Abstract

The analysis of charcoal fragments in peat and lake sediments is the most widely used approach to reconstruct past biomass burning. With a few exceptions, this method typically relies on the quantification of the total charcoal content of the sediment. To enhance charcoal analyses for the reconstruction of past fire regimes, and to make the method more relevant to studies of both plant evolution and fire management, more information must be extracted from charcoal particles. Here, I burned in the laboratory seven fuel types comprising 17 species from boreal Siberia, and build on published schemes to develop morphometric and finer diagnostic classifications of the experimentally charred particles. As most of the species used in this study are common to Northern Hemisphere forests and peatlands, these results can be directly applicable over a broad geographical scale. Results show that the effect of temperature on charcoal production is fuel dependent. Graminoids and *Sphagnum*, and wood (trunk) lose the most mass at low burn temperatures, whereas heathland shrub leaves, brown moss, and ferns retain the most mass at high burn temperatures. In contrast to the wood of trunk, the wood of twigs retained their mass at intermediate temperature. This suggests that species with low mass retention at hotter burning temperatures might be underrepresented in the fossil charcoal record. Charred particle aspect ratio (L/W) appeared to be the strongest indicator of the fuel type burnt. Graminoid charcoals are more elongate than those of all other fuel types, leaf charcoals are the shortest and bulkiest, and twig and wood charcoals are intermediate. Finer diagnostic features were the most useful in distinguishing between wood, graminoid, and leaf particles, but further distinctions within these fuel types are difficult. High-aspect-ratio particles dominated by graminoid and *Sphagnum* morphologies are robust indicators of cooler surface fires. Contrastingly, abundant wood and leaf morphologies and low-aspect-ratio particles likely indicate higher-temperature fires. However, the overlapping morphologies of leaves and wood from trees and shrubs make it hard to distinguish between high-intensity surface fires combusting living shrubs and dead wood and leaves or high-intensity crown fires combusting living trees. Despite these limitations, the combined use of charred-particle aspect ratios and fuel morphotypes can aid in more robustly interpreting changes in fuel source and fire type, thereby substantially refining histories of past wildfires. Further fields of investigation to improve the interpretation of the fossil charcoal records will require: i) More in-depth knowledge of plant anatomy for a better determination of fuel sources; ii) Relate the proportion of particular charcoal morphotypes to the quantity of biomass; iii) Link the chemical composition of fuels, combustion temperature, and charcoal production. The advanced use of image-recognition software to collect data on other charcoal features could also aid in extracting fire temperatures as well as a change in particles morphology and morphometry during particles transportation.

35 1 Introduction

Boreal forests are among the ecosystems most significantly impacted by wildfires as a consequence of climate change (Jones et al., 2020). Although most of the global boreal forest area is in Siberia (Furayev, 1996), its vast extent and restricted access have limited datasets recording changes in wildfire activity, especially from a longer-term perspective (Marlon et al., 2016). Such long-term records of wildfire activity are vital to understanding how fire regimes vary with changes in climate and human-vegetation interaction, as well as the impacts of fires on boreal forests.

Charcoal is an inorganic carbon compound resulting from the incomplete combustion of plant tissues, which typically occurs at temperatures of 280–500 °C (Rein, 2014). Charcoal particles vary in size and form, but can preserve characteristics such as edge aspects, surface features, cleavage, lustre, or anatomical details (tracheids with border pits, leaf veins, cuticles, etc.) that can be used to determine the origin of the fuel (Ward and Hardy, 1991; MacDonald et al., 1991; Scott 2010; Enache and Cumming, 2006; Jensen et al., 2007; Courtney-Mustaphi and Pisaric, 2014). Although macroscopic charcoal analysis, typically counting charcoal pieces or charcoal area per unit sediment volume, is widely applied, the full potential of this method has not been explored. This analytical limitation restricts the reconstruction of fuel sources, a crucial factor in determining fire type, i.e., the burning of surface fuels in cool or hot fires, or distinguishing between surface and crown fires, which requires greater distinction of fuel types (Courtney-Mustaphi and Pisaric, 2014; Feurdean et al., 2017; Hawthorne et al., 2018). Furthermore, the determination of fire type is not only critical to palaeofire reconstructions, but it is an accessible tool for ecosystem managers and modellers, and for assessing and mitigating the risks of fires that might impact settlements and infrastructures (Moritz et al., 2014).

Ongoing efforts have advanced the utility of charcoal analyses for fuel type identification and fire regime reconstruction. Umbanhowar and McGrath (1998) and Pereboom et al. (2020) conducted morphometric measurements of the length, aspect ratio (length/width), and surface area of charcoal particles by burning in the laboratory known plant materials originating from American prairie and arctic environments, and concluded that longer (higher aspect ratio) fragments correspond to graminoids, whereas shorter fragments originate from wood, shrubs, and leaves. Other studies have focused on the effects of burning conditions, i.e., open-flame ignition, muffle furnace experiments, and combustion calorimetry on charcoal production (Umbanhowar and McGrath, 1998; Orvis et al., 2005; Hudspith et al., 2018). Jensen et al. (2005) and Courtney-Mustaphi and Pisaric (2014) investigated subtler diagnostic features (morphology, surface features, lustre) of laboratory-produced charcoal morphotypes of a small number of North American grasses and leaves of coniferous and deciduous trees. Furthermore, Enache and Cumming (2006, 2007) and Mustaphi and Pisaric (2014) classified charcoal morphologies in Canadian lake sediments based on particle shape (morphology), aspect ratio, and surface features, and linked them to fuel types. Based on published morphotype categorisations, more recent studies have attributed fossil charred particles to certain fuel and fire types (Walsh et al., 2010, Daniau et al., 2013; Aleman et al., 2013; Courtney-Mustaphi and Pisaric, 2014; Feurdean et al., 2017, 2019a, 2019b, 2020; Unkelbach et al., 2018).

