust estimations the COS of the fermenting OM in epilimnetic sediments and shallow freshwater environments (e.g., ponds, wetlands), since these environments were shown to be the main contributors to freshwater CH<sub>4</sub> release to the atmosphere (Bastviken et al., 2008; DelSontro et al., 2016). One potential solution is to investigate trends in the oxygen isotope signatures in the sedimentary DIC in addition to δ<sup>13</sup>C values since it is also influenced by the source of the OM undergoing degradation (e.g., Sauer et al., 2001).

740 **Figure 1:** Location map and bathymetry of Lakes Tantaré and Bédard. The bathymetric map of Lake Tantaré was reproduced from the map C-9287 of the Service des eaux de surface of the Québec Ministry of Environment. The map of Lake Bédard was reproduced from D'Arcy (1993). Dioxygen concentrations in the water column of Lake Tantaré basins A and B, and of Lake Bédard are given for June (black lines) and October (red lines).

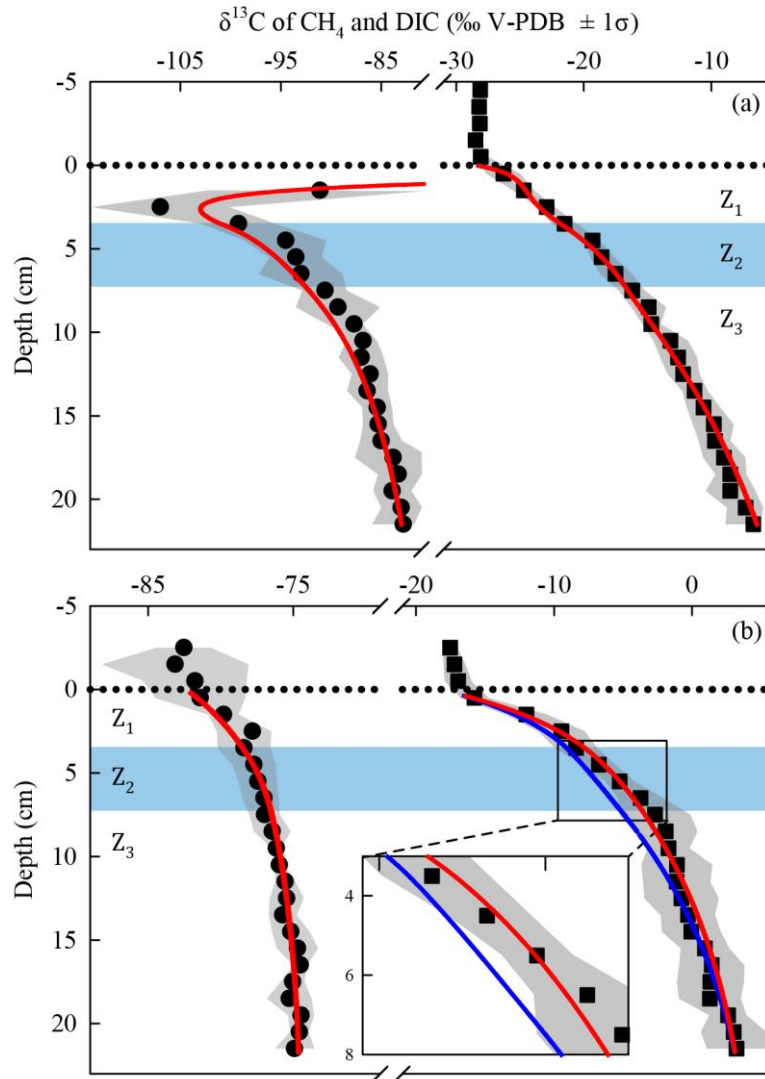

745

**Figure 2: Depth profiles of the organic C concentrations and of the C : N molar ratio in sediment cores collected at the deepest sites of Lake Bédard (a) and Lake Tantaré Basin A (b).**

