19 **Abstract**

20 Grasslands are major terrestrial ecosystems in arid and semiarid regions, and play
21 important roles in the regional carbon dioxide (CO₂) balance and cycles. Sandy
22 grasslands are sensitive to climate change, yet the magnitudes, patterns, and
23 environmental controls of their CO₂ flows are poorly understood for some regions (e.g.,
24 China's Horqin Sandy Land). Here, we report the results from continuous year-round
25 CO₂ flux measurements in 5 years from a sandy grassland in China's Horqin Sandy
26 Land. The grassland was a net CO₂ source at an annual scale, with a mean annual net
27 ecosystem CO₂ exchange (NEE) of $49 \pm 8 \text{ g C m}^{-2} \text{ yr}^{-1}$ in the years for which a complete
28 dataset was available (2015, 2016, and 2018). Annual precipitation had the strongest
29 effect on annual NEE; grassland carbon sequestration increased with increasing
30 precipitation, since NEE depended on annual precipitation. In the spring, NEE
31 decreased (i.e., C sequestration increased) with increasing magnitude of effective
32 precipitation pulses, total monthly precipitation, and soil temperature (T_{soil}). In the
33 summer, NEE was dominated by the total seasonal precipitation and high-precipitation
34 pulses (>20 mm). In the autumn, NEE increased (i.e., C sequestration decreased) with
35 increasing effective precipitation pulses, T_{soil}, and near-surface soil water content
36 (SWC), but decreased with increased SWC deeper in the soil. In the winter, NEE
37 decreased with increasing T_{soil} and SWC. The sandy grassland was a net annual CO₂
38 source because drought decreased carbon sequestration by the annual plants. Long-term
39 observations will be necessary to reveal the true source or sink intensity and its response
40 to environmental and biological factors.

41 **Keywords:** Net ecosystem CO₂ exchange (NEE); Gross primary productivity (GPP);
42 ecosystem respiration (R_{ec}); Eddy covariance; Horqin Sandy Land

43 **1 Introduction**

44 Arid and semiarid ecosystems cover 30 to 40 % of the global terrestrial surface
45 (Poulter et al., 2014). The extent and distribution of these areas are increasing in
46 response to factors such as climate change, changes in wildfire frequency and intensity,
47 and changes in land use (Asner et al., 2003; Hastings et al., 2010). These ecosystems

48 are important because they account for 30 to 35 % of terrestrial net primary productivity
49 (Gao et al., 2012; Liu et al., 2016a) and approximately 15 % of the global soil organic
50 carbon pool (Lal, 2004; Liu et al., 2016a). Thus, these areas are important contributors
51 to the global carbon budget due to their wide distribution (Emmerich, 2003; Noretto et
52 al., 2006; Poulter et al., 2014; Zhou et al., 2020), and arid and semiarid ecosystems will
53 have significant effects on the global carbon cycle and carbon balance (Lal, 2004;
54 Biederman et al., 2017). However, the availability of continuous, long-term
55 measurements of water and net ecosystem CO₂ exchange (NEE) has lagged in arid and
56 semiarid ecosystems (Baldocchi et al., 2001; Hastings et al., 2010; Biederman et al.,
57 2017). Recent research on the relationship between NEE and water in drylands has
58 focused on the southwestern United States (Scott et al., 2015; Biederman et al., 2016,
59 2017) and Australia (Cleverly et al., 2016; Li et al., 2017). **Compared with the more
60 constant sink that is typically measured in mesic ecosystems, dryland ecosystems
61 showed a wide range of carbon sink or source functions for diverse vegetation types
62 (Biederman et al., 2017). Moreover, water availability (e.g., precipitation,
63 evapotranspiration, soil moisture) plays a dominant role in regulating ecosystem carbon
64 fluxes and their responses to climatic change in dryland ecosystems (Niu et al., 2008;
65 Biederman et al., 2016; Ago et al., 2016). However, to our knowledge, there has been
66 no report on the intra-annual and interannual variation of ecosystem-scale carbon fluxes
67 in China's Horqin Sandy Land, an important dryland ecosystem in northern China.
68 Therefore, we designed the present study to reveal how changes in water availability
69 (e.g., total precipitation, pulse size) affect carbon fluxes in the sandy grassland
70 ecosystems of the Horqin Sandy Land.**

71 The Horqin Sandy Land is the largest sandy land in China, and nearly 80 % of the
72 area has been desertified (Li et al., 2019). Here, we define "sandy land" as land covered
73 by a sandy soil, with a vegetation cover less than 5 %, which includes areas of sandy
74 desert (Yan et al., 2003). Sandy land includes multiple overlapping ecotones, including
75 transition zones between areas with different population pressures and between semi-
76 humid and semiarid areas, and occurs in typical agro-pastoral ecotones. The ecological

77 environment is fragile and extremely sensitive to climate change and human activities
78 (Bagan et al., 2010; Zhao et al., 2015). The region's sandy grassland grows on aeolian
79 sandy soils or areas with sandy soils as the substrate, and is typical of the grassland
80 vegetation that develops in sandy land (Munkhdalai et al., 2007). This grassland
81 ecosystem is widespread in the Horqin Sandy Land (Zhao et al., 2007). Research
82 showed that the restoration of degraded sandy grassland can increase its productivity
83 and carbon sequestration, and that the ecosystem can begin to act as a carbon sink (Ruiz-
84 Jaen and Aide, 2005; Zhao et al., 2016). However, other studies showed that it was a
85 carbon source (Li et al., 2012; Niu et al., 2018). Moreover, we do not yet fully
86 understand the characteristics of NEE and its components (gross primary productivity
87 [GPP] and ecosystem respiration [R_{ec}]) at an ecosystem scale, particularly for sandy
88 grassland protected by grazing exclosures, and more data are needed, particularly for
89 semiarid sandy land (Barrett, 1968; Czobel et al., 2012). **Therefore, long-term**
90 **monitoring of carbon fluxes, of their dynamics, and of the carbon budget of sandy**
91 **grassland ecosystems will clarify the factors that determine whether sandy grassland**
92 **ecosystems function as carbon sources or sinks and fill gaps in our knowledge of the**
93 **current carbon budget of the world's drylands.**

94 Precipitation is one of the factors that most strongly affects NEE in arid and semiarid
95 areas (Scott et al. 2015; Biederman et al. 2016). Slight changes to the amount and
96 frequency of precipitation may trigger complex interactions among biochemical
97 processes at the ecosystem level (Emmerich and Verdugo, 2008; Cleverly et al., 2016).
98 **Small precipitation pulses promote ecosystem carbon loss, chiefly through microbial**
99 **respiration, and large precipitation pulses are necessary to elicit net carbon gain by the**
100 **ecosystem's autotrophic components (Huxman et al., 2004; Schwinning and Sala, 2004;**
101 **Hao et al., 2010).** To better understand the effects of precipitation on NEE, we asked
102 the following question: Is there a threshold of "effective precipitation" that determines
103 whether ecosystem carbon fluxes will lead to net sequestration or net emission in sandy
104 grasslands?