This paper presents the first results of laboratory-produced charcoal morphologies spanning a range of fuel types originating from 17 boreal Siberian species. It aims to facilitate more robust interpretations of fuel sources and fire types, which will substantially refine wildfire histories in boreal forests. Specifically, it tested (i) whether morphological distinctions exist
70 between species and fuel types, and (ii) the effect of burning temperature on the mass, morphometrics, and finer anatomical features of charred plant material. The papers also discuss the advantages and limitations of laboratory-based burning studies for palaeofire reconstruction. Because this combination of factors has never been tested to such an extent in the laboratory, this study has the potential to significantly advance our understanding of the link between sedimentary charcoal morphologies and fire types. As most of the species used in this study are common to Northern Hemisphere forests and peatlands, these
75 results are directly applicable over a broad geographical scale.

2 Material and Methods

2.1 Laboratory analysis

Plant materials were identified in the field, stored in plastic bags for transportation, and air-dried to complete dryness. Selected
80 materials include a range of fuel types (graminoid, trunk wood, twigs of tree and shrub, and the leaves of coniferous and deciduous trees, shrubs, forbs, and ferns, moss, and fern stems with leaves) from the most common tree, shrub, herb, fern, and moss species around a forested bog near Teguldet village, Tomsk district, Russia. This light boreal taiga forest is primarily composed of *Pinus* and *Betula*. Additionally, needles and twigs of *Picea abies* were collected from Taunus, near Frankfurt am Main, Germany (see Table 1 for a full list of species and fuel types).

85 This paper builds on previous morphological classifications of charcoal particles and tested the effects of increasing burning temperatures on the mass, morphometrics, and finer diagnostic features of residual charred remains of various fuel types as follows. Dried remains of individual plant species were placed in ceramic crucibles, weighed, covered with a lid to limit oxygen availability, and heated for 2 h in a muffle oven (preheated for 1 h) at 250, 300, 350, 400, or 450 °C. No burning experiments were conducted at higher temperatures because all plant material turned to ash at 450 °C under these conditions. The
90 experimental temperatures were chosen based on the range of temperatures reported in the literature (250–500 °C; Umbanhower and McGrath, 1998; Orvis et al., 2005; Jensen et al., 2007; Peereboom et al., 2020). It also tested the effect of mixing plant material in known ratios on charred mass and morphometrics at 300 °C, an intermediate temperature. For this, the plant material was combined in the following volume: 25% graminoid and moss, 75% shrub; 50% graminoid, shrub, and moss, 50% wood and leaf; 50% graminoid and moss, 50% shrub; 75% graminoid, shrub, and moss, 25% wood and leaf; 75%
95 graminoid and moss, 25% shrub; and 50% graminoid, 50% moss and fern. These samples represent the predominant fuel mixtures of cold surface fires (graminoid and moss), intermediate- to high-intensity surface fires (shrub), and high-intensity crown fires (wood and tree leaf).

The influence of increasing burn temperature on the mass of residual charred plant material was determined to establish whether different fuel types produced different amounts of charcoal. After cooling each sample, the remaining charred mass
100 was weighed and calculated the ratio of charred to pre-combustion mass.

Charred samples were then split into two subsets. The first was left intact and stored as reference material. The second was gently disaggregated with a mortar and pestle to mimic the natural breakage that charcoal particles would incur overtime in sediment (Crawford and Belcher, 2014; Umbanhowar and McGrath, 1998), then washed through a 125- μm sieve to remove smaller fragments. This second sample split was subjected to both morphometric measurements and characterization of finer diagnostic features. Morphometric measurements of individual charred particles were obtained from photographs taken at 4 \times magnification with a digital camera (Kern DXM 1200F). Between 100 and 300 charcoal particles larger than 150 μm were automatically detected in most samples and the measurement of the major (L) and minor (W) axes, and surface area (A) of each particle following the algorithm presented in Appendix A1, the calculated aspect ratio as L/W . These measurements were performed for all experiments producing residual charred material (i.e., below 450 °C). Finer diagnostic features such as shape, surface features (reticulates, tracheids with border pits, leaf veins, the arrangement of epidermal cells, cuticles with stomata, etc), and cleavage were characterized at 4 \times by inspection of microphotographs or the charred particles themselves under a microscope or stereomicroscope.

2.2 Numerical analysis

The medians and standard deviations of charcoal morphometrics (L , L/W , A) were aggregated for each species, fuel type, and burn temperature, and are displayed as box plots. The two-tailed Mann-Whitney test was used to test whether the medians of the charcoal morphometrics of various fuel types were equal. This test does not assume a normal distribution, only equally-shaped distributions in both groups.

