25 Abstract

26

27 We introduced a sediment-induced light attenuation algorithm into a biogeochemical model of the
28 Coupled Ocean-Atmosphere-Wave-Sediment Transport (COAWST) modeling system. A fully
29 coupled ocean-atmospheric-sediment-biogeochemical simulation was carried out to assess the
30 impact of sediment-induced light attenuation on primary production in the northern Gulf of Mexico
31 during the passage of Hurricane Gustav in 2008. When compared with model results without
32 sediment-induced light attenuation, our new model showed a better agreement with satellite data
33 on both the magnitude of nearshore chlorophyll concentration and the spatial distribution of
34 offshore bloom. When Gustav approached, resuspended sediment shifted the inner shelf ecosystem
35 from a nutrient-limited one to light-limited. One week after Gustav's landfall, accumulated
36 nutrient and favorable optical environment induced a post-hurricane algal bloom in the top 20 m
37 of water column, while the productivity in the lower water column was still light-limited due to
38 slow-settling sediment. Corresponding with the elevated offshore NO_3 flux (38.71 mmol N/m/s)
39 and decreased chlorophyll flux (43.10 mg/m/s), the outer shelf post-hurricane bloom should be
40 resulted from the cross-shelf nutrient supply instead of the lateral dispersed chlorophyll. Sensitivity
41 tests indicated that sediment light attenuation efficiency affected primary production when
42 sediment concentration was moderately high. Model uncertainties due to colored dissolved organic
43 matter and parameterization of sediment-induced light attenuation are also discussed.

44

45 1 Introduction

46 Light, nutrient and temperature play a vital role in photosynthesis and marine ecosystems.
47 The vertical structure of light availability in an aquatic environment is mainly modulated by the
48 shading effects of chlorophyll, colored dissolved organic matter (CDOM), detritus, and sediment
49 (Cloern, 1987; Devlin et al., 2008; Schaeffer et al., 2011; Ganju et al., 2014; McSweeney et al.,
50 2017). The optical environment in river-dominated shelves are more complex due to the interaction
51 between riverine inputs and regional hydrodynamics (Bierman et al., 1994; Lin et al., 2009; Zhu
52 et al., 2009). As the largest river in North America, the Mississippi-Atchafalaya River system
53 delivers 380 km³ of freshwater and 115 Mt of sediments each year into the northern Gulf of Mexico
54 (nGoM; Meade and Moody, 2010; Allison et al., 2012). Along the Louisiana-Texas shelf in the
55 nGoM, suspended sediment concentration (SSC) in the water column exhibits strong seasonality:
56 high in winter and spring seasons due to strong sediment resuspension and high fluvial sediment
57 discharge, while largely reduced in summer and fall owing to the relatively low river inputs and
58 weak resuspension (Zang et al., 2019). Episodic hurricane events in summer and fall can disturb
59 vertical stratification and resuspend large amount of shelf sediment (D'Sa et al., 2011; Xu et al.,
60 2016; Zang et al., 2018). Enhanced resuspension during a hurricane might greatly change the shelf
61 ecosystem via modifying light availability. In addition, enhanced organic matter remineralization
62 in the bottom boundary layer could also introduce sharp changes to the ecosystem (Wilson et al.,
63 2013; Hurst et al., 2019). Yet studies of the impact from hurricane-induced resuspension are still
64 limited due to the challenge of *in-situ* data collection under extreme weather conditions.

65 As an alternative tool to fill the spatial and temporal gaps in *in-situ* datasets, coupled
66 physical-biogeochemical models have been widely applied to the Gulf of Mexico (GoM; e.g.,
67 Fennel et al., 2008; Laurent et al., 2012; Xue et al., 2013; Yu et al., 2015; Gomez et al., 2018). In
68 these models, photosynthetically available radiation was estimated using a similar method, namely,
69 light availability decreasing exponentially with water depth and the concentrations of light
70 absorbers (e.g., sediment and CDOM) in the overlying water column. Due to the lack of long-term

71 observations of CDOM, however, its impact on the optical environment was either not included
72 (e.g., Fennel et al., 2006; Gomez et al., 2018) or simply expressed as a function of salinity (Justić
73 and Wang 2014). Although most of these studies considered sediment-induced light attenuation
74 when estimating primary production, the related parameterization was uniform over the entire
75 research domain and did not vary with sediment dynamics (e.g., Zhou et al., 2017; Thewes et al.,
76 2020). Such an oversimplified treatment of sediment-induced light attenuation could substantially
77 impact a model's robustness in river-dominated shelves that encompass a wide range of SSC. In
78 the nGoM, Justić and Wang (2014) tentatively employed a new scheme by connecting sediment-
79 induced light attenuation with river discharge (salinity) and hydrodynamics (bottom shear stress).
80 However, the horizontal distribution of SSC in a realistic environment is not necessarily correlated
81 with that of the freshwater plume, and the contribution of resuspension to SSC at different depths
82 might be significantly different (Xu et al., 2011, 2016).

83 Gustav was the first major hurricane that made a landfall in Louisiana after Katrina (2005).
84 It passed through the center of GoM and landed near Cocodrie, Louisiana on September 1st, 2008
85 as a Category 2 hurricane (Forbes et al., 2010). Sediment resuspension and transport were strong
86 during the passage of Gustav, and thick post-hurricane deposition (up to 40 cm) was simulated on
87 the inner shelf (Zang et al., 2018) and in the bays (Liu et al., 2018). Korobkin et al. (2009) identified
88 a post-Gustav algal bloom around the Mississippi Delta on satellite images. High respiration and
89 stratification after the landfall of Gustav was reported to be connected with possible hypoxia
90 development on the shelf (McCarthy et al., 2013).