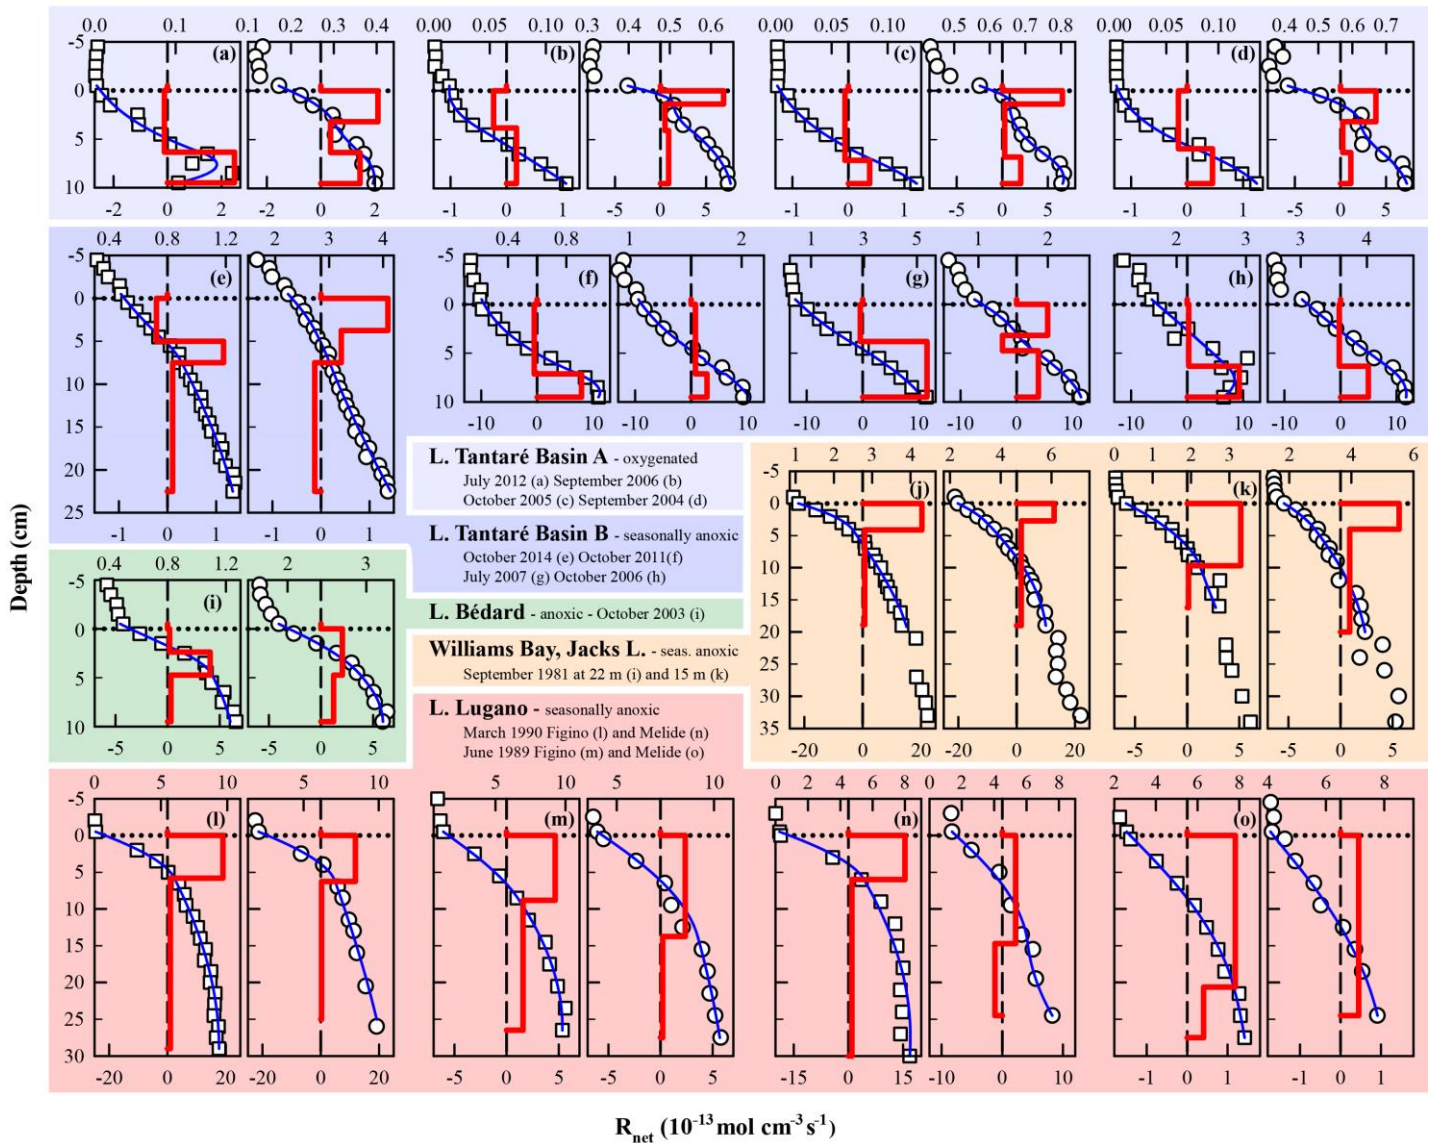

750 **Figure 3 : Replicate porewater profiles of  $\text{CH}_4$  (a and i),  $\delta^{13}\text{C}-\text{CH}_4$  (b and j), DIC (c and k),  $\delta^{13}\text{C}-\text{DIC}$  (d and l),  $\text{SO}_4^{2-}$  (e and m), Fe and  $\Sigma\text{S}(-\text{II})$  (f and n), and comparison of the modeled (blue lines) and average ( $n = 3$ ) measured (symbols) concentration profiles of  $\text{CH}_4$  (g and o) and DIC (h and p) in Lakes Tantaré Basin A (a–h) and Bédard (i–p). Different symbols indicate data from different peepers and empty symbols are for concentrations below detection limit. The horizontal dotted line indicates the sediment-water interface. The thick and thin blue lines represent the net solute reaction rate ( $R_{\text{net}}^{\text{solute}}$ ) and the modeled concentration profiles, respectively. The red area fills correspond to the sediment zones  $Z_2$ .**

755 **Figure 4 : Comparison of the simulated (lines) and measured average ( $n = 3$ )  $\delta^{13}\text{C}$  profiles of  $\text{CH}_4$  (circles) and DIC (squares) in the porewater of Lake Tantaré Basin A (a) and Lake Bédard (b). The horizontal dotted line indicates the sediment-water interface. The variability in  $\delta^{13}\text{C}$  values ( $\pm$  one standard deviation  $-\sigma$ ) related to the spatial heterogeneity within the sampling area is shown by the grey area fills. The zone  $Z_2$  is delimited by the blue area fill. In panel b, the blue lines are the profiles simulated with the default rate values and optimal  $\alpha_1$  and  $f$  values as described in section S2.2.1. The red lines in panel (b) are the profiles simulated with  $\alpha_2$  values of 0.980–0.984 (see section 4.1 for details).**

CH<sub>4</sub> -□- and DIC -○- concentrations (mM)