3. Results

3.1 The influence of temperature on charred mass production

Only a few fuel types (needles, shrub leaves) were partly charred after burning at 250 °C and were greenish or brownish in colour. Plant materials of all species were black with a typical charcoal appearance after burning at 300 and 350 °C. A few fuel types (graminoid, *Sphagnum*, and some twigs) became fully carbonised (ash) at 400 °C, and all others were only partly carbonised. All plant tissue was reduced to ash at 450 °C (Fig. S1). The majority of the charred materials remained intact and retained all their morphological characteristics. However, those burnt at higher temperatures tended to easily break during sample manipulation.

The percentage of charred mass retained at 300 °C (an intermediate temperature) was as follows, in decreasing order: brown moss and fern > twig (shrub) > leaf (shrub) > leaf (forb) > leaf (coniferous tree) > twig (tree) > needles > graminoid > *Sphagnum* > wood (trunk) (Fig. 1). This mass-loss trend was largely the same at all temperatures. Trunk wood, graminoids, and *Sphagnum* lost most of their mass at lower temperatures (up to 350 °C), whereas leaves of shrub, forbs, and ferns retained the most charred mass at 400 °C. The charred mass of mixed-fuel samples at 300 °C reflected the dominant fuel type; it was lowest for samples with high contents of graminoid and *Sphagnum* and highest for samples with greater proportions of the shrub.

3.2 Fuel-dependent variations in length, aspect ratio, and surface area

135 Graminoid charcoals burnt at 300 °C ($L/W = 9.1$, Fig. 2b, f) were consistently more elongate than those of twigs (shrub, 4.6;
tree, 3.1), moss and fern stems (3.7), and leaves (2.1). Among leaves, charred needles were more elongate (2.7) than those of
140 forb (2), heathland shrub (1.94), and broadleaf tree leaves (1.84). The Mann-Whitney test confirmed that (i) the median aspect
ratio of graminoids was significantly different from those of all other fuel types ($p < 0.001$), (ii) those of woods (all types)
were different from those of leaves ($p < 0.001$) and moss (except at 350 °C) and (iii) those of leaves were different from those
of moss ($p < 0.001$; Table 2). The size distribution of charred particles indicates that the smaller fractions tend to be rounder
(lower aspect ratio) than the larger fractions (not shown). In contrast to the median aspect ratio, the lengths (major axis, L) of
charred particles from different fuel types were less clearly differentiated (Figs. 3a, c, S2; Table 2). The surface area (A) varied
greatly between individual taxa and fuel types, however, fragments of shrub leaves tended to be larger than all other fuel types
(Figs. 3b, d, S3; Table 2).

145 The aspect ratios and lengths of individual taxa and fuel types changed slightly with temperature, but the general trends were
similar across all temperatures (Figs. 2, 3a, c, S2). In contrast, relative surface areas varied more with temperature changes
(Figs. 3b, d, S3).

The morphometrics of mixed-fuel samples reflected those of the dominant fuel types: charcoals of samples with abundant
graminoids and moss were more elongate (higher L/W) than those with higher proportions of shrubs, wood, and/or leaves (Fig.
150 2h). Similarly, the longest charcoal particles (higher L) were from samples with greater proportions of graminoids and moss
(Fig. 3e), whereas the charcoals with the largest surface areas were from samples with more abundant shrubs and leaves (Fig.
3f).

3.3 Finer diagnostic features of the charcoal morphologies of various fuel types

155 3.3.1 Graminoid charcoal

Graminoid (*Carex*, *Calamagrostis*, *E. vaginatum*) charred particles were consistently flat, rectangular, and elongated (Figs. 4a,
A2a). They mostly broke parallel to the long axis when pressured, resulting in highly elongated pieces with straight margins.
They can also appear as featureless long, thin filaments. Charcoals produced at higher temperatures (350 °C) often had more
irregular, zig-zag, or denticulate margins. Their surface features more commonly preserved rectangular epidermal cells or
160 contained oval voids, reticulated or mesh patterns, and/or isolated veins.

3.3.2 Wood charcoal (trunk, tree and shrub twigs)

Wood charcoal pieces from trunk (*P. sylvestris*) were blocky and quadrilateral with corner angles of 90° (Figs. 4b, A2b). Wood
charcoal from tree (*P. sylvestris*, *P. sibirica*, *Picea abies*, *B. pendula*) and shrub (Ericaceae) twigs showed both quadrilateral
165 and polygonal shapes. For both trunks and twigs, edges were smooth, serrated, or denticulate, and surface textures were
smooth, foliated, or striated (Fig. 4b). Trunk charcoals of *P. sylvestris* showed rows of brown, open pits in the tracheid walls.

Under the microscope, trunk charcoal fragments were shinier and darker than twig charcoals. Large charcoal pieces often broke parallel to the long axis, producing many tiny, elongated pieces (trunks) or pieces of various forms (twigs).