91 In this study, we introduce a new biogeochemical model with sediment-induced light
92 attenuation to the three-way coupled (atmospheric-wave-ocean-sediment transport) Gustav model
93 (Zang et al., 2018). While sediment dynamics can also impact nutrient dynamics via changing the
94 intensity of remineralization near the bottom (Moriarty et al., 2018), the scope of this study is to
95 investigate the influence of suspended sediment on the optical environment and thus primary
96 production. The impact from elevated remineralization of resuspended particular organic matter
97 during hurricane events is not considered as detailed processes because relevant parameterizations
98 are still largely unknown. The objectives of this paper are to: 1) evaluate the impact of sediment-
99 induced light attenuation on the spatiotemporal variation of nutrient-phytoplankton dynamics
100 during a hurricane event; 2) explore the driving mechanism of the post-hurricane bloom on the
101 shelf; and 3) investigate the response of primary production to sediment optical characteristics.

102 103 **2 Model Description**

104 **2.1 Physical, sediment and biogeochemical models**

105 Our model covered the entire GoM (Fig. 1a) and was built on the coupled ocean-
106 atmosphere-wave-and-sediment transport (COAWST) modeling system (Warner et al., 2008,
107 2010). COAWST is an open source model platform that consists of three numerical models: the
108 Weather Research and Forecasting model (WRF; Skamarock et al., 2005), the Regional Ocean
109 Modeling System (ROMS; Shchepetkin and McWilliams, 2005; Haidvogel et al., 2008), and the
110 Simulating Waves Nearshore model (SWAN; Booij et al., 1999). The Community Sediment
111 Transport Modeling System (CSTMS) is included in ROMS to simulate sediment transport,
112 stratigraphy, and geomorphology. Model Coupling Toolkit (MCT; Jacob et al., 2005) enables the
113 interaction among these three models. The details of model setup and validation of the three-way
114 coupled hydrodynamic-sediment transport model (WRF-ROMS-SWAN-CSTMS) were described
115 in Zang et al. (2018), where four types of sediment (two cohesive and two non-cohesive) were
116 defined with different grain diameters and settling velocities. There were 40 sediment layers on

117 the sea floor with a total thickness of 1 m to resolve sediment bed erosion and deposition. The
118 driving force of sediment resuspension was determined by bottom shear stress induced by wave
119 and current.

120 Given the importance of diatom in phytoplankton community in the nGoM (Zhao and
121 Quigg, 2014), it is necessary to have both nitrogen and silicon cycles in the model. The
122 biogeochemical model in this study was largely built on the North Pacific Ecosystem Model for
123 Understanding Regional Oceanography (NEMURO; Kishi et al., 2007), which incorporated both
124 nitrogen and silicon flows. There were 11 state variables included in the model: nitrate, ammonium,
125 two types of phytoplankton (small and large), three types of zooplankton (microzooplankton,
126 mesozooplankton and predatory zooplankton), particulate and dissolved nitrogen, particulate silica,
127 and silicic acid concentration. River nutrient discharge during the hurricane were retrieved
128 from United States Geological Survey (USGS) Water Data for the Nation website
129 (<http://nwis.waterdata.usgs.gov>; Station 07374000). The growth of phytoplankton was driven by
130 water temperature, light availability, and nutrient concentration. Instantaneous remineralization of
131 particulate organic nitrogen at the bottom was estimated following Fennel et al. (2006). Our model
132 did not include phosphate because its limitation on primary production in the nGoM was mainly
133 between May to July (Laurent et al., 2012; Laurent and Fennel, 2014). We incorporated two types
134 of chlorophyll corresponding to the large and small phytoplankton tracers, respectively. Following
135 Fennel et al. (2006), chlorophyll dynamics was derived from phytoplankton equation by
136 multiplying the ratio of chlorophyll to phytoplankton biomass. To get an ideal parameterization
137 set and a stable initial condition for the biogeochemical variables, we first conducted a 20-yr (1993-
138 2012) coupled physical-biogeochemical simulation using only ROMS model, where WRF and
139 SWAN were disabled to achieve a feasible computation load (Step 1 in Fig. 2). The atmospheric
140 forcing was provided by the 6-hourly, 38 km horizontal resolution Climate Forecast System
141 Reanalysis (CFSR; Saha et al., 2010, 2011; <http://cfs.ncep.noaa.gov>). The physical setup of the
142 20-yr simulation was the same as Zang et al. (2019). The biogeochemical parameterizations (Table
143 S1) were largely adapted after a recent GoM biogeochemical modeling study by Gomez et al.
144 (2018). Since this study focused on the response of biogeochemical process to hurricane events,
145 details of the 20-yr simulation setup and model-observation comparison were provided in the
146 supplementary material. Once validated, the biogeochemical variables were extracted from the 20-
147 yr model on August 30th, 2008 as the initial condition for this Gustav simulation (Step 2 in Fig. 2).

148 The light available for photosynthesis (I) is estimated using the following equation:
149

$$150 \quad I = I_0 \cdot par \cdot \exp \left\{ -Z \left[\alpha_w + \alpha_{chl} \int_z^0 (PSn + PLn) dz + \alpha_{sed} \int_z^0 SSC dz \right] \right\},$$

151
152 where I_0 is the light intensity at the surface layer, and Z is water depth. par is the fraction of light
153 available for photosynthesis (specified as 0.43). α_w and α_{chl} are the light attenuation coefficients
154 of sea water and chlorophyll, respectively. PSn and PLn represent concentrations of small and
155 large phytoplankton. Compared with the original biogeochemical model, we added a new
156 sediment-induced light attenuation term in this equation. α_{sed} is the light attenuation coefficient
157 due to suspended sediment, and SSC is total suspended sediment concentration in the respective
158 layer. We performed a benchmark run ($\alpha_{sed} = 0.059$; McSweeney et al., 2017) to represent the
159 scenarios with sediment-induced light attenuation. The simulation period was from August 30th to
160 September 10th, 2008.