105 Precipitation is characterized by discrete events in arid and semiarid regions, with

106 high variability in the amount, duration, and frequency of precipitation at intra-annual
107 (e.g., seasonal) and inter-annual scales (Hao et al., 2010; Ponce Campos et al., 2013).
108 These discrete and largely unpredictable events may lead to pulsed availability of soil
109 water and nutrients, with both spatial and temporal variation (Noy-Meir, 1973; Zhao
110 and Liu, 2011). The responses of photosynthesis and respiration to precipitation are
111 seasonally specific because of differences in the depth of soil water infiltration and
112 because these processes differ in their sensitivity to temperature (Li and Zhou, 2012).
113 Spring and autumn precipitation are important controls on the beginning and end dates
114 of the growing season, so the ability of these events to change carbon accumulation or
115 emission should not be ignored, especially in semiarid and arid regions (Prev éy et al.,
116 2014; Shen et al., 2015). This is particularly true when relatively low temperatures limit
117 soil microbial respiration during certain periods (Knorr et al., 2005). **Summer**
118 **precipitation tends to comprise a relatively large total amount, provided by relatively**
119 **large pulses, and can infiltrate the soil to a depth where it becomes plant-available and**
120 **can trigger net photosynthesis, but a combination of high temperatures and high soil**
121 **moisture also stimulate respiration by soil microbes (Huxman et al., 2004; Chen et al.,**
122 **2009; Liu et al., 2016a; Zhou et al., 2020). The total amount and pulse size of summer**
123 **precipitation** may therefore play an important role in regulating inter-annual variations
124 of the ecosystem carbon balance (Chen et al., 2009; Scott et al., 2009; Wu et al., 2012).
125 **Understanding the consequences of climate change, and particularly the changes in**
126 **precipitation patterns and their effect on soil water regimes, may be critical for**
127 **developing strategies to preserve or restore these sandy grasslands.**

128 In this paper, we present the results from continuous (14 September 2014 to 31
129 December 2018) *in situ* monitoring of **CO₂ fluxes** (NEE, GPP, and R_{ec}) in the Horqin
130 Sandy Land's sandy grassland using the eddy covariance technique. We quantify the
131 **CO₂ fluxes over different timescales**, and identify the factors that control the
132 ecosystem's carbon balance. We had the following goals: (1) To quantify the annual,
133 seasonal, and diurnal variation in NEE, GPP, and R_{ec}. We hypothesized that the sandy
134 grassland is a carbon source at the ecosystem scale, because the sandy grassland is

135 dominated by annual plants that are vulnerable to drought (Li et al., 2016; Kang et al.,
136 2018), and that GPP would depend strongly on precipitation in this ecosystem, so that
137 years with low precipitation would cause the ecosystem to become a net carbon source.
138 (2) To determine whether there is a threshold of “effective precipitation” in this sandy
139 grassland. Based on the response thresholds of shrubs and herbs to precipitation in arid
140 and semiarid areas (Hao et al., 2010; Zhou et al., 2020), we hypothesized that an
141 “effective precipitation” threshold would exist at around 5 mm, and that precipitation
142 greater than this threshold would alter soil moisture in deeper layers and thereby affect
143 carbon fluxes in the sandy grassland ecosystem. (3) To explore the effects of changes
144 in total precipitation and pulse size on NEE, GPP, and R_{ec} . We also hypothesized that
145 spring, summer, and autumn precipitation would have different impacts on the
146 ecosystem CO_2 exchange through their differential effects on plant photosynthesis and
147 soil respiration (Scott et al., 2009).

148 **2 Materials and methods**

149 **2.1 Experimental site**

150 Our study was conducted in a sandy grassland in the southern part of the Horqin
151 Sandy Land, Inner Mongolia, China, at the Naiman Desertification Research Station of
152 the Chinese Academy of Sciences (42°55' N, 120°42' E) (Fig. 1a). The terrain is flat,
153 and it evolved from reclamation of sandy grassland for agriculture that led to severe
154 desertification, after which cultivation was abandoned and grazing exclosures were
155 established to allow natural recovery of the vegetation, starting in 1985 (Zhao et al.,
156 2007). Thus, the grassland had been recovering naturally for nearly 30 years when our
157 study began. At an elevation of 377 m a.s.l., the study area has a continental semiarid
158 monsoon temperate climate regime. The mean annual temperature is 6.8 °C, with mean
159 monthly temperatures ranging from -9.63 °C in January to 24.58 °C in July. Average
160 annual precipitation is approximately 360 mm, with about 70 % of the precipitation
161 occurring during the growing season, between June and August. Annual mean potential
162 evaporation is approximately 1973 mm. The annual frost-free period is 130 to 150 days.
163 The most common soil type in the study region is a sandy chestnut soil, but most of the

164 soil has been degraded by a combination of climate change and anthropogenic activity
165 (unsustainable grazing or agriculture) into an aeolian sandy soil under the action of
166 wind erosion (Zhao et al., 2007), with coarse sand, fine sand, and clay-silt contents of
167 92.7, 3.3, and 4.0 %, respectively, in the topsoil to a depth of 20 cm. The contents of
168 soil organic carbon and total nitrogen were 1.27 and 0.21 g kg⁻¹, respectively.
169 Vegetation cover in the study area ranged from 50 to 70 %. The dominant plant species
170 were annual herbs, including *Artemisia scoparia*, *Setaria viridis*, *Salsola collina*, and
171 *Corispermum hyssopifolium* (Niu et al., 2018).

172 **2.2 Micrometeorological measurements**

173 Along with the flux measurements obtained by the eddy covariance equipment (see
174 the next section for details), we measured standard meteorological and soil parameters
175 continuously with an array of sensors. A propeller anemometer was installed at the top
176 of the meteorological tower to measure the wind speed and direction. Net solar radiation
177 (R_n , W m⁻²) was measured by a four-component radiometer (CNR-1, Kipp and Zonen,
178 Delft, the Netherlands) installed at 1 m above the ground. The air temperature (T_{air} , °C)
179 and relative humidity (%) instrument (HMP45C, Vaisala Inc., Helsinki, Finland) was
180 mounted at 2 m above the ground to measure the T_{air} , relative humidity, and atmospheric
181 pressure (kPa). Precipitation (mm) measurements were obtained from a meteorological
182 station 400 m from the study site. Total daily precipitation was treated as a single event
183 rather than as a series of events.

184 We installed five CS109 temperature probes (Campbell Scientific, Logan, UT, USA)
185 and five CS616 moisture probes (Campbell Scientific) in the soil at depths of 10, 20,
186 30, 40, and 50 cm to measure soil temperature (T_{soil} , °C) and soil water content
187 (SWC, %). Two self-calibrating HFP01 soil heat flux (SHF, W m⁻²) sensors (Hukseflux,
188 Delft, the Netherlands) were buried 5 and 10 cm below the ground to obtain the SHF
189 data that was used to calculate the energy closure. All of the environmental parameters
190 were measured simultaneously with the eddy covariance measurements, and all data
191 were recorded as 30-min mean values with a CR3000 datalogger (Campbell Scientific).

192 **2.3 Eddy covariance observations**

193 An eddy covariance flux tower (2.0 m high) was installed at the center of the
194 observation field (Fig. 1b, c). We have continuously monitored CO₂, water, and heat
195 fluxes at the tower using the eddy covariance system since late 2014. The site was flat
196 and comprised homogeneous vegetation. The upwind fetch was about 200 m under
197 unstable atmospheric conditions, which was greater than the flux footprint (Schmid,
198 1997; Xu and Baldocchi, 2004). **The eddy covariance system consisted of an LI-7500**
199 **infrared gas analyzer (Li-Cor Inc., Lincoln, NE, USA), with an accuracy of 1 % or**
200 **better, and recorded measurements at a frequency of 10 Hz, and a CSAT 3 three-**
201 **dimensional ultrasonic anemometer (Campbell Scientific), with an accuracy of 2 % or**
202 **better, and recorded measurements at a frequency of 10 Hz.** Raw 10-Hz data were
203 recorded by a CR3000 datalogger. The operation, calibration, and maintenance of the
204 eddy covariance system followed the manufacturers' standard procedures. The LI-7500
205 was calibrated every 6 months for CO₂, water vapor, and dew point values using
206 calibration gases and dew point generator measurements supported by the China Land-
207 Atmosphere Coordinated Observation System (Yun et al., 2018). We cleaned the mirror
208 of the LI-7500 every 15 days to maintain the automatic gain control value below its
209 threshold (55 to 65). All of the instruments were powered by solar panels connected to
210 a battery.