170 3.3.3 Leaf charcoal (needles, deciduous tree and shrub, forb, and fern)

Charred needle fragments were elongated and rectangular (corner angles of 90°; Figs. 4c, A2a). Their edges were smooth, but became serrated and denticulate when broken. Surface features included visible venation and ridges. Charcoals from the leaves of deciduous trees (*Betula*), heathland shrubs (*Oxycoccus*, *Ledum*, *Camadaphne*, *Vaccinium*), herbaceous plants (*Rubus*), and ferns (Polypodiaceae) were polygonal. Only those of *Cnidium* leaves were elongated, reflecting their needle shape. Edges were
175 mostly undulate, but sometimes smooth or denticulate. Surface textures were generally smooth (featureless), but sometimes included visible venation and ridges. When broken, they showed voids, reticulated mesh patterns, and curly fibres. Birch leaves produced visible charred veins with three branches diverging from a node. When pressured and broken, small leaf pieces had fracture lines radiating out at a variety of angles.

180 3.3.4 Moss and fern stems

Sphagnum produced two types of charcoal morphologies. One type originates from stems were elongate with ramifications (scars) where leaves branched from the stem, and the other originates from leaves preserved the anatomical features of the unburned leaves, i.e., a mesh-like appearance (Figs. 4a, A2a). *Politrichum* produced several charcoal morphologies (quadrilateral, polygonal, or curved with angular edges) with generally featureless surfaces, although some showed mesh
185 patterns. This charcoal type often splits along the main axis. *Equisetum* stems were generally quadrilateral with straight, undulate, or denticulate margins, and oval voids and reticulated mesh patterns on their surfaces.

4 Discussion

Results from laboratory-produced charred morphologies evaluate the morphometrical aspects, fine diagnostic features, and
190 charcoal production for 17 plant species and seven fuel types from boreal Siberia. This dataset substantially broadens the geographical cover of fuel types researched and improves the interpretation of fire types based on charcoal morphologies.

4.1 The influence of combustion temperature on charred mass production: implications for charcoal-based fire reconstructions

195 Knowledge of the charred mass is critical for determining biases in charcoal production to biomass quantity and fire temperature (Walsh and Li, 1964). Results from this study clearly show that the effect of temperature on charcoal production is fuel dependent. When averaged across all temperatures, graminoid, *Sphagnum*, and trunk wood produce the lowest amounts of charcoal per unit biomass, whereas leaves of shrubs (Ericaceae), forbs, and ferns (Polypodiaceae), as well as fern stems (*Equisetum*), produced the highest (Fig. 1). The charred mass of mixed-fuel samples also changed according to the dominant
200 fuel type (at 300 °C). Peerboom et al. (2020) burned plant tissue from the Alaskan tundra at 500 °C, and similarly found that

graminoids have lower charred-mass retention than shrubs. However, they neither tested leaves and wood of shrubs separately, nor the effect of various temperatures on charred mass. In my experiments, the charred mass of graminoid and *Sphagnum* declined quickly with increasing burn temperature, whereas the leaves of shrubs and forbs and the stems of ferns and brown moss retained the most charred mass at higher temperatures; twigs were intermediate (Fig. 1). Note, however, that the trunk wood used in the current experiments was collected from a dead trunk, and may have burned faster than wood from living trees. In partial agreement with findings from this study, burning experiments of American forest steppe plants showed that the mass retention of grass and deciduous leaf charcoal decrease more rapidly with temperature compared to wood charcoal (Umbanhowar and McGrath, 1998). More recent calorimetric combustion of various fuel types found the charr mass of wood, needles and *Equisetum* to be higher than other leaf types, mostly originating from tropical species (Hudspith et al., 2017).

The burn conditions in the experiments (oxygen level, temperature, fuel moisture and arrangement, etc.) do not fully replicate those of natural wildfires. Nonetheless, these findings present some practical implications for charcoal-based fire reconstructions. First, fuel types with low charred-mass retention at hotter burn temperatures might be underrepresented in the sedimentary charcoal record. Specifically, Cyperaceae (sedges) are the most common graminoids in fens and meso- and eutrophic bogs, and *Eriophorum* (sedge) and *Sphagnum* (moss) are common in oligotrophic bogs. These fuel types are likely to be the first to turn to ash, even in relatively cool fires, and thus may leave little or no trace of charcoal in sediments. Second, Ericaceae (heathland shrubs), typical of oligotrophic bogs, and *Polytrichum commune* (brown moss) common to all habitat types, have a high charred-mass retention until 300 °C (woody biomass). However, their masses decline strongly at higher temperatures (350–400 °C), indicating that they are likely to be preserved as charcoal only in low- to intermediate-intensity fires. Third, leaves of shrub, forb, and fern, and stems with leaves of *Equisetum* are more likely to persist as charcoal after high-temperature fires, and thus may contribute excessively to sedimentary charcoal. Mineral constituents can slow the pyrolysis, and this is probably why *Equisetum* steams with high silica content, preserve more charcoal. Fuel with higher lignin content (wood) should also produce more charcoal than fuels higher in cellulose and hemicellulose i.e., leaves (Yang et al., 2007). Contrasted to this expectation, leaves in the present laboratory experiments, retained a higher charred mass than the wood with increasing burn temperature, which calls into extending such research to fuels with various chemical proprieties.