760 **Figure 5 :** Comparison of the modeled (blue lines) and average ( $n = 3$ ) measured concentration profiles of CH<sub>4</sub> (squares) and DIC (circles) in Lakes Tantaré Basin A (a–d) and Basin B (a–h), Bédard (i), Jacks Lake (j–k) and Lake Lugano (l–o) at various sampling dates. The thick red lines represent the net solute reaction rate ( $R_{net}^{solute}$ ).

**Table 1: Reactions (r1–r7) considered, their reaction rates ( $R_1$ – $R_7$ ) and carbon isotopic fractionation factors ( $\alpha_1$ – $\alpha_7$ ).**

Description	Reaction	ID
<b>CO<sub>2</sub> production due to complete fermentation of labile OM <sup>a</sup></b>		
	$C_xH_yO_z + (x + v_1 - z)H_2O \xrightarrow[\alpha_1]{R_1} \left(\frac{x - v_1}{2}\right)CH_3COOH + v_1CO_2 + \left(\frac{y}{2} - z + 2v_1\right)H_2$	r1
<b>CO<sub>2</sub> production due to partial fermentation of HMW OM <sup>a,b</sup></b>		
	$v_2HMW\ OM \xrightarrow[\alpha_2]{R_2} v_3\ LMW\ OM + v_4CO_2$	r2
<b>Methanogenesis via</b>		
acetoclasty	$CH_3COOH \xrightarrow[\alpha_3]{R_3} CH_4 + CO_2$	r3
hydrogenotrophy	$CO_2 + 4H_2 \xrightarrow[\alpha_4]{R_4} CH_4 + 2H_2O$	r4
<b>CO<sub>2</sub> production due to</b>		
methanotrophy	$CH_4 + 2\ Oxidants \xrightarrow[\alpha_5]{R_5} CO_2 + 2\ Reducers$	r5
OM oxidation	$OM + Oxidant \xrightarrow[\alpha_6]{R_6} CO_2 + Reducer$	r6
<b>Precipitation of siderite</b>	$Fe^{2+} + CO_2 + H_2O \xrightarrow[\alpha_7]{R_7} FeCO_{3(s)} + 2H^+$	r7

765 <sup>a</sup> where  $v_1$  can have any value between 0 and  $x$ , and values for  $v_2$ – $v_4$  are unknown.

<sup>b</sup> HMW OM and LMW OM designate high and lower molecular weight organic matter, respectively.

**Table 2: Net production rates ( $R_{\text{net}}^{\text{solute}}$ ) of CH<sub>4</sub>, DIC and oxidants obtained with the code PROFILE in the three CH<sub>4</sub> consumption/production zones (Z<sub>1</sub>, Z<sub>2</sub> and Z<sub>3</sub>) for both sampling sites.**