211 **2.4 Data quality and gap-filling method**

212 We used the EddyPro 6.2.0 software (Li-Cor) to process the 10-Hz raw eddy
213 covariance data. Processing **(based on the manufacturer's recommendations and**
214 **previous research)** included spike removal, lag correction, secondary coordinate
215 rotation, Webb-Pearman-Leuning correction, sonic virtual temperature conversion,
216 **and infrared gas analyzer self-heating correction during the coldest days (with**
217 **temperatures <-10 °C)** (Webb et al., 1980; Burba et al., 2008). We used the data
218 processing method of Lee et al. (2004) to process the 30-min mean raw flux
219 measurements to ensure their quality. Processed data were further corrected for weather
220 effects and sensor uncertainty using the following procedure: (1) We removed data
221 gathered during precipitation events, and during periods of sensor maintenance or

222 malfunction. (2) We excluded unrealistic CO₂ flux data (values outside the range of –
223 45.45 to 45.45 μmol CO₂ m⁻² s⁻¹). (3) We rejected data collected during periods of
224 insufficient turbulent mixing using a friction-velocity filter ($u^* < 0.1 \text{ m s}^{-1}$) for data
225 collected at night (Reichstein et al., 2005; Scott et al., 2009). This screening resulted in
226 the rejection of 20 to 30 % of the flux data, depending on the period.

227 We used several strategies to compensate for missing data. We used linear
228 interpolation to fill gaps that were shorter than 2 h. For longer gaps, NEE was classified
229 based on the R_n as the daytime exchange (NEE_{day}; R_n ≥ 1 W m⁻²) or the night-time
230 exchange (NEE_{night}; R_n < 1 W m⁻²). We handled gaps in the NEE_{day} using the mean
231 diurnal variation with a 7-day window centered on the day with missing data (Falge et
232 al., 2001), and handled gaps in the NEE_{night} using equation 1, with the parameter values
233 calculated with a 7-day moving window centered on the day with missing data using
234 version 22 of the SPSS software (IBM, Armonk, NY, USA) (Lloyd and Taylor, 1994;
235 Reichstein et al., 2005).

$$236 \quad \text{NEE}_{\text{night}} = R_0 \exp(b T_{10}) \quad (1)$$

237 where R₀ is the base ecosystem respiration rate when the soil temperature is 0 °C, b
238 is an empirically determined coefficient, and T₁₀ is the soil temperature at a depth of 10
239 cm. Daytime ecosystem respiration can be estimated by extrapolation from the
240 parameterization derived from Eq. (1). We did not attempt to fill gaps longer than 7
241 days, and treated those gaps as missing data. Gross primary productivity (GPP) was
242 obtained as follows:

$$243 \quad \text{GPP} = R_{\text{ec}} - \text{NEE} \quad (2)$$

244 We used the standard sign convention for NEE, with NEE > 0 indicating a net loss
245 of CO₂ to the atmosphere (source) and NEE < 0 indicating net CO₂ uptake by the
246 ecosystem (sink).

247 We evaluated the data quality based on the degree of energy closure (sensible heat
248 + latent heat – net radiation – soil heat flux). The energy closure values for the sandy
249 grassland from 2015 to 2018 were 87, 83, 58, and 86 %, respectively (Fig. S1).

250 **2.5 Statistical analyses**

251 We performed correlation analysis (Pearson's r) and regression analysis using the
252 SPSS software. Unless otherwise noted, we defined statistical significance at $p < 0.05$.
253 Pearson's r was applied to confirm the strength of the relationships between parameters.
254 Before regression analysis, we tested for collinearity (using a variance inflation factor
255 of $0 < VIF < 10$) using the Kaiser–Meyer–Olkin (KMO) test and Bartlett's sphericity
256 test. Collinearity was used to repartition the T_{soil} and SWC data. We considered KMO
257 values > 0.50 and $p < 0.05$ for Bartlett's sphericity test to indicate acceptable data (Hair
258 et al., 2005). The KMO value ranged from 0.52 to 0.78 and $p < 0.001$ for all Bartlett's
259 sphericity test results for our data.

260 **3 Results**

261 **3.1 Meteorological conditions**

262 Figures S2 to S5 show the diurnal and seasonal variation of the meteorological
263 factors during the observation period. The mean daily T_{air} , R_n , and T_{soil} at depths of 10,
264 20, 30, 40, and 50 cm showed unimodal seasonal variations in all 4 years. These
265 parameters were therefore largely stable and did not differ greatly between years, except
266 for the precipitation and SWC at all depths; precipitation and SWC were lower in 2014
267 and 2015 than in the other years (Fig. S5b). Thus, precipitation and SWC were the main
268 factors that influenced NEE, and we focused on them in our analysis. The annual
269 precipitation totaled 208 mm in 2015, 277 mm in 2016, 313 mm in 2017, and 351 mm
270 in 2018 (Fig. S5b). Zhao and Liu (2010) showed that precipitation less than 5 mm in
271 arid and semiarid areas changes SWC primarily in the near-surface soil, and that
272 precipitation events greater than 5 mm can effectively supplement root layer moisture
273 at greater depths; these larger pulses are therefore called "effective precipitation". Our
274 results (Fig. 2) were consistent with this view.

275 The essence of effective precipitation is that precipitation enters the soil below the
276 surface layer, and becomes part of the soil water; that soil water is then used either
277 directly or indirectly by the vegetation, and has an impact on **the ecosystem's carbon**
278 **absorption and emission processes** (Joseph Turk et al., 2012). Therefore, we studied the
279 influence of precipitation on NEE and its components in each season from the

280 perspective of SWC. The climate was drier in 2015, 2016, and 2017 than in a normal
281 year. Based on the mean annual precipitation of 360 mm from 1960 to 2014,
282 precipitation was 58 % of this total in 2015, versus 77 % in 2016 and 87 % in 2017,
283 whereas 2018 was close to a normal year. The variation in soil water content was related
284 to precipitation patterns. During the spring (March, April, and May), precipitation was
285 relatively abundant, with mean total spring precipitation of about 42 mm, which
286 accounted for 12 to 20 % of the total annual precipitation. The majority of the
287 precipitation (56 to 95 %) occurred in the summer (June, July, and August), with mean
288 precipitation of about 197 mm. The autumn (September, October, and November)
289 precipitation was similar to that in spring, with a mean total autumn precipitation of
290 about 49 mm, which accounted for 14 to 24 % of the annual total. During the winter
291 (December, January, and February), the mean total precipitation of 0.6 mm accounted
292 for less than 1 % of the annual total, and was largely stable, with small differences
293 among the years.

294 **3.2 Annual, seasonal, and diurnal variability of NEE, GPP and R_{ec}.**

295 We also observed clear seasonal variations in daily mean NEE, GPP, and R_{ec} from
296 2014 to 2018 (Fig. 3). Our results suggest that the sandy grassland was a net CO₂ source
297 at an annual scale, with an annual mean NEE, GPP, and R_{ec} of 49 ± 8 , 303 ± 29 , and 352
298 ± 21 g C m⁻² yr⁻¹, respectively, in the years for which a complete dataset was available
299 (2015, 2016, and 2018) (Fig. 3f). We omitted 2017 from this calculation because of
300 large gaps in the data, described below. NEE ranged from 35 g C m⁻² yr⁻¹ in 2018 to 63
301 g C m⁻² yr⁻¹ in 2015, whereas GPP ranged from 256 g C m⁻² yr⁻¹ in 2015 to 356 g C m⁻²
302 yr⁻¹ in 2018 and R_{ec} ranged from 319 g C m⁻² yr⁻¹ in 2015 to 391 g C m⁻² yr⁻¹ in 2018.
303 From 15 September to 23 December 2014, we measured a cumulative carbon release
304 of 47 g C m⁻², with cumulative GPP and R_{ec} of 25 and 72 g C m⁻², respectively. From
305 15 February to 26 April 2017 and from 14 October to 6 November 2017, approximately
306 3 months of data were missing due to instrument maintenance and calibration, and the
307 cumulative NEE, GPP, and R_{ec} were 64, 274, and 338 g C m⁻², respectively, for the
308 remaining 9 months of the year. Note that the periods covered by the data are therefore

309 not identical.