225

4.2 Fuel-dependent variability in morphometrics: implications for fuel-type reconstructions

Some of the charred fragments produced herein show consistent morphometrics among species within the same genus and family, suggesting their utility for fuel-type identification. Graminoid charcoal particles are at least two times more elongated than all other charcoal types and differ the most from leaf charcoals (Fig. 2). Highly elongate and narrow graminoid charcoals are posited to result from the occurrence of conspicuous veins parallel to the long axis (Umbanhowar and McGrath, 1998). Charred fragments of forb and shrub leaves are also markedly rounder than those of other fuel types, but there is some degree of overlap between the aspect ratios of the remaining fuel types. In practice, this translates to a high degree of confidence in using aspect ratio in identifying sedimentary charcoals of graminoids, including those typical of wetlands, and most leaf types (Fig. 2). Charcoal fragments from mixed-fuel samples also preserve the aspect ratio of the dominant fuel type; the longest

230

235 particles were found in samples with higher proportions of graminoids. Because smaller charred fractions tend to be rounder
(lower aspect ratio) than larger fractions, it suggests that larger charcoal fragments can be more confidently used to
morphometrically categorise fuel types. Results also show that changes in the length of fuel types are largely similar to changes
in aspect ratio. However, length alone provides a less clear distinction between fuel types (Figs. 3, S2). In contrast, there is
little confidence in using the mean surface area to distinguish between fuel types, except for the slightly tendency that charred
240 shrub leaf particles are larger than those of all other fuel types (Figs. 3, S3). The larger shrub leaf fragments may be explained
by the arrangement of leaf venation, with fragments breaking along the three branching veins that diverge from nodes
(Umbanhowar and McGrath, 1998; Jenssen et al., 2007). The shape of charcoal particles also affects their transport, with
elongate particles transported over shorter distances than round ones (Clark and Hussey, 1996; Higuera et al., 2014). This
implies that graminoid, moss, and fern charcoals may be deposited closer to the origin of fire than the rounder, polygonal leaf
245 particles.

The morphometrics of graminoids and forb and shrub leaves observed herein are most similar to those from the Alaskan arctic
(Pereboom et al., 2020), but significantly more elongate (9.1) than those from American steppe forests (3.62; Umbanhowar
and McGrath, 1998) and tropical African forests and grasslands (>2.0; Aleman et al., 2013). Mustaphy and Pisaric (2014) also
observed that burning monocotyledons from boreal Canada in the laboratory generally produced more elongated charcoal
250 morphologies than other fuels (deciduous leaves, needles, wood, rootlets).

Results from measurements of the effect of temperature on charred-particle morphometrics show that the aspect ratio is
generally preserved for all fuel types over the temperatures explored. However, the length and surface area of fuel types
changed less consistently with increasing temperature. Umbanhowar and McGrath, (1998) found that burn temperature did not
significantly change the aspect ratios of graminoid and leaf charcoals, but that it marginally reduced those of wood.
255 Nevertheless, the aspect ratios for many fuel types overlap, which requires the use of fine anatomical features to improve the
utility of the charcoal morphologies in fuel type identification (see section 4.3)

4.3 Finer diagnostic features of the charcoal morphologies for fuel type identification

Results from fine diagnostic features on charcoal particles show that these can be more confidently used to attribute charcoal
260 particles to certain fuel types. Apart from the extremely elongated shape that differentiates graminoid charred particles from
all other fuel types, graminoids are further distinguished under both microscope and stereomicroscope by their flat appearance
and breakage into thin filaments (Figs. 4a, A2a). Rectangular epidermal cells, reticulate meshes, oval voids of former epidermal
stomata are also good diagnostic features of graminoids. The graminoid charcoals produced in this study are most similar to
types C4, C6, D1, D2, and D3 described by Mustaphy and Pisaric (2014) and Enache et al. (2006).

265 A distinct feature of woody charcoal is that they are layered with foliated or striated textures and break into many tiny particles
when pressured (Figs. 4b, A2b). This is due to the abundance of fibres and xylem, which leads to charcoals splitting at various
angles (Vaughan and Nichols, 1995). Additionally, conifer wood charcoal presents distinct rows of open pits in the tracheid
walls. Attempts to distinguish between charred trunk and twig particles were less successful, although charred trunk particles

are blockier. Foliated charred wood fragments also share appearance with moss and fern stems. These woody charcoals are most similar to types A1, B1, B2, and B3 (Mustaphi and Pisaric, 2014; Enache et al., 2006).

Typical features of charred deciduous leaves are their polygonal shapes with surfaces characterised by void spaces or undulated surfaces (Figs. 4c, A2a). Netted venation is also sometimes visible, mostly with three branches diverging from a node. In contrast, conifer needles are elongated, often show ramification, and can have a wood-like appearance. The deciduous leaf charcoals found here are most similar to morphologies A2, A3, A4, A5, and A46, and conifer needle charcoals to C1, C2, and C3 (Mustaphi and Pisaric, 2014; Enache et al., 2006).

Charred *Sphagnum* leaves preserve the meshed pattern of fresh plant material. Often, stems contain ramification, likely scars of former leaves (Figs. 4a, A2a). Both *Sphagnum* and *Politrichum* charcoals present curvy fragments not seen in other fuel types. However, stems of *Sphagnum* and *Polytrichum* can be easily be mistaken for shrub twigs. Burnt *Equisetum* can resemble graminoid charcoal. Charred moss is similar to morphologies C4 and C7 (Mustaphi and Pisaric, 2014; Enache et al., 2006).