2.2 Sensitivity tests

High turbidity in the Mississippi River Delta due to fluvial sediment discharge and resuspension suggested the vital role of sediment in the underwater optical environment. To quantitatively evaluate the importance of suspended sediment in light attenuation, we conducted a sensitivity test (test 1) without sediment-induced light attenuation ($\alpha_{sed} = 0$). Since the physical properties of a sediment particle (e.g., size, shape, roughness, and color) determine its light attenuation efficiency (Baker and Lavelle, 1984; Storlazzi et al., 2015), a wide range of α_{sed} has been applied in previous studies (e.g., Pennock, 1985; Arndt et al., 2007; McSweeney et al., 2017). Here we increased/decreased the benchmark α_{sed} (0.059) by 20% and 40% to examine the sensitivity of primary production to sediment-induced light attenuation (tests 2–5). The rest of the model setup were the same between the benchmark run and sensitivity tests (tests 1-5). The deviation due to the chaotic nature of turbulence was not considered in this study.

3 Model Validation

Direct measurements of ocean conditions during the passage of a hurricane are still challenging. In Zang et al. (2018) we validated the physical model's performance against the air pressure, sea level, and wave heights recorded at available buoy stations. The sediment model's performance was evaluated against satellite images. In this study, we used the five-day composites of SeaWiFS chlorophyll data (OC4) obtained before (Aug 25th–29th) and after (September 5th–9th) Gustav's landing to calibrate our biogeochemical model's initial condition and results. Surface chlorophyll distribution during initial condition (Fig. 3a) was similar to that in the pre-hurricane composite imagery (Fig. 3b), with high chlorophyll concentration ($> 4 \text{ mg/m}^3$) located around the bird-foot delta and the Atchafalaya inner shelf, and values declined seaward to $\sim 0.1 \text{ mg/m}^3$.

Compared with the pre-hurricane composite imagery, the post-hurricane composite showed higher chlorophyll concentration around the bird-foot delta and on the Atchafalaya shelf (Figs. 3b and 3c). Another major increase was identified in waters between the 50 and 200 m isobaths off the Atchafalaya Bay with chlorophyll concentration increasing from 1 to 4 mg/m^3 after Gustav, indicating a possible post-hurricane algal bloom on the outer shelf. When comparing with model run without sediment-induced attenuation, the intensity of the offshore bloom was better reproduced ($\sim 4 \text{ mg/m}^3$) with the new sediment-induced light attenuation algorithm (see difference between Figs. 3d and 3e). To quantitatively evaluate the model's performance, we calculated the root mean square error (RMSE) and correlation coefficient (R) between model-simulated and satellite-derived chlorophyll concentrations over the inner shelf (water depth $< 50 \text{ m}$; Fig. 4). The reduced RMSE in the benchmark run in comparison to sensitivity test (2.33 to 1.91) suggested improved model performance with sediment-induced light attenuation. However, with only marginal differences in the correlation coefficients between the two experiments (0.82 and 0.81), the spatial distributions of chlorophyll were comparable (Fig. 4). Nevertheless, the model's performance in the high productivity waters (both simulated and observed chlorophyll concentrations $> 1 \text{ mg/m}^3$) was significantly improved (R increased from 0.55 to 0.61, and RMSE decreased from 5.93 to 3.97; Fig. 4). The improvement of model results confirmed the importance of sediment-induced light attenuation in biogeochemical cycling during a hurricane event, particularly in coastal regions where chlorophyll concentration was high.

4 Results and Discussion

4.1 Temporal variability of biogeochemical variables

204
205
206

207 To examine the temporal variation of biogeochemical variables during the passage of
208 Gustav, we plotted the time series of spatially averaged net primary production (growth of
209 phytoplankton minus the respiratory losses; NPP), surface chlorophyll concentration, surface NO₃
210 concentration, SSC, downward solar short wave radiation, and sea surface temperature (SST) over
211 the nGoM inner shelf (Fig. 5; < 50 m water depth). NPP exhibited strong diel variation and the
212 peaks were strongly correlated with short wave radiation maximum (Figs. 5a and 5e). Such diel
213 cycle could also be found in chlorophyll concentration, but with a 3- to 4-hour delay (Fig. 5b).
214 Before the arrival of Gustav, daily-averaged NPP was around 0.05 g C/m²/hr, and the differences
215 of NPP and chlorophyll concentration between the benchmark run and test 1 were minor (Figs. 5a
216 and 5b).

217 Following hurricane Gustav's landfall along coastal Louisiana at 16:00:00 UTC on
218 September 1st, surface SSC increased to 3.8 kg/m³ because of strong seabed resuspension (Fig. 5d).
219 Daily-averaged NPP reduced to 0.03 g C/m²/hr in test 1. Once sediment-induced light attenuation
220 was included, daily-averaged NPP further declined to 0.01 g C/m²/hr, suggesting that light
221 availability severely limited short-term productivity on the inner shelf. Chlorophyll concentrations
222 in the benchmark run and test 1 were reduced by 40% as Gustav approached. Hurricane-related
223 surface cooling, together with decreased light (Figs. 5e and 5f), contributed to the reductions of
224 both chlorophyll and NPP.

225 The difference of daily-averaged NPP between the benchmark run and test 1 maximized
226 on September 2nd due to light limitation modulated by resuspended sediment (Figs. 5a and 5d). On
227 September 3rd, daily-averaged NPP of test 1 recovered to 0.04 g C/m²/hr and remained steady
228 through the end of our simulation (Fig. 5a). For the benchmark run, however, the recovery of NPP
229 was much slower: daily-averaged NPP was lower than that of test 1 until September 7th, when most
230 suspended sediment settled back onto the seabed. NO₃ concentration went up gradually between
231 September 2nd - 7th in the benchmark run (Fig. 5c) as nutrient consumption was constrained by the
232 decline in photosynthetic activity. Accumulated NO₃, together with the improved optical
233 environment due to low SSC, resulted in higher NPP and algal bloom after September 7th (Figs.
234 5a and 5b).