310 Figures 4 and 5 show the seasonal NEE, GPP, and R_{ec} and their diurnal cycles,
311 respectively. In the spring, the sandy grassland was an atmospheric CO_2 source in all
312 years, with NEE, GPP, and R_{ec} averaging 0.14 ± 0.04 , 0.60 ± 0.06 , and 0.74 ± 0.02 g C
313 $m^{-2} d^{-1}$, respectively (Fig. 4a). The diurnal NEE cycle was characterized by a single
314 peak, and between 7:30 and 16:30, the ecosystem showed net CO_2 absorption (Fig. 5a);
315 the rest of the day was characterized by weak CO_2 emission. Note that although all
316 times in China are reported as the Beijing time, the study site was not sufficiently far
317 east of Beijing for this to affect the physiological meaning of these times. The average
318 diurnal GPP was also characterized by a single peak, with positive values from around
319 05:00 to around 19:30, and the diurnal R_{ec} was characterized by an approximately
320 horizontal line at about $0.75 \mu mol m^{-2} s^{-1}$, but with slightly higher respiration during
321 the day.

322 In summer, the sandy grassland was a CO_2 sink in all years, with NEE, GPP, and R_{ec}
323 averaging -0.66 ± 0.08 , 2.45 ± 0.09 , and 1.79 ± 0.04 g C $m^{-2} d^{-1}$, respectively (Fig. 4b).
324 The diurnal cycles of NEE and GPP were also characterized by a single peak, and the
325 ecosystem CO_2 uptake reached its peak from around 10:30 to 12:00 (Fig. 5b). NEE
326 decreased (C sequestration increased) with increasing light intensity during the day,
327 reached its peak value around noon, then increased until sunset, when the ecosystem
328 changed from net carbon absorption to net carbon release. The diurnal R_{ec} pattern was
329 the opposite of the spring pattern, and the peak R_{ec} occurred at night.

330 In autumn, the sandy grassland was a net source of atmospheric CO_2 in all years,
331 with NEE, GPP, and R_{ec} averaging 0.50 ± 0.03 , 0.26 ± 0.03 , and 0.76 ± 0.04 g C m^{-2}
332 d^{-1} , respectively (Fig. 4c). The diurnal dynamics of NEE, GPP, and R_{ec} in autumn (Fig.
333 5c) were similar to those in spring (Fig. 5a), but the magnitudes of NEE and GPP in
334 autumn were lower than in the spring. The diurnal R_{ec} was similar to the value in the
335 spring, at about $0.73 \mu mol m^{-2} s^{-1}$ and with higher values during the day.

336 In winter, the grassland ecosystem functioned as a net CO_2 source in all years, with
337 an average seasonal NEE of 0.59 ± 0.02 g C $m^{-2} d^{-1}$ (Fig. 4d). It should also be noted

338 that since the investigation started on 14 September 2014 and ended on 31 December
339 2018, the 2017 to 2018 winter was only about one-third of the usual length (i.e., it did
340 not include data from January and February 2019). The diurnal dynamics of the winter
341 NEE differed from the other seasons (Fig. 5d), with a minimum release value of 0.36
342 $\mu\text{mol m}^{-2} \text{s}^{-1}$, and with two emission peaks: at 0.78 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (08:00) and 0.85 μmol
343 $\text{m}^{-2} \text{s}^{-1}$ (16:30).

344 **3.3 Responses of NEE, GPP, and R_{ec} to changes in environmental factors**

345 At an annual scale, the major environment difference among the years with a
346 complete dataset (2015, 2016, and 2018) was the amount of precipitation (Fig. S5b).
347 We analyzed the relationship between precipitation and the annual NEE, GPP, and R_{ec}
348 in 2015, 2016, and 2018 (Fig. 6). We found that GPP and R_{ec} increased significantly
349 with increasing annual precipitation, whereas NEE decreased significantly with
350 increasing annual precipitation, indicating that the ecosystem's carbon sequestration
351 capacity increased with increasing precipitation. Taken together, these results indicated
352 different magnitudes and directions of response of the three parameters to annual
353 precipitation.

354 The temperature, precipitation, and CO_2 fluxes (NEE, GPP, and R_{ec}) were relatively
355 stable in winter (Fig. 4d, S5). We therefore focused on the relationships between NEE,
356 its components, and the associated environmental factors in the other three seasons (Fig.
357 4, 7). In the spring, the monthly precipitation was significantly negatively correlated
358 with NEE, but significantly positively correlated with GPP and R_{ec} , and GPP responded
359 more strongly than R_{ec} to precipitation: $\text{slope}_{\text{GPP}}(0.88) > \text{slope}_{\text{Rec}}(0.43)$ (Fig.7). That is,
360 plants were affected more strongly than soil microbes by changes in water availability.
361 In summer, the monthly precipitation was not significantly correlated with NEE, GPP,
362 and R_{ec} (Fig.7). **However, the trends for seasonal average NEE, GPP, and R_{ec} were**
363 **similar to that for total seasonal precipitation in different years. With increasing**
364 **precipitation, GPP and R_{ec} increased, whereas NEE decreased (Fig. 4b), and the**
365 **summer precipitation therefore increased the carbon sequestration capacity of the**
366 **ecosystem.** In autumn, the monthly precipitation was significantly positively correlated

367 with GPP and R_{ec} , with a similar strength of the response to precipitation: $slope_{R_{ec}}$ (0.75)
368 and $slope_{GPP}$ (0.72) (Fig.7), therefore, NEE was not significantly correlated with
369 monthly precipitation (i.e., because the responses for GPP and R_{ec} offset each other).

370 At a daily scale, the responses of NEE, R_{ec} , and GPP to precipitation pulses < 5 mm
371 were minimal (Fig. 2B; e.g., day of year (DOY) 104 and 107 in the 2016 spring, DOY
372 176 and 219 in the 2018 summer, DOY 283 and 284 in the 2015 autumn), whereas a
373 precipitation pulse > 5 mm led to a large response of NEE, R_{ec} , and GPP (Fig. 2B; e.g.,
374 DOY 123 and 133 in the 2016 spring, DOY 180 and 185 in the 2018 summer, DOY 254
375 in the 2015 autumn). This confirms that effective precipitation resulted from a
376 precipitation pulse > 5 mm. In spring, the effective precipitation pulses significantly
377 increased the magnitude of R_{ec} and GPP as the size of the precipitation pulse increased,
378 and this triggered a significant decrease of NEE (i.e., increased C sequestration; Fig.
379 2C). In summer, the effective precipitation pulses triggered small changes of NEE, GPP
380 and R_{ec} , which rapidly returned to their pre-pulse values (Fig. 2B, e.g., DOY 218 in the
381 2018 summer). This may have been because of the high temperature and faster
382 evaporation in summer. However, the high precipitation pulses (>20 mm) significantly
383 increased GPP, and led to significant decreases of NEE (Fig. 2B, C; e.g., DOY 180, 185,
384 202, and 224 in the 2018 summer). In autumn, the effective precipitation pulses
385 significantly decreased GPP and increased NEE (i.e., less C sequestration; Fig. 2C).