280

4.4 Charcoal morphometrics and morphologies as indicators of fire type: applications and recommendations

The physical and chemical characteristics of fuel are key factors influencing ignition and fire propagation. Major chemical components of fuels are cellulose, hemicellulose, and lignin, and minor ones include terpenes, resins, and minerals (Plana and Pastor, 2014). Fuels rich in cellulose and hemicellulose (i.e., leaves) pyrolyse at a lower and narrow temperature range (200 and 400 °C), whereas those rich in lignin (i.e., wood) pyrolyse at a higher and over a wider range of temperatures (160-900°C; Yang et al., 2007). Fuel types rich in terpene and resins (conifer wood, needles, Ericaceae) burn faster and hotter, whereas those rich in mineral components (graminoids) burn cooler (200 °C) and less efficiently (Plana and Pastor, 2014). Fuel arrangements also strongly influences fire propagation: living grasses, shrubs, and trees are arranged vertically, whereas dead woody fuels and litter are mostly oriented horizontally. Continuous horizontal fuel layers favour fire propagation, whereas vertical arrangements allow fires to pass from the understory to the canopy, thus affecting fire severity (Cruz and Alexander, 2010).

Siberian forests burn alternatively as cool surface fuelled by graminoids, forbs, ferns, mosses or as hot, high-intensity surface (burning shrubs) and crown fires (Andreson, 1982). Results from this study suggests that the combined use of morphometric and morphological features and charred mass can help distinguish the predominant fuel source. Knowledge of the fuel source may in turn provide clues on fire type, i.e., the combination of fire intensity (temperature) and severity (effect on vegetation). This has a practical importance for determining the ranges of fire severity and frequency that Siberian boreal tree taxa have tolerated in the past, and helps to evaluate their potential to adapt to new fire regimes in the future. For example, charcoal particles with a higher aspect ratio, typical for graminoids, and dominantly graminoid morphologies that tend to preserve only at a lower temperature, likely indicate a graminoid fuel source, and therefore a cooler, lower-intensity fire (Fig. 5). Charred moss, especially *Sphagnum*, is only preserved at low temperatures and has intermediate aspect ratios; thus, its identification as a fuel source would also point to a cool surface fire. Shorter, bulkier particles likely indicate the increased incidence of leaves (low aspect ratio) or wood (intermediate aspect ratio) as a fuel source, and thus the occurrence of a hotter

300

305 fire (Figs. 2, 5). Besides, charred wood and leaves are easily distinguished based on their morphological features. However, the morphologies and aspect ratios of leaves of deciduous trees overlap with leaves of shrubs, and those of wood of tree overlap wood of shrub. This makes it hard to disentangle whether such charred particles originated from high-intensity surface fires fuelled by living shrubs and dead wood and leaves, or from high-intensity crown fires that combusted living trees. In such cases, charred mass can offer further information on fire temperature. In the case of hot fires (surface and crown), the present experiments show that shrub leaves are more likely to persist after high-temperature fires than woody biomass. Leaves from shrubs, forbs, and ferns and stems of fern and brown moss are more likely to remain as charred particles after high-temperature 310 fires than graminoids and *Sphagnum*. The burning experiments also reveal that charred particles identified as forbs originate from several fuel types including ferns and brown moss, which tend to have similar morphologies (see section 4.3).

The aspect ratio, dominant morphotypes, and amount of charcoal particles can also help to distinguish the severity of peat burning, i.e., between cold peat fire, combusting graminoids, and moss, and hot fires additionally combusting shrubs. Correct identification of the type of peat burning is a key to evaluate the consequences of burning intensity on peat plant 315 composition and carbon (C) stock. High fire intensity leads to deeper peat burns, which may trigger shifts in plant composition, and results in augmented C loss. As most of the species used in this study are common to Northern Hemisphere forests and peatlands, results can be directly applicable over a broad geographical scale.

The consistency of results from this study with some of those found in the literature on other vegetation types (boreal forest, temperate and tropical woodlands, and grasslands, see 4.1 and 4.2) suggests the applicability of charcoal aspect ratio and morphologies to a wider variety of vegetation types. For example, the expansion of open habitats (opening up of the 320 forests, expansion of forest steppe and grasslands and latitudinal treeline, or depression of elevational treeline) and increased availability of herbaceous biomass and fuel burnt may be reflected in an increase in aspect ratio and graminoid morphologies. Conversely, the closing up of the forests or tundra shrub encroachment may show itself in a decreased aspect ratio of particles and increased bulky morphologies derived from leaves and wood. The insights gained by these experiments can be used to determine the role of palaeofires in the ecological and evolutionary processes. Further investigations are, however, necessary 325 to relate the proportion of particular charcoal morphotypes or groups of morphotypes (woody vs. graminoid) to the quantity of biomass. These experiments should also clarify the link between chemical composition of fuels, combustions temperature and charcoal production. In all instances, additional information on ecosystem composition and structure derived from pollen and plant macrofossils can greatly complement and exchange the usefulness of charcoal morphologies for the 330 interpretation of palaeofires.