235 236 4.2 Vertical structure of biogeochemical variables

237 We extracted concentrations of chlorophyll, NO₃, sediment and water density anomaly
238 along the transect D in Rabalais et al. (2001; Fig. 1b for transect location) at three time points
239 (August 31st, September 2nd, and September 10th) to represent pre-, during-, and post-hurricane
240 stages, respectively (Figs. 6 and 7). Before the approach of Gustav, offshore water was well
241 stratified (Fig. 7d). Chlorophyll concentration decreased seaward from 5 to 0.3 mg/m³ (Figs. 6a
242 and 6d). Sediment-induced light attenuation did not alter the vertical structure of chlorophyll and
243 NO₃ much (Figs. 6a, 6d, 6g, and 6j) owing to low SSC in the water column (Fig. 7a). On September
244 2nd, strong vertical mixing increased the SSC to more than 1 kg/m³ over the entire water column
245 (Figs. 7b and 7e). Chlorophyll concentration in waters < 40 m in the benchmark run was ~ 4 mg/m³,
246 lower than that in test 1 due to sediment-induced light attenuation (Figs. 6b and 6e). Higher NO₃
247 concentration in the benchmark run was a result of the weakened primary production and nutrient
248 consumption (Figs. 6h and 6k). The most striking differences of chlorophyll and NO₃ between the
249 two simulations were in water shallower than 20 m.

250 In test 1, chlorophyll concentration during the post-hurricane stage was lower than that of
251 the pre-hurricane stage (Figs. 6a and 6c), in contrast to the condition captured by satellite imagery
252 (Figs. 3b and 3c). The benchmark run, however, successfully reproduced the magnitude and

253 seaward extension of the post-hurricane bloom (Fig. 6f). High chlorophyll concentration (> 1
254 mg/m^3 ; Fig. 6f) with low NO_3 (Fig. 6l) was simulated in the top 20 m of the water column where
255 stratification partially recovered (Fig. 7f) and sediment concentration was low after the passage of
256 Gustav (Fig. 7c). At water deeper than 20 m, chlorophyll concentration dropped drastically to less
257 than $0.1 \text{ mg}/\text{m}^3$, while NO_3 concentration further increased to $> 1 \text{ mmol}/\text{m}^3$. The synchronized
258 high turbidity and low chlorophyll concentration implied that, nine days after Gustav's landfall,
259 the primary production in deeper water could still be constrained by light availability. A similar
260 vertical structure (high SSC and low chlorophyll at the bottom) was also simulated in the Delaware
261 estuary, where near bottom productivity was constrained by the estuarine turbidity maximum
262 (McSweeney et al., 2017). Such a stratified water column with high/low productivity at the
263 surface/bottom is generally favorable for bottom oxygen depletion. The elevated surface
264 phytoplankton growth following the hurricane could thus result in increased particulate organic
265 matter (POM) whose remineralization contributes to bottom water hypoxia (Wiseman et al., 1997).
266 Meanwhile, the post-hurricane stratification recovery in the summer and fall seasons would have
267 likely prevented oxygen ventilation to the bottom. The high respiration rate caused by resuspended
268 POM could further lower the oxygen level (Bianucci et al., 2018). McCarthy et al. (2013) reported
269 a post-Gustav respiration peak associated with organic matter resuspension in the bottom boundary
270 layer. A recent numerical model study also simulated a substantial increase of near-bottom oxygen
271 consumption due to resuspended POM remineralization during moderate resuspension events
272 (Moriarty et al., 2018). These past studies and the new finding of this study suggest particulate
273 matter (both organic and inorganic) dynamics might substantially contribute to bottom oxygen
274 depletion and hypoxia development following a hurricane passage. More in situ observations of
275 oxygen dynamics in the bottom boundary layer are needed.

276 277 4.3 The post-hurricane offshore bloom

278 Post-hurricane blooms have been widely observed in the mid- and low-latitude oceans
279 (Davis and Yan, 2004; Miller et al., 2006; Pan et al., 2017; D'Sa et al. 2019). A bloom in the open
280 ocean was usually isolated and patchy, and its formation was mainly related to nutrients supplied
281 from deep waters via vertical mixing (Walker et al., 2005; Pan et al., 2017). The mechanism of the
282 bloom formation on the outer shelf, however, was more complex due to possible impacts from the
283 inner shelf water. Strong post-Gustav cross-shelf transport has been reported by previous studies
284 (Korobkin et al., 2009; Zang et al., 2018). The seaward dispersal of higher nutrient and chlorophyll
285 coastal waters could have potentially contributed to the outer shelf bloom, but their respective
286 contributions remained unclear. To quantify the cross-shore exported nutrient and chlorophyll, we
287 estimated depth-integrated offshore (seaward) NO_3 and chlorophyll flux along the 50 m isobath
288 transect (Fig. 1b; Table 1). Compared with test 1 (NO_3 : $7.35 \text{ mmol N}/\text{m}/\text{s}$; chlorophyll: 66.88
289 $\text{mg}/\text{m}/\text{s}$), the benchmark run estimated a higher NO_3 flux ($38.71 \text{ mmol N}/\text{m}/\text{s}$) and a lower
290 chlorophyll flux ($43.10 \text{ mg}/\text{m}/\text{s}$). The differences in NO_3 and chlorophyll fluxes between the two
291 simulations could be explained by nutrient accumulation and NPP reduction on the inner shelf
292 associated with resuspended sediment (Figs. 5a and 5c). Given the better offshore bloom intensity
293 reproduced by the benchmark run (Figs. 3d and 3e), we conclude the post-hurricane offshore
294 bloom was mainly triggered by nutrient exported from the inner shelf water.

295 296 4.4 Sensitivity to sediment light attenuation coefficient (α_{sed})

297 A wide range of particle physical properties (e.g., size, shape, roughness and color)
298 influence sediment light attenuation efficiency, which contributes to the difficulty in

299 parameterization of α_{sed} over a large region such as the nGoM (Baker and Lavelle, 1984; Storlazzi
300 et al., 2015). To examine the sensitivity of primary production to sediment light attenuation
301 efficiency, the results of sensitivity tests with different α_{sed} (tests 2–5) were compared against the
302 benchmark run.