386 We also calculated the correlations between the three CO₂ fluxes (NEE, R_{ec} , and GPP)
387 and both SWC and T_{soil} and then performed regression analysis to further understand
388 their relationship with SWC at depths of 10, 20, 30, 40, and 50 cm in the spring, summer,
389 and autumn periods (Table S1, Fig. 8). In spring, NEE was significantly negatively
390 correlated with T_{soil} from 0 to 50 cm, with SWC from 10 to 50 cm, and with SWC from
391 0 to 10 cm. GPP and R_{ec} were significantly positively correlated with these
392 environmental factors. In summer, NEE was significantly negatively correlated with
393 T_{soil} from 0 to 50 cm and with SWC from 40 to 50 cm, but was not significantly
394 correlated with SWC from 0 to 10 cm. GPP and R_{ec} were significantly positively
395 correlated with T_{soil} from 0 to 50 cm, SWC from 10 to 50 cm, and SWC from 0 to 10

396 cm. T_{soil} from 0 to 50 cm had a smaller impact on NEE, GPP, and R_{ec} in summer than
397 in spring. In autumn, NEE was significantly positively correlated with T_{soil} from 0 to
398 50 cm and with SWC from 0 to 10 cm, but was significantly negatively correlated with
399 SWC from 10 to 30 cm. GPP and R_{ec} were significantly positively correlated with T_{soil}
400 from 0 to 50 cm, SWC from 10 to 50 cm, and SWC from 0 to 10 cm.

401 **4 Discussion**

402 **4.1 Annual and seasonal mean and diurnal variability**

403 **4.1.1 Comparison with other arid and semiarid ecosystems**

404 As we hypothesized, the sandy grassland ecosystem in the present study was a net
405 CO_2 source at an annual scale, with an annual mean NEE of $49 \pm 8 \text{ g C m}^{-2} \text{ yr}^{-1}$ in the
406 years for which a complete dataset was available (2015, 2016, and 2018). This result
407 was consistent with results for other ecosystems with similar climate and geographical
408 conditions. For example, a grassland in New Mexico, United States, was a net source
409 of $31 \text{ g C m}^{-2} \text{ yr}^{-1}$ during dry study periods (Petrie et al., 2015). A savanna in southern
410 Arizona, United States, was also a net source of CO_2 to the atmosphere, with emission
411 ranging from 14 to $95 \text{ g C m}^{-2} \text{ yr}^{-1}$ and the strength of the source increasing with
412 decreasing precipitation (Scott et al., 2014). A woodland in central Australia was
413 carbon-neutral during a dry year (Cleverly et al., 2013). In contrast, many other arid
414 and semiarid dry ecosystems were a significant net sink for CO_2 . For example, a desert
415 ecosystem in the United States had net C sequestration of 102 to $110 \text{ g C m}^{-2} \text{ yr}^{-1}$
416 (Wohlfahrt et al., 2008); an artificial sand-binding vegetation system in China's Tengger
417 Desert had net sequestration of 14 and $23 \text{ g C m}^{-2} \text{ yr}^{-1}$ in two consecutive years (Gao et
418 al., 2012); a phreatophyte-dominated desert ecosystem in China's Gurbantunggut
419 Desert had net sequestration of 5 to $40 \text{ g C m}^{-2} \text{ yr}^{-1}$ (Liu et al., 2016a); and a shrubland
420 in China's Mu Us desert had net sequestration of $77 \text{ g C m}^{-2} \text{ yr}^{-1}$ (Jia et al., 2014).

421 The most likely reason for these differences among studies relates to the effects of
422 vegetation cover differ and moisture. Our observations in 2015 and 2016 were in dry
423 years, with precipitation considerably below the long-term average, and because NEE
424 was negatively related to precipitation (Fig. 6), this would have decreased carbon

425 sequestration by the ecosystem. Previous studies showed that annual species such as
426 the vegetation in our study area can be extremely vulnerable to drought (Jongen et al.,
427 2011; Sun et al., 2015; Liu et al., 2016a). Drought was the main source of inter-annual
428 variation in previous research on terrestrial carbon sequestration, as it decreases GPP
429 and increases NEE (Webb et al., 1978; Sala et al., 1988; Ciais et al., 2005). It will be
430 necessary to study NEE for a longer period to reveal when that change occurs and the
431 ecosystem's long-term response to environmental and biological factors (Su et al., 2003;
432 Niu et al., 2018).

433 **4.1.2 The seasonal and diurnal characteristics of carbon fluxes in the sandy** 434 **grassland ecosystem**

435 In spring, the sandy grassland was a net CO₂ source in all years (Fig. 4a). Before the
436 **summer** growing season, both GPP and R_{ec} increased with increasing temperature and
437 precipitation (Niu et al., 2011; Rey et al., 2011). However, plants are just beginning to
438 germinate in the spring, so the carbon sequestration capacity of the ecosystem is less
439 than the carbon release capacity (Delpierre et al., 2010; Liu et al., 2016a; Zhang et al.,
440 2016). Therefore, the ecosystem was a net CO₂ source.

441 In summer, the sandy grassland was a CO₂ sink in all years (Fig. 4b). Our results
442 agree with previous results for the study area (Li et al., 2015), as well as with results
443 for a semiarid savanna in Australia (Hutley et al., 2005) and a grassland in California
444 (Ma et al., 2007). GPP and R_{ec} increased because of the favorable temperature and
445 moisture conditions. Some studies showed that photosynthesis is greater than
446 respiration during the peak of the growing season (Kemp, 1983; Liu et al., 2016a; Niu
447 et al., 2018). **Our result was consistent with these studies, since Figure 8 shows that**
448 **these conditions increased carbon uptake (i.e., NEE became more negative). Then,**
449 **because the sensitivity of GPP to T_{soil} and moisture was greater than that of R_{ec},** the
450 ecosystem became a net CO₂ sink.

451 In the autumn and winter, the sandy grassland was a net CO₂ source in all years (Fig.
452 4c, d). At the end of the growing season (in autumn), annual plants begin to die and
453 photosynthesis weakens (Fang et al., 2014). As a result, the ecosystem gradually

454 transforms from a carbon sink to a carbon source (Keenan et al., 2009; Kiely et al.,
455 2009). In winter, plants are either dead or dormant, so there is no C uptake.

456 At the diurnal scale, NEE in the spring and summer showed CO₂ uptake during the
457 day (06:00-18:00), and CO₂ emission during the night (Fig. 5a, b), which agrees with
458 previous research (Wagle and Kakani, 2014; Jia et al., 2014). In summer, the nighttime
459 R_{ec} was higher than that in daytime (Fig. 5b). This may relate to two factors. On the one
460 hand, soil respiration depends on photosynthesis because the litter and root exudates
461 released by the plants are essential for microbial metabolism. However, the carbon
462 sequestered by photosynthesis is transported to the roots after several hours, and is
463 released at night through rhizosphere respiration (Dilkes et al., 2004; Tang et al., 2005).
464 On the other hand, the air temperature in daytime is higher than the soil temperature,
465 and the gas pressure is also high, which can inhibit soil CO₂ emission; because the soil
466 temperature is higher than the air temperature at night, this is conducive to the diffusion
467 and release of soil CO₂ (Cao et al., 2005).