5. Conclusions

This study presents the first results of the morphometric aspects and finer diagnostic features of charred particles produced in the laboratory from seven fuel types comprising 17 plant species from boreal Siberia. The use of a higher number of fuel types 335 from species with broad geographical coverage combined with an exploration of various combustion temperatures improves the link between charcoal morphologies, fuel types, and fire characteristics.

340 In terms of charred mass production, results from this study show that graminoid, *Sphagnum*, and trunk wood lose their charred mass at lower temperatures than leaves of heathland shrub, brown moss, and fern. The distinct effect of temperature on fuel types suggests that species with low mass retention during hotter fires are likely to be underrepresented in the fossil charcoal record.

345 Among the three charcoal morphometrics measured (length, aspect ratio, and surface area), the aspect ratio appeared to be the strongest indicator of fuel type. Graminoid charred particles are more elongate than all other fuel types, leaves are the shortest and bulkiest, and twigs and wood are intermediate. The use of fine diagnostic features was more successful in separating wood, graminoids, and leaves. However, it is hard to make further distinctions within these fuel types, especially between tree and shrub wood and between deciduous trees, shrubs, and fern leaves.

350 The charcoal morphologies and metrics can be used to infer changes in fire temperature (intensity) and impact on vegetation (severity). High-aspect-ratio particles, typical of graminoids, and the dominance of morphotypes derived from surface fuels (graminoids, *Sphagnum*) could indicate cool, surface fires, whereas lower-aspect-ratio particles and the increased abundance of wood and leaf morphologies may indicate hotter fires. However, the morphologies and aspect ratios of leaves of deciduous trees overlap with leaves of shrubs, and those of wood of tree overlap wood of shrub. This makes it hard to disentangle whether such charred particles originated from high-intensity surface fires fuelled by living shrubs and dead wood and leaves, or from high-intensity crown fires that combusted living trees.

355 Despite these limitations, the combined use of particle aspect ratio and charred morphotypes allows more robust interpretations of changes in fuel source and fire type based on charcoal records. This can substantially refine histories of past wildfires. Future efforts to determine fuel sources based on analyses of small charcoal fragments will require a more detailed examination of plant anatomy. The use of image-recognition software to collect data on other features may improve estimations of fire temperature.

Data sets: A limited amount of burnt plant material can be made available upon request.

360 **Author contribution:** AF designed the burning experiments and carried them out. AF performed the morphometrical and morphological analyses; AF performed numerical analysis and data presentation; AF wrote the manuscript; AF acquired the financial support for the project leading to this publication.

Competing interests: The author declare that they have no conflict of interest.

365 **Special issue statement:** The role of fire in the Earth system: understanding interactions with the land, atmosphere, and society (ESD/ACP/BG/GMD/NHESS inter-journal SI)

Acknowledgements I would like to thank Markus Rosenstihl for the help to develop the code for automatic detection of charred particles and drawing the pictograms in Fig 5; Dagmar Fritzsich for initial brainstorming on the burning experiments;

Doris Schneider for help with burning plant material in muffle oven; and Sergey Kirpotin for help with identification of plant species in field.

370

Financial support: This work was supported from the Deutsche Forschungsgemeinschaft grant number FE_1096/6.

Tables

530 **Table 1.** List of plant materials burned. All plants are from Siberia, Russia, except *Picea abies*, originating from Taunus, Germany.

Plant type	Scientific name	Family	Common name	Plant burned
Trees				
535 Conifer tree	<i>Pinus sylvestris</i>	Pinaceae	Scots pine	Needles
Conifer tree	<i>Pinus sylvestris</i>	Pinaceae	Scots pine	Twigs
Conifer tree	<i>Pinus sylvestris</i>	Pinaceae	Scots pine	Dead wood
Conifer tree	<i>Pinus sibirica</i>	Pinaceae	Siberian pine	Needles
Conifer tree	<i>Pinus sibirica</i>	Pinaceae	Siberian pine	Twigs
540 Conifer tree	<i>Picea abies</i>	Pinaceae	Norway spruce	Needles
Conifer tree	<i>Picea abies</i>	Pinaceae	Norway spruce	Twigs
Deciduous tree	<i>Betula pendula</i>	Betulaceae	Silver birch	Leaves
Deciduous tree	<i>Betula pendula</i>	Betulaceae	Silver birch	Twigs
Shrubs				
545 Shrub	<i>Vaccinium myrtillus</i>	Ericaceae	Bilberry	Leaves
Shrub	<i>Vaccinium myrtillus</i>	Ericaceae	Bilberry	Twigs
Shrub	<i>Oxycoccus palustre</i>	Ericaceae	Bilberry	Leaves
Shrub	<i>Oxycoccus palustre</i>	Ericaceae	Bilberry	Twigs
550 Shrub	<i>Empetrum nigrum</i>	Ericaceae	Bilberry	Leaves
Shrub	<i>Empetrum nigrum</i>	Ericaceae	Bilberry	Twigs
Shrub	<i>Ledum palustre</i>	Ericaceae	Bilberry	Leaves
Shrub	<i>Ledum palustre</i>	Ericaceae	Bilberry	Twigs
Shrub	<i>Chamaedaphne calyculata</i>	Ericaceae	Bilberry	Leaves
555 Shrub	<i>Chamaedaphne calyculata</i>	Ericaceae	Bilberry	Twigs
Herbaceous				
Graminoid	<i>Eriophorum vaginatum</i>	Cyperaceae	Cotton grass	Leaves
Graminoid	<i>Calmagrosti.</i>	Poaceae	Reed grass	Leaves
560 Graminoid	<i>Carex spp.</i>	Cyperaceae	Sedge	Leaves
Forb	<i>Cnidium dubium</i>	Apiaceae		Leaves
Forb	<i>Rubus spp.</i>	Rosaceae	Raspberry	Leaves
Fern	<i>Polypodium</i>	Polypodiaceae	Fern	Leaves
Fern	<i>Equisetum palustre</i>	Equisetaceae	Horsetail	Stem
565 Moss	<i>Sphagnum</i>	Sphagnaceae	Peat moss	Stem +leaves
Moss	<i>Polytrichum commune</i>	Polytrichiaceae	Hair moss	Stem +leaves

