15 **Abstract.** We evaluate a range of blue intensity (BI) tree-ring parameters in eight conifer species (12 sites) from Tasmania and New Zealand for their dendroclimatic potential, and as surrogate wood anatomical proxies. Using a dataset of ca. 10-15 trees per site, we measured earlywood maximum blue reflectance intensity (EWB), latewood minimum blue reflectance intensity (LWB) and the associated delta blue intensity (DB) parameter for dendrochronological analysis. No resin extraction was performed, impacting low frequency trends. Therefore, we focused only on the high frequency signal by detrending all  
20 tree-ring and climate data using a 20-year cubic smoothing spline. All BI parameters express low relative variance and weak signal strength compared to ring-width. Correlation analysis and principal component regression experiments identified a weak and variable climate response for most ring-width chronologies. However, for most sites, the EWB data, despite weak signal strength, expressed strong calibrations with summer temperatures. Significant correlations for LWB were also noted, but the sign of the relationship for most species is opposite to that reported for all conifer species in the Northern  
25 Hemisphere. DB performed well for the Tasmanian sites but explained minimal temperature variance in New Zealand. Using the full multi-species/parameter network, excellent summer temperature calibration was identified for both Tasmania and New Zealand ranging from 52% to 78% explained variance, with equally robust independent validation (Coefficient of Efficiency = 0.41 to 0.77). Comparison of the Tasmanian BI reconstruction with a wood anatomical reconstruction shows that these parameters record essentially the same strong high frequency summer temperature signal. Despite these excellent  
30 results, a substantial challenge exists with the capture of potential secular scale climate trends. Although DB, band-pass and other signal processing methods may help with this issue, substantially more experimentation is needed in conjunction with comparative analysis with ring density and quantitative WA measurements.

## 1 Introduction

The range of variables that are now routinely measured from the rings of trees, including width, stable isotopes, multiple wood anatomical features and density, has increased substantially in recent years (McCarroll et al. 2002; McCarroll and Loader, 2004; Drew et al. 2013; von Arx et al. 2016; Björklund et al., 2020). However, our knowledge of the climatic, environmental, and physiological processes that modulate the year-to-year variability of these different tree-ring parameters is still far from comprehensive. Since the early seminal work of Fritts et al. (1965), a well-known rule of thumb for ring-width (RW) based dendroclimatology is that trees sampled near their high elevation or latitude treelines will be predominantly temperature limited, while at lower elevations or latitudes, moisture limitation becomes the primary driver of growth (Fritts 1976; Kienast et al. 1987; Buckley et al. 1997; Wilson and Hopfmüller 2001; Briffa et al., 2002; Babst et al. 2013; St. George 2014). Such targeted sampling is strategically vital in “traditional” dendroclimatology and robust reconstructions can be derived so long as tree-line sites are sampled where a single dominant climate parameter controls growth (Bradley 1999). However, the climatic influence on RW can be complex and there are many published studies where the relationship between RW and climate is shown to be temporally unstable and/or non-linear (Wilmking et al. 2020) or is unexpected but consistent between many sites (Cook and Pederson 2011).

Ring density parameters, especially maximum latewood density (MXD), have been shown to provide substantially more robust estimates of past summer temperature compared to RW (Briffa et al., 2002; Wilson and Luckman, 2003; Esper et al., 2012; Büntgen et al., 2017; Ljungqvist et al., 2020). Density data may also retain a strong temperature signal at elevations below the upper treeline, minimising the non-linear influence of a changing tree-line elevation through time (Kienast et al. 1987). The use of ring-density variables from lower elevation or latitude sites to reconstruct past hydroclimate is rare (Camarero et al. 2014, 2017; Cleaveland 1986; Seftigen et al. 2020) and is clearly an area demanding further attention.

The reconstructive value of tree ring stable isotopes (carbon and oxygen) appears to be less constrained to climate limited locations and substantial potential exists from mid-latitude regions where traditional dendroclimatological approaches are less reliable (McCarroll and Loader, 2004; Loader et al. 2008; Young et al. 2015; Loader et al. 2020; Büntgen et al. 2021). However, within the mechanistic framework of stable isotopes, there is still much to explore regarding the complex associations between fractionation and climate for different species and across different ecotones.