468 In autumn and winter, the sandy grassland ecosystem showed CO₂ emission
469 throughout the day (Fig. 5c, d). At a diurnal scale, there were two peaks for NEE (at
470 sunrise and sunset), and a minimum during the day (Fig. 5d). This phenomenon may
471 have resulted from heating effects in the open-path infrared gas analyzer, since the
472 surface of an open-path instrument can become substantially warmer than the ambient
473 air due to heat generated by the electronics and by the radiation load during the day. In
474 contrast, radiative cooling at night moderated the temperature increases in the optical
475 path, especially under a clear sky. The instrument surfaces would warm the air to a
476 temperature slightly higher than it was before it entered the optical path, and air
477 expansion would take place. As a result, the CO₂ number density would be lower than
478 it would have been without the heating (Burba et al., 2008). Yearly estimates of NEE
479 may be significantly biased toward CO₂ uptake in cold-climate ecosystems, and may
480 need to be revised (Goulden et al., 2006; Grelle and Burba, 2007; Burba et al., 2008).
481 We used the EddyPro software to calibrate the infrared gas analyzer by providing a self-
482 heating correction during the winter. After correction, the NEE value changed from

483 negative to positive (i.e., net emission), which realistically reflects the characteristics
484 of NEE in winter. However, the correction does not completely eliminate the self-
485 heating of the infrared gas analyzer (Burba et al., 2008), so the magnitude of the NEE
486 value in the daytime in winter is smaller than that at night, which may also explain the
487 two NEE peaks in the winter. We recently created a Li-Cor LI-8150 gas analyzer system
488 with six long-term monitoring chambers and installed the system in the footprint area
489 for the eddy covariance measurements, and we will use the data it generates in future
490 research to test that hypothesis.

491 **4.2 Impacts of the environment on NEE, GPP, and R_{ec}**

492 **4.2.1 Effects of precipitation on carbon fluxes**

493 Understanding the relationships between precipitation patterns and inter-annual
494 variations of carbon flux is an important step towards predicting how future climate
495 change will affect carbon cycles in arid and semiarid ecosystems (Poulter et al., 2014;
496 Scott et al., 2014; Liu et al., 2016a). Our results demonstrated the important roles of the
497 environmental factors in regulating the direction and amount of NEE between the
498 atmosphere and the ecosystem in a sandy grassland in the Horqin Sandy Land. The
499 dominant environmental factors differed among seasons at different scales, as has been
500 reported in previous research (Nakano et al., 2008; Ueyama et al., 2010).

501 At an annual scale, the amount of precipitation was the dominant factor in regulating
502 the annual carbon exchange of this sandy grassland. NEE was negatively linearly
503 related to precipitation **on a monthly basis throughout the year** (Fig. 6). This result is
504 consistent with data from a northern temperate grassland in Canada (Flanagan et al.,
505 2002) and a tallgrass prairie in the United States (Suyker et al., 2003). Annual
506 herbaceous plants are vulnerable to decreased precipitation, which decreases their
507 productivity by reducing stomatal conductance and leaf area, while simultaneously
508 increasing the soil water deficit (Ford et al., 2008). Soil water deficits and decreased
509 substrate availability for soil microbes can also decrease R_{ec} (Shi et al., 2014). In
510 addition, GPP generally responds more strongly than R_{ec} to drought in arid and semiarid
511 areas (Schwalm et al., 2010; Litvak et al., 2015; Delgado-Balbuena et al., 2019). Our

512 result was consistent with these studies, as the slope of the regression line that relates
513 precipitation to GPP (0.98) was much higher than that for R_{ec} (0.51) (Fig. 6). However,
514 we must improve our understanding of the responses of the ecosystem to precipitation
515 and the underlying mechanisms that control whether the ecosystem will be a carbon
516 source or sink. To accomplish this, it will be necessary to observe the ecosystem
517 continuously for a longer period of time.

518 **4.2.2 Effects of environmental factors on seasonal carbon fluxes**

519 The dominant factors varied seasonally. In the spring, NEE was most strongly
520 affected by T_{soil} (Fig. 8), SWC (Fig. 8), **pulses of effective precipitation (Fig. 2B, C)**,
521 and the amount of total monthly precipitation (Fig. 7). After experiencing the winter
522 cold and drought, GPP and R_{ec} increased with increasing temperature and precipitation
523 during the spring (Chu et al., 2013; Wolf et al., 2016). In the present study, NEE was
524 negatively related to the amount of spring precipitation (Fig. 7), which suggests that
525 spring precipitation leads to increased ecosystem carbon uptake in sandy grassland,
526 likely because the water replenishes the soil water storage in time to facilitate the
527 emergence and growth of shallow-rooted annual plants (Scott et al., 2000; Liu et al.,
528 2016a). In turn, this increases ecosystem CO_2 uptake. Therefore, spring precipitation
529 results in greater emergence and growth of annuals, which leads to a higher contribution
530 of this season to the ecosystem productivity (Huang et al., 2015).

531 In semiarid ecosystems such as our study site, summer precipitation supplies the
532 majority of the annual precipitation and soil moisture for most of the annual plant
533 growth (Emmerich and Verdugo, 2008; Sun et al., 2015). Our results showed that **NEE**
534 **was dominated by the total summer precipitation and by SWC at depths of 40 and 50**
535 **cm. This is likely to be related to the total precipitation and the size of effective pulses.**
536 **For example, the large precipitation pulses (>20 mm) significantly promoted carbon**
537 **uptake by the ecosystem (Fig. 2B, C). Large precipitation pulses** penetrate deeper into
538 the soil, thereby recharging soil water in deeper layers, which stimulates plant growth
539 and carbon absorption (Harper et al., 2005; Bell et al., 2012); on the other hand, the
540 water can potentially move below the rooting zone and become unavailable to plants.

541 However, our results indicated that the relationship between SWC from 0 to 10 cm and
542 NEE was not significant in summer. The near-surface SWC would be closely linked to
543 small precipitation amounts (<5 mm) that would not be effective (Fig. 2). Studies
544 suggest that small precipitation amounts may be intercepted by the plant canopy or may
545 replenish only the near-surface soil, where water may evaporate before plants can take
546 advantage of it, thereby reducing its impact on NEE (Schwinning and Sala, 2004; Hao
547 et al., 2010). Therefore, the events with high precipitation appear to be more efficient
548 than events with small precipitation for regulating NEE in sandy grassland in the
549 summer.

550 In the autumn, NEE increased with increasing pulses of effective precipitation (Fig.
551 2C), with T_{soil} , and with SWC from 0 to 10 cm (Fig. 8). As was the case in the summer,
552 the near-surface SWC was closely related to small precipitation events (<5 mm).
553 However, unlike in the summer, autumn is cooler and moisture evaporates more slowly
554 from the near-surface soil, and microbial respiration is sensitive to precipitation when
555 the temperature is suitable for microbial activity in semiarid regions (Huxman et al.,
556 2004; Sponseller, 2006; Roby et al., 2019). Thus, small rainfall events can stimulate
557 ecosystem CO_2 loss chiefly through their effect on microbial respiration (Reynolds et
558 al., 2004; Hao et al., 2010). However, the relationship between NEE and SWC in deeper
559 soil layers was negative (Fig. 8c), which was similar to the relationship in summer,

560 In winter, the annual plants had withered, so there was no GPP and the entire
561 ecosystem was characterized by carbon emission (Morgner et al., 2010; Gao et al.,
562 2012). Our results showed that NEE increased with decreasing SWC below a depth of
563 20 cm and with decreasing temperature at all depths (Table S1). Previous studies found
564 that when SWC decreases sufficiently to create water stress, it may replace temperature
565 as the main factor that controls soil respiration in arid and semiarid areas in winter (Wu
566 et al., 2010; Escobar et al., 2015), and as a result, soil respiration decreased with
567 decreasing SWC (Manzoni et al., 2011; Oikawa et al., 2011). Our results were
568 inconsistent with these previous studies. This may be due to the effects of drought, since
569 precipitation during the winter amounted to between less than 1 % of the annual

570 precipitation, and this drought would be exacerbated by strong winter winds in the
571 Horqin Sandy Land (Fig. S6; Wang et al., 2005; Liu et al., 2016b). The soil organic
572 matter and nutrients would also be lost faster when SWC decreases and the wind
573 strengthens, resulting in increased carbon emission (Lal, 2004; Munodawafa, 2011).