Appendix

Appendix A. The watershed algorithm used to calculate morphometrics of charred particles.

625 The algorithm for automatic detection of morphometrics is based on functions from the Python module skimage (watershed
 algorithm). First, the picture is converted to a grey scale. A Sobel gradient of the picture is then calculated, which results in an
 elevation map. In order to use the watershed algorithm to detect the charcoal particles, a map of markers in the grey picture
 with grey values higher than 140 was then create. These are the starting points of the watershed region fill algorithm. Finally,
 any holes in the watershed regions were filled with the help of a binary fill method (Soille and Vincent, 1990). The detected
 630 particles were subject to the calculation of morphometrics such as surface area and lengths along the major and minor axis via

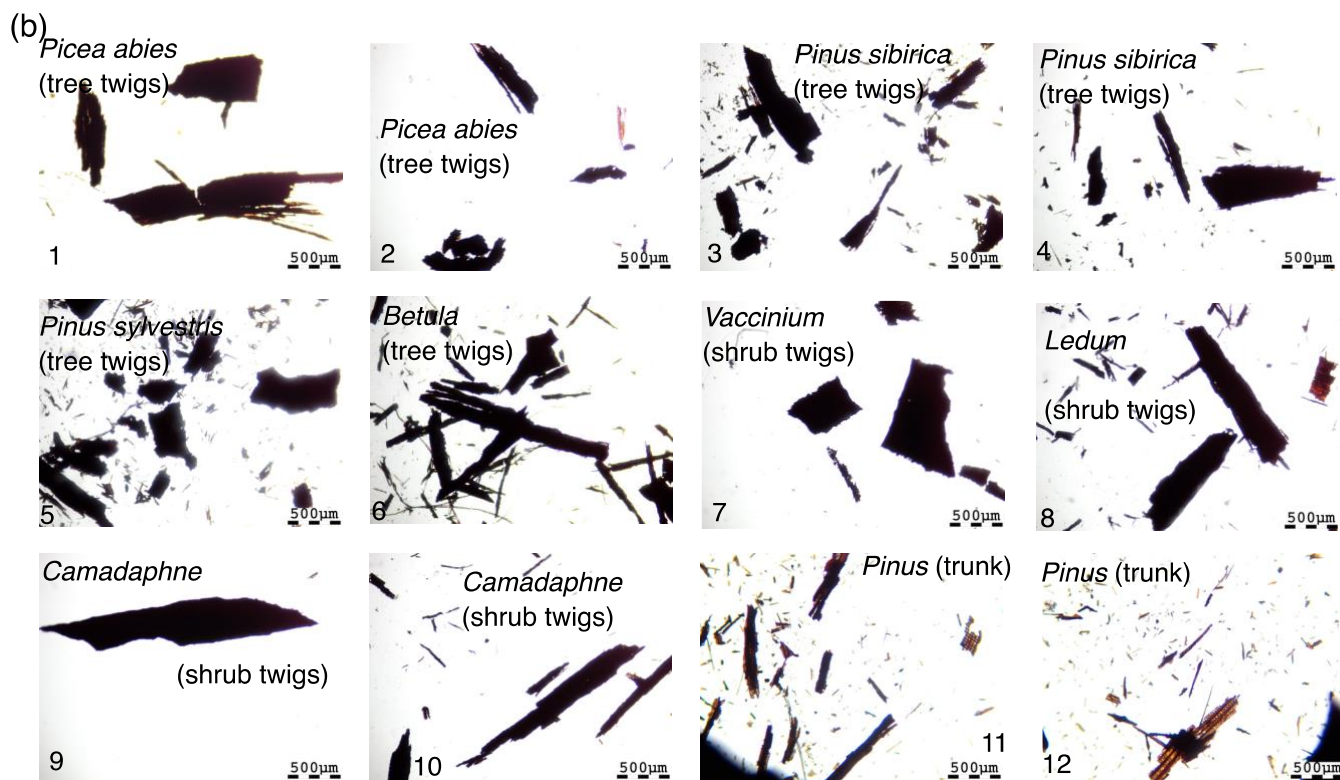

supported functions. Particles with the length of major axis smaller than 150 μm were excluded from these calculations. The pixel area has been calibrated with a micrometre scale and the results scaled accordingly.