303 Ahead of Gustav’s landfall, the difference in primary production between the benchmark
304 run and sensitivity tests was limited (Fig. 8a), which suggested that the nGoM ecosystem was
305 mainly limited by nutrient rather than light (Fennel et al., 2011). Two days after the landfall
306 (September 1st – 3rd), high SSC suppressed photosynthesis in the entire water column which
307 overwhelmed the response associated with different α_{sed} settings. As such, primary production
308 was not sensitive to α_{sed} from September 1st to 3rd, although the nGoM ecosystem was also light
309 limited. After September 3rd, the differences in primary production and NO₃ concentration
310 increased among the sensitivity tests through September 8th (Fig. 8). Primary production became
311 more sensitive to α_{sed} than SSC, which largely decreased due to settling (Fig. 5d). In the last two
312 days of our simulation, the primary production differences reduced again to pre-hurricane
313 conditions as the nGoM ecosystem shifted back to a nutrient-limited system.

314 In general, the influence of α_{sed} is significant when underwater light is limited by sediment
315 and SSC was moderately high. The optical environment over the muddy inner Louisiana shelf is
316 dominated by CDOM and chlorophyll under normal condition (D’Sa and Miller, 2003). During
317 energetic events (e.g., hurricanes, cold fronts), however, high concentrations of resuspended
318 sediment become the most important light absorber. Given the high frequency of cold fronts in
319 winter (once every 3–7 days) and energetic hurricanes in summer (Walker and Hammack, 2000;
320 Keim et al., 2007), it is reasonable to speculate that the ecosystem along coastal Louisiana would
321 be sensitive to α_{sed} not only on event scale, but also on seasonal to annual scales. The role of
322 long-term sediment dynamics in water clarity and marine ecology has been reported in other
323 regions (Dupont and Aksnes, 2013; Capuzzo et al., 2015; Wilson and Heath, 2019). To prove this
324 hypothesis in the nGoM, we need a long-term biogeochemical simulation that explicitly include
325 sediment-induced light attenuation effects in the future.

326

327 4.5 Model uncertainties

328 The optical environment over the muddy Louisiana shelf is dominated by phytoplankton,
329 suspended sediment, CDOM, and detritus particle (Le et al., 2014). The model presented in this
330 study only includes the light attenuation due to the former two constituents, and the potential
331 influence from CDOM and detritus warrants future study. Light attenuation due to CDOM was
332 simply parameterized using salinity in a previous model study (Justić and Wang, 2014), yet few
333 biogeochemical models incorporate dissolved/detritus-induced light attenuation. In the nGoM,
334 CDOM plays an indispensable role in modulating optical properties of inner shelf waters (D’Sa
335 and Miller, 2003; D’Sa et al. 2018), thus including CDOM-induced light attenuation would likely
336 lower the threshold of sediment resuspension above which the nGoM ecosystem would be light-
337 limited. To estimate the importance of CDOM-induced light attenuation in the biogeochemical
338 models, a long-term CDOM climatology is desired in the future.

339 We use SeaWiFS-derived chlorophyll concentration to evaluate model performance.
340 However, deriving high quality chlorophyll data during hurricanes is still a challenge because: 1)
341 the presence of thick clouds limits the availability and quality of satellite images (Huang et al.,
342 2011); 2) the uncertainty of chlorophyll estimation can be amplified by strong CDOM absorption
343 (D’Sa and Miller, 2003; D’Sa et al., 2006); and 3) conducting chlorophyll measurements during a
344 hurricane to calibrate bio-optical algorithms is limited by cost and safety. Given the rapid change

345 and a wide range of sediment and chlorophyll concentrations after hurricanes, the algorithms based
346 on observations under normal conditions might incur a bias. To achieve a high-quality satellite-
347 derived chlorophyll data, it is essential to optimize an algorithm based on field observations during
348 hurricane events.

349 In this study we simplified α_{sed} as a constant over the entire GoM. When water is highly
350 turbid, the availability of light for photosynthesis could be more related to sediment concentration
351 rather than α_{sed} (McSweeney et al., 2017). Thus, using a constant to represent the sediment light
352 attenuation coefficient when sediment concentration is high should not introduce considerable bias.
353 The optical characteristics of sediment particles, however, could greatly modify light availability
354 underwater when SSC is relatively low (Storlazzi et al., 2015). Our sensitivity tests also suggest
355 the importance of α_{sed} in photosynthesis and primary production as resuspended sediment settle
356 back to the sea floor. Therefore, it is necessary to develop a spatially explicit α_{sed} to better
357 parameterize the sediment's impact on light attenuation in future work.

358 Organic matter remineralization in sediment can dramatically increase nutrient
359 concentration in the bottom boundary layer during strong resuspension (Couceiro et al., 2013).
360 Field measurements after hurricanes Gustav and Ike suggested that the resuspension can expose
361 the organic material in sediment to a more favorable environment for respiration (McCarthy et al.,
362 2013). Nevertheless, so far most biogeochemical models either neglect or simply parameterize this
363 process (Fennel et al., 2006; Chai et al., 2007; Kishi et al., 2007). Moriarty et al. (2018) developed
364 a particulate organic matter resuspension model and found remineralization intensity increased by
365 an order of magnitude during moderate resuspension events in the nGoM. Given the strong storm-
366 driven resuspension during hurricanes, nutrient dynamics can be modified greatly by
367 remineralization after the storm passage as well. Thus, incorporating organic matter resuspension
368 and remineralization, in conjunction with the light attenuation effects addressed in this study, will
369 help to improve our understanding of hurricane's impact on the biogeochemical cycling in shelf
370 waters.

371 Our biogeochemical model include freshwater and terrestrial nutrient input via river
372 channel. Du et al. (2019) estimated freshwater budget during hurricane Harvey and found that
373 surface runoff and groundwater accounted for ~34% of the total freshwater load during the
374 hurricane. Although our understanding of nutrient flux associated with these two types of
375 freshwater inputs is still limited, excluding surface runoff and groundwater flux in the model
376 implies our underestimation of terrestrial nutrient discharge from the land. Coupling groundwater
377 and hydrology models with ocean model is a feasible way to achieve a comprehensive assessment
378 of a hurricane's impact on the coastal and shelf ecosystem. In addition, water heating due to light
379 absorption can also impact the ecosystem (Cahill et al., 2008; Mobley et al., 2015), but it has yet
380 to be considered in our model.