574 **5 Conclusions**

575 Our field data indicated that the sandy grassland has functioned as a net CO₂ source
576 at an annual scale, with a mean annual NEE of $49 \pm 8 \text{ g C m}^{-2} \text{ yr}^{-1}$. At the seasonal scale,
577 the sandy grassland showed net CO₂ absorption during the summer, but net CO₂ release
578 in the other seasons. At the diurnal scale, the ecosystem showed a strong single daytime
579 absorption peak in the spring and summer, but strong CO₂ emission at night. In autumn
580 and winter, the ecosystem was characterized by CO₂ emission throughout the day.

581 The amount of precipitation was significantly negatively correlated with NEE on
582 annual basis; **that is, more CO₂ was sequestered at higher precipitation levels.**
583 Seasonally, NEE was mainly affected by T_{soil}, **the pulses of effective precipitation,** and
584 **the total** amount of monthly precipitation in the spring, **by the amount of total seasonal**
585 **precipitation and large-pulse precipitation** in summer, by T_{soil} and SWC at all depths in
586 autumn, and by T_{soil} at all depths and by SWC from 30 to 50 cm in winter. Our findings
587 demonstrated the importance of long-term, high-frequency field monitoring in sandy
588 land to improve our understanding of CO₂ cycling and its likely responses to a changing
589 climate. However, it will be necessary to study the ecosystem's NEE for a longer period
590 to reveal its long-term response to environmental and biological factors and learn when
591 the ecosystem will recover sufficiently to become a net carbon sink on an annual basis.

592 *Data availability.* In agreement with the FAIR Data standards, the data used in this
593 article are archived, published, and available in a dedicated repository:
594 <http://doi.org/10.4121/uuid:35deeb02-8165-49b7-af8d-160d537ae15a>.

595 *Competing interests.* The authors declare that they have no conflict of interest.

596 *Author contributions.* YQL, YYN, HBY, XYW, and YLD designed the study; YYN,
597 XWG, and JL performed the experiments. YYN and HBY analyzed the data. YYN
598 drafted the manuscript. All co-authors had a chance to review the manuscript before

599 submission and contributed to discussion and interpretation of the data.

1029 **Figure captions**

1030 **Fig. 1.** (a) Locations of the Horqin Sandy Land and the Naiman station. (b) and (c) are
1031 photos of the eddy covariance site at the Naiman station during the growing and
1032 dormant seasons, respectively.

1033 **Fig. 2.** (A) Changes in soil water content (SWC) at depths of 10, 20, 30, 40, and 50 cm
1034 that resulted from precipitation events in spring, summer, and autumn (DOY, day of
1035 year). Precipitation ≥ 5 mm represents effective precipitation. (B) **Daily net ecosystem**
1036 **exchange (NEE), respiration (R_{ec}), and gross primary productivity (GPP) responses to**
1037 **precipitation pulses during the spring of 2016, summer of 2018, and autumn of 2015.**
1038 **The black arrows indicate the trends for carbon fluxes after effective precipitation. (C)**
1039 **Comparison of the mean carbon fluxes before and after effective precipitation pulses**
1040 **based on daily data. We chose the effective precipitation pulses that had no precipitation**
1041 **for 7 days after this precipitation (i.e., the period represented by the dashed lines circled**
1042 **in (B). “Before” values represent the average carbon fluxes for 7 days before the**
1043 **precipitation pulse, and “after” values represent the average carbon fluxes for 3 to 5**
1044 **days after the precipitation pulse; the error bars represent standard errors (**, $p < 0.01$;**
1045 ***, $p < 0.05$); The horizontal dashed lines in (B) and (C) indicate 5 mm of precipitation**
1046 **in spring and autumn, and 5 mm and 20 mm in summer.**

1047 **Fig. 3.** Seasonal and inter-annual variation in the daily average net ecosystem CO₂
1048 exchange (NEE), gross primary productivity (GPP), and ecosystem respiration (R_{ec})
1049 from (a-e) 2014 to 2018, by day of year (DOY). (f) Annual cumulative NEE, GPP, and
1050 R_{ec} from 2014 to 2018. Positive NEE values indicate net CO₂ release, whereas negative
1051 values indicate net CO₂ uptake by the ecosystem. Note that the initial measurements
1052 were from 15 September to 23 December 2014, so no data are available for the first
1053 part of 2014.

1054 **Fig. 4.** Seasonal mean net ecosystem CO₂ exchange (NEE), gross primary productivity
1055 (GPP), and ecosystem respiration (R_{ec}) **and the total seasonal precipitation** from 2014
1056 to 2018: (a) spring (March, April, and May), (b) summer (June, July, and August), (c)
1057 autumn (September, October, and November), and (d) winter (December, January, and

1058 February). Note that the y-axis scales differ greatly between the graphs, and that the
1059 initial measurements were from 15 September to 23 December 2014, so no data are
1060 available for the first part of 2014. The final measurements were obtained on 31
1061 December 2018, so the winter period from 2017 to 2018 was only about one-third of
1062 the usual length (i.e., it did not include data from January and February 2019). **The error**
1063 **bars for the mean carbon fluxes represent standard errors.**

1064 **Fig. 5.** Diurnal changes in mean net ecosystem CO₂ exchange (NEE), gross primary
1065 productivity (GPP), and ecosystem respiration (R_{ec}) from 2014 to 2018: (a) spring
1066 (March, April, and May), (b) summer (June, July, and August), (c) autumn (September,
1067 October, and November), and (d) winter (December, January, and February). Note that
1068 the y-axis scales differ greatly between the graphs, and that the initial measurements
1069 were from 15 September to 23 December 2014, so the spring and summer data in this
1070 year do not include the period before 15 September. The final measurements were
1071 obtained on 31 December 2018, so the winter period from 2017 to 2018 was only about
1072 one-third of the usual length (i.e., it did not include data from January and February
1073 2019). **The error bars for the mean carbon fluxes represent standard errors.**

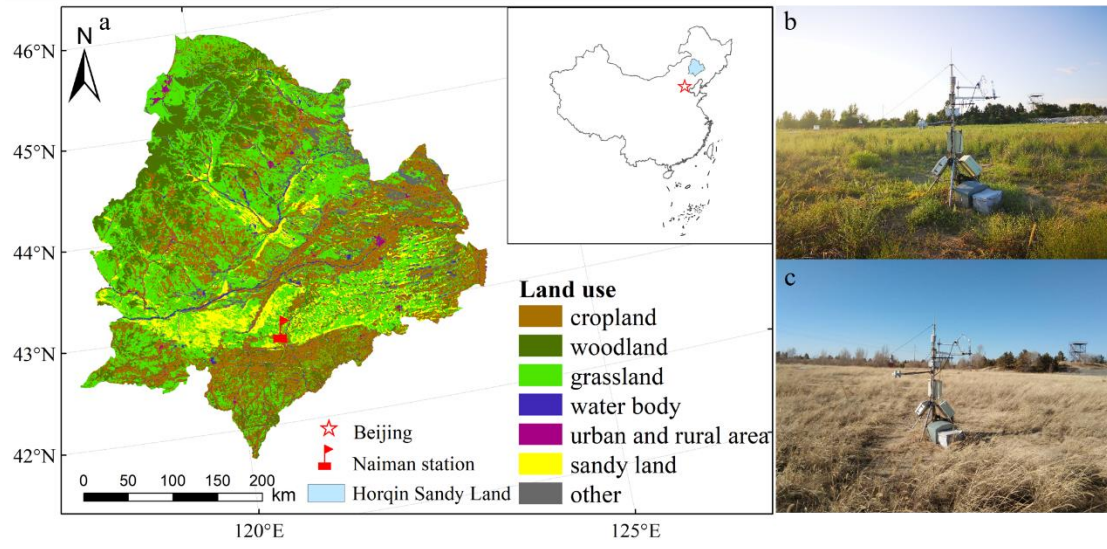

1074 **Fig. 6.** Relationship between total **monthly** precipitation (PPT) and **monthly** net
1075 ecosystem carbon exchange (NEE), gross primary productivity (GPP), and ecosystem
1076 respiration (R_{ec}) for the years with a complete dataset (2015, 2016, and 2018).