381

382 **5 Conclusions**

383 We introduced a sediment-induced light attenuation algorithm to ROMS' biogeochemical
384 model. The new model reproduced the biogeochemical cycling during hurricane Gustav in the
385 northern Gulf of Mexico. Improved model performance suggested suspended sediment can play
386 an important role in underwater optical environment and primary production. During the passage
387 of Gustav, the high SSC changed the inner shelf from a nutrient-limited environment to a light-
388 limited one. NPP reduced from 0.05 to 0.01 g C/m²/hr, then recovered to pre-hurricane condition
389 after one week of hurricane landfall. As sediment further settled back on the seabed, nutrient
390 accumulation and increased light availability incurred a strong surface post-hurricane bloom on

391 the inner shelf. Nine days after Gustav's arrival, NPP below 20 m water depth was still light-
392 limited due to slow settling of sediment. The post-hurricane bloom on the outer shelf was
393 significantly enhanced by the laterally transported nutrient from inner to outer shelf. Suspended
394 sediment affected primary production when SSC was moderately high after Gustav's landfall. For
395 aquatic environments with great spatiotemporal variation of SSC (e.g., estuaries and lagoons), an
396 optimal parameterization of sediment-induced light attenuation is imperative to better evaluate
397 hurricane's impact on coastal productivity and biogeochemical cycling.

640

641 **Figure 1.** panel a: Model domains applied in this study. The entire panel a is the WRF
642 model domain (6 km resolution) overlaid with water depth (color-shading). The black solid
643 box represents the model grid used by ROMS and SWAN with 5 km resolution. The black
644 dashed line box (lat: 27°N–31°N; lon: 94°W–86°W) covers the northern Gulf of Mexico
645 (nGoM). More details in the nGoM are shown in panel b. The thick purple/red lines indicate
646 locations of 50m-isobath transect and transect D (Rabalais et al., 2001), respectively.

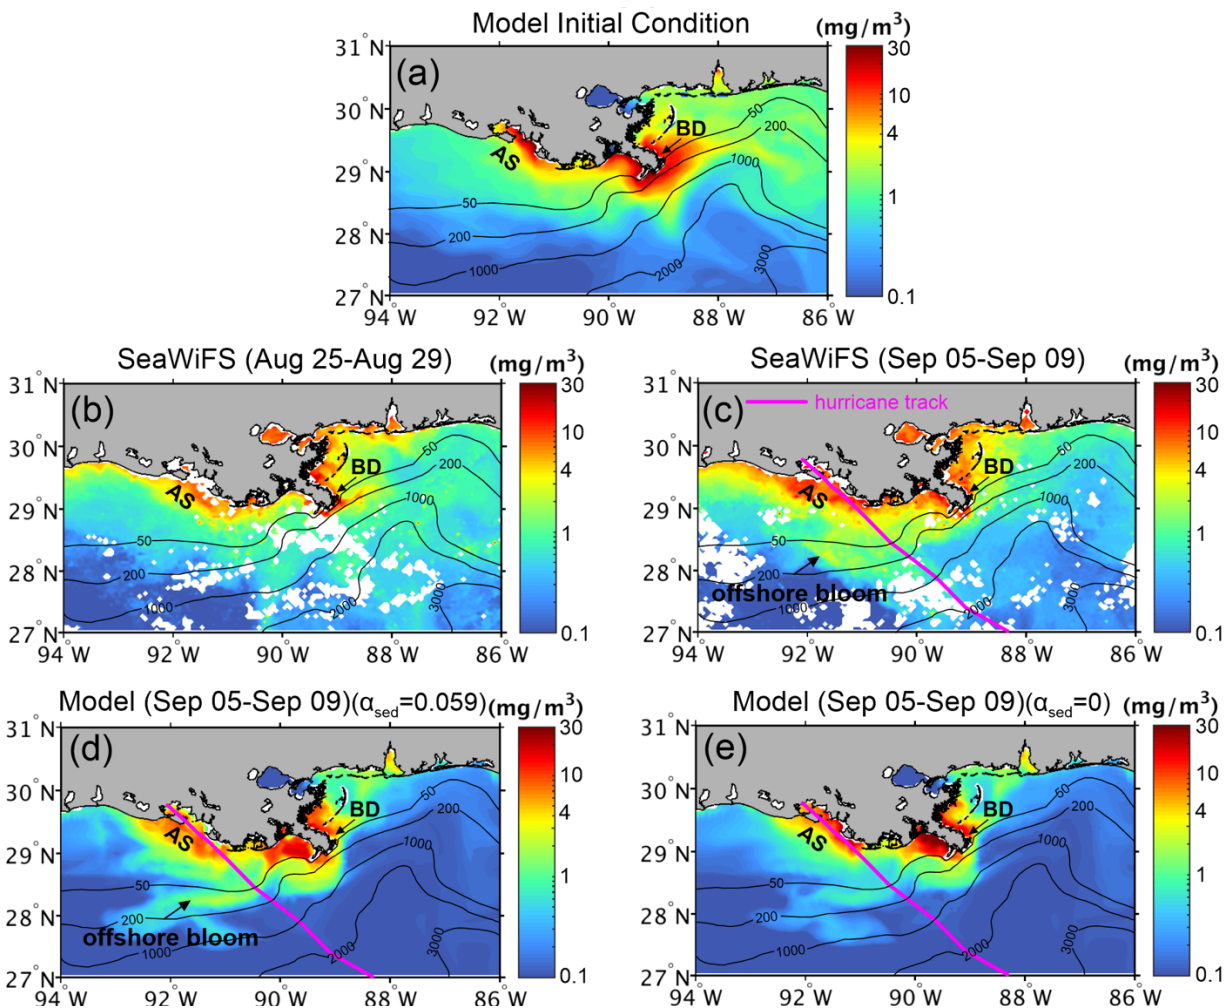

647
648

649 **Figure 2.** Flow chart of long-term (20 years) and hurricane (11 days) simulations. In Step 1 we
 650 only run ocean (ROMS) and biogeochemical (NEMURO) models, which provide initial inputs for
 651 the next step. Step 2 couples ocean (ROMS), wave (SWAN), atmosphere (WRF), sediment
 652 (CSTMS) and new biogeochemical (NEMURO) models with new sediment-induced light
 653 attenuation term.

654
 655

656 **Figure 3.** Initial condition of surface chlorophyll extracted from 20-year simulation (a) and five-
 657 day composite of surface chlorophyll concentration in the year 2008: (b) SeaWiFS data before
 658 Gustav (August 25th–29th); (c) SeaWiFS data after Gustav (September 05th–09th); (d) benchmark
 659 run result ($\alpha_{sed} = 0.059$) after Gustav; (e) test 1 result ($\alpha_{sed} = 0$) after Gustav. White color in
 660 panels (b) and (c) represents no data. Magenta curve shows hurricane track in panels b, c, and d.
 661 (BD: bird-foot Mississippi delta; AS: Atchafalaya shelf).
 662

663
 664

665 **Figure 4.** Simulated five-day composite (September 05th–09th) of surface chlorophyll
666 concentration after hurricane Gustav compared to corresponding SeaWiFS-derived surface
667 chlorophyll results over the nGOM inner shelf ($h < 50$ m) for model results based on (a)
668 benchmark ($\alpha_{sed} = 0.059$) and (b) test 1 ($\alpha_{sed} = 0$) runs.

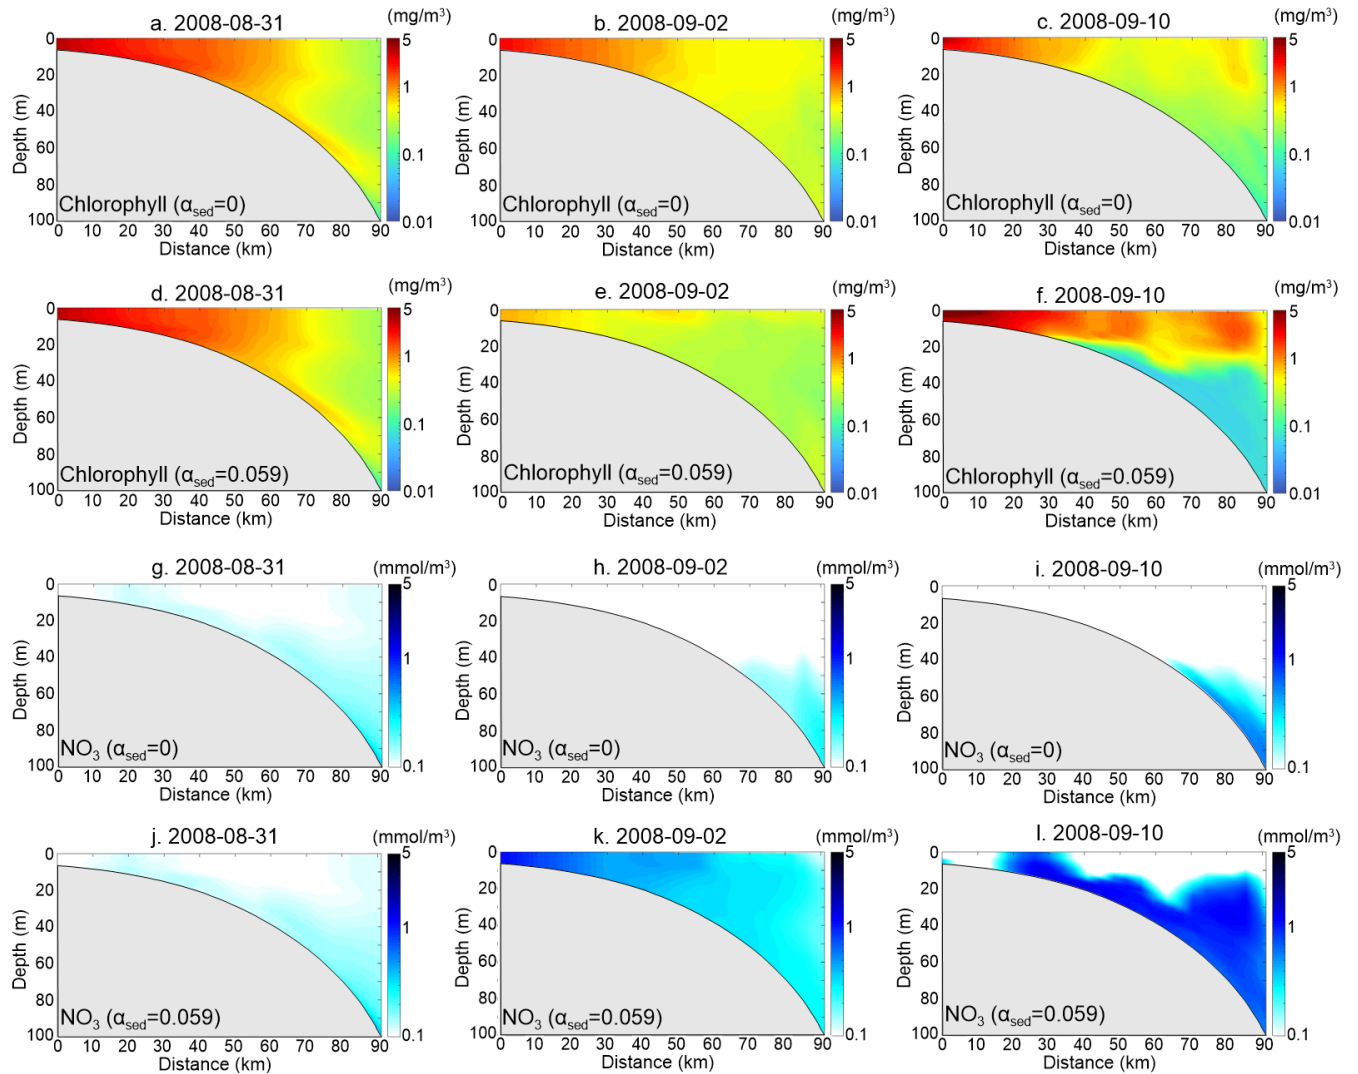

669
670

671 **Figure 5.** Time series of spatially averaged (inner shelf, water depth < 50 m) net primary
 672 production (a), surface chlorophyll concentration (b), surface NO₃ concentration (c), surface
 673 suspended sediment concentration (d), solar shortwave radiation (e), and sea surface temperature
 674 (f). In panels a, b, and c, blue represents benchmark run ($\alpha_{sed} = 0.059$) and red represents test 1
 675 ($\alpha_{sed} = 0$). Dots in panel (a) are daily-averaged net primary production. The black dashed line
 676 shows the time of Gustav landfall.
 677