1077 **Fig. 7.** Relationship between monthly net ecosystem carbon exchange (NEE), gross
1078 primary productivity (GPP), and ecosystem respiration (R_{ec}) and the corresponding
1079 monthly precipitation in the spring (March, April, and May), summer (June, July, and
1080 August), and autumn (September, October, and November).

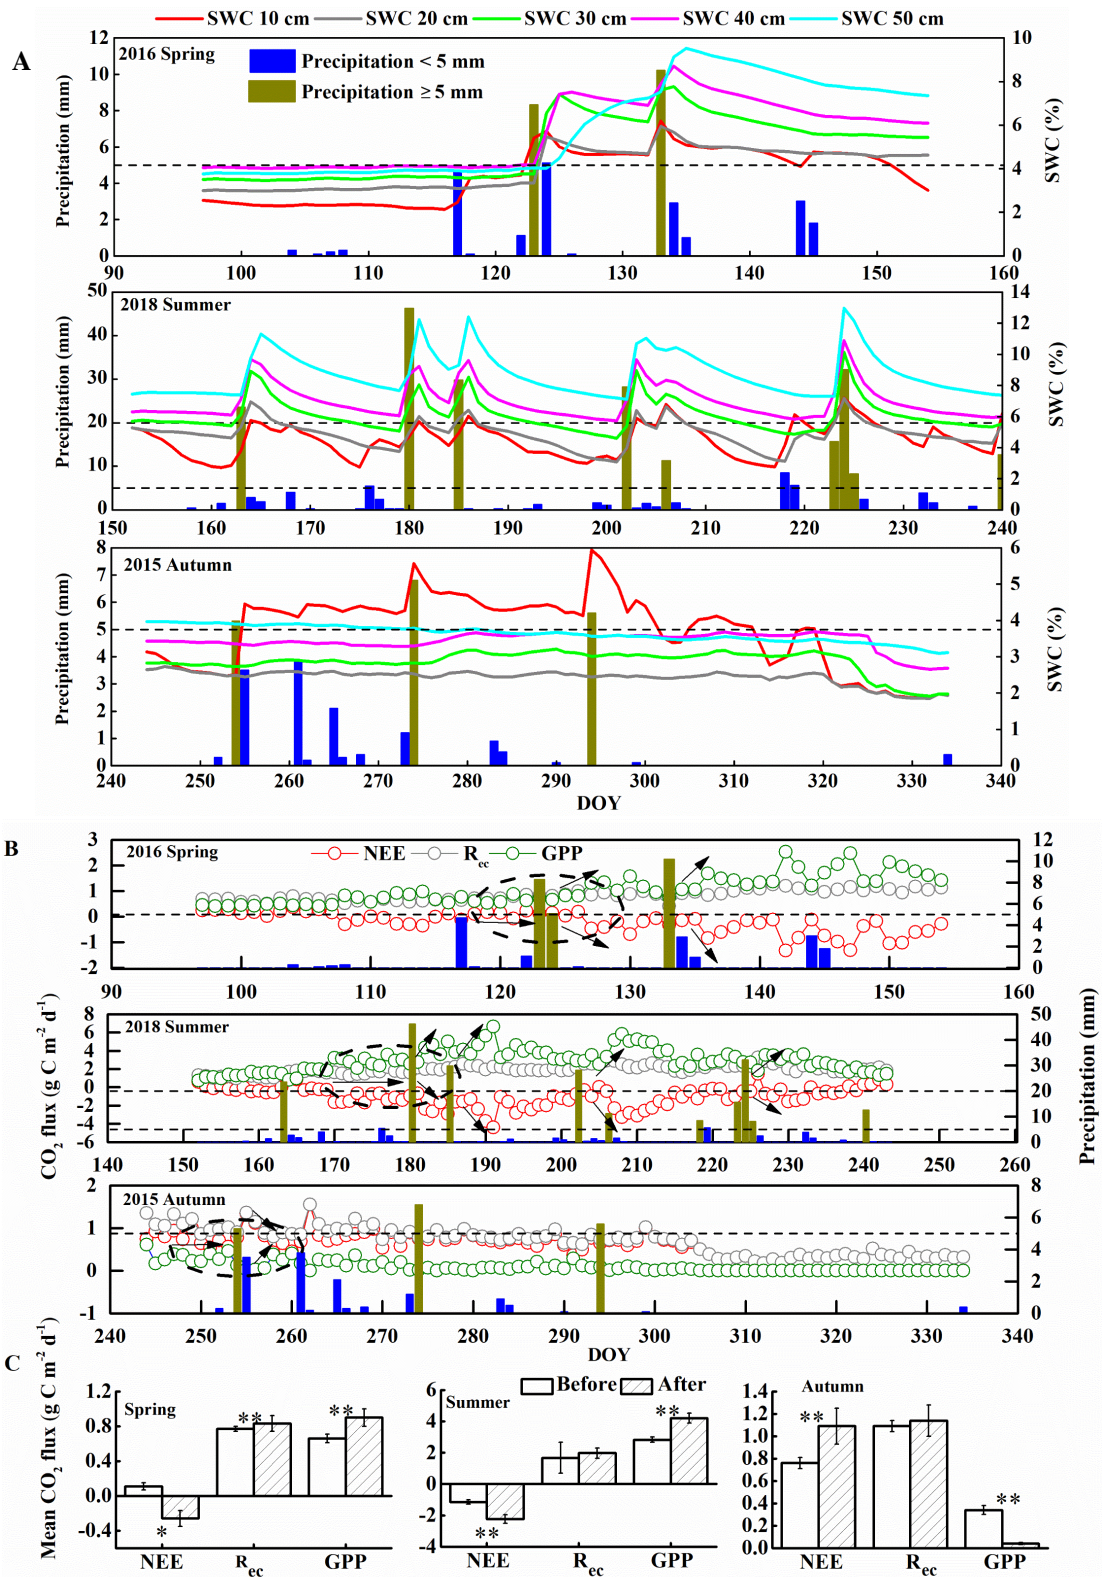

1081 **Fig. 8.** Relationships between daily net ecosystem carbon exchange (NEE), gross
1082 primary productivity (GPP), and ecosystem respiration (R_{ec}) and the average soil
1083 temperature to a depth of 50 cm (T_{soil}) and soil water content (SWC). Before the
1084 regression analysis, SWC was divided into two depth ranges: the near-surface soil (0 to
1085 10 cm) and deeper soil (10 to 50 cm). However, NEE was only correlated with SWC at
1086 depths of 40 and 50 cm in the summer and 20 and 30 cm in the autumn based on the

1087 results of a collinearity test for the three seasons. T_{soil} was divided into a single range
1088 (0 to 50 cm) based on the results of a collinearity test for the three seasons: Spring
1089 (March, April, and May), summer (June, July, and August), autumn (September,
1090 October, and November).