678
 679

680 **Figure 6.** Model simulated chlorophyll and NO₃ along transect D on August 31st (first column),
 681 September 2nd (second column), and September 10th (third column). The first and second rows
 682 represent chlorophyll concentration of the test 1 and benchmark run, respectively (note the color
 683 scale is different from Fig. 3). The third and fourth rows show NO₃ concentration of test 1 and
 684 benchmark run, respectively.
 685

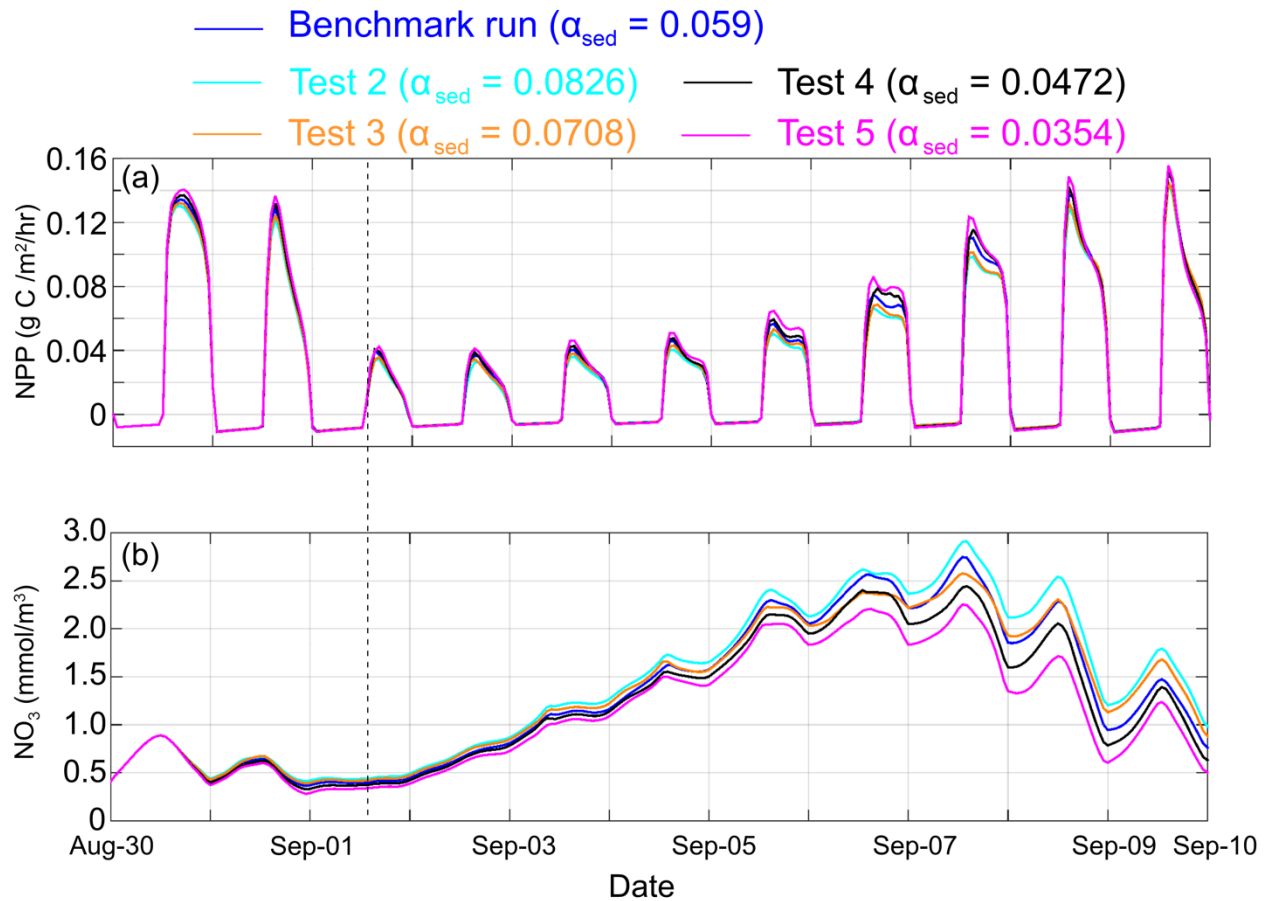

686
 687
 688

689 **Figure 7.** Model simulated suspended sediment concentration (SSC; first row) and water density
690 anomaly (second row) along transect D on August 31st (a, d), September 2nd (b, e), and September
691 10th (c, f), respectively.

692

693 **Figure 8.** Comparison of spatial averaged (inner shelf, water depth < 50 m) net primary production
694 (panel a) and NO₃ concentration (panel b) between benchmark run (blue) and sensitivity tests with
695 different α_{sed} (test 2: cyan; test 3: orange; test 4: black; test 5: magenta). The black dashed line
696 shows the time of Gustav landfall.
697

698
699

700 **Table 1.** Offshore fluxes of NO₃ and chlorophyll along the 50-m isobath transect (see location
 701 in Fig. 1b).

702

Model Runs	Net offshore NO ₃ flux (mmol N/m/s)	Net offshore Chl flux (mg/m/s)
benchmark run ($\alpha_{sed} = 0.059$)	38.71	43.10
test 1 ($\alpha_{sed} = 0$)	7.35	66.88

703