60

The use of wood anatomical parameters for dendroclimatology has gained traction in recent years due to improvements in measurement methodologies allowing for the development of well replicated chronologies (Drew et al. 2013; von Arx et al. 2016; Prendin et al., 2017; Björklund et al. 2020). The strength of relationships between climate parameters and wood anatomical properties such as latewood cell wall thickness, tracheid radial diameter and microfibril angle is comparable to

65 maximum latewood density (Yasue et al., 2000; Wang et al., 2002; Panyushkina et al., 2003; Fonti et al., 2013; Allen et al.  
2018).

Despite the strong climate signal often noted in such non-RW tree-ring parameters, their procurement is expensive, often  
requires specialised equipment, and is time consuming. Consequently, there are substantially less published data available  
70 for inspection. In recent years, blue intensity (BI) has been championed by many groups as a cheaper surrogate for maximum  
latewood density (Björklund et al., 2014, 2015; Rydval et al., 2014; Wilson et al., 2014). In its common usage, BI measures  
the intensity of the reflectance of blue light from the latewood of scanned conifer samples so that a dense (dark) latewood  
would result in low reflectance values. MXD and BI essentially measure similar wood properties. Most studies that have  
directly compared MXD and latewood BI show no significant difference in the climate response of the two parameters  
75 (Wilson et al., 2014; Björklund et al. 2019; Ljungqvist et al., 2020; Reid and Wilson 2020). Though the acceptance of BI in  
dendrochronology was initially slow after publication of the original concept paper (McCarroll et al. 2002), over the past  
decade many BI-based studies have been published. These studies have examined the use of BI as an ecological and  
climatological indicator in a variety of conifer species from several locations around the Northern Hemisphere (Campbell et  
al., 2007, 2011; Helama et al., 2013; Rydval et al., 2014, 2017, 2018; Björklund et al., 2014, 2015; Wilson et al., 2014,  
80 2017a, 2017b, 2019; Babst et al., 2016; Dolgova, 2016; Arbella et al., 2018; Buras et al., 2018; Fuentes et al., 2018; Kaczka  
et al., 2018; Wiles et al., 2019; Harley et al. 2020; Heeter et al. 2020; Reid and Wilson 2020).

Only three studies that utilise BI data south of 30°N have been published. Buckley et al. (2018) explored the potential of  
reflectance parameters from the tropical conifer Fujian cypress (*Fokienia hodginsii*) from central Vietnam and found a  
85 significant positive relationship between earlywood maximum BI and December–April maximum temperature. Although a  
spring/early summer temperature signal is extant in Northern Hemisphere conifer minimum density data (Björklund et al.  
2017), correlations are generally not as strong as the earlywood results detailed by Buckley et al. (2018). In the Southern  
Hemisphere, Brookhouse and Graham (2016) measured latewood BI from *Errinundra plum-pine* (*Podocarpus lawrencei*)  
samples taken from the Australian Alps and identified a strong inverse ( $r = -0.79$ ) relationship with August–April maximum  
90 temperatures, suggesting substantial potential for this species if long-lived specimens could be found. Finally, Blake et al.  
(2020) recently explored the climate signal in BI parameters measured from Silver pine (*Manoao colensoi*) samples growing  
on the New Zealand's South Island and found strong significant relationships between both earlywood and latewood BI  
parameters and summer temperatures. Although the sign (positive) of the earlywood BI relationship with temperature agreed  
with results detailed in other studies (Björklund et al. 2017; Buckley et al. 2018), the latewood relationship was inverse to  
95 that detailed for Northern Hemisphere conifers (Briffa et al. 2002) and observed by Brookhouse and Graham (2016). This  
difference in latewood response begs the intriguing question as to whether some Southern Hemisphere conifers may have  
evolved differently to their Northern Hemisphere counterparts, resulting in a different anatomical and physiological response  
to climate.

Here we expand upon the pilot studies of Brookhouse and Graham (2016) and Blake et al. (2020) and explore the climate  
 100 signal of earlywood and latewood BI from several key conifer species from Tasmania and New Zealand. To minimise  
 nomenclature confusion, we refer to the reflectance parameters as earlywood blue intensity (EWB) and latewood blue  
 intensity (LWB). Based on ecophysiological theory (Buckley et al. 2018) we posit that EWB, derived from maximum  
 intensity values of the whole-ring reflectance spectrum, essentially provides a surrogate for mean lumen size of the  
 earlywood cells, while LWB, derived from minimum reflectance values, reflects the relative density of the darker latewood  
 105 cell walls. We further suggest these reflectance measures are useful surrogate measures of mean tracheid diameter and cell  
 wall thickness, which are proven to be excellent proxies of past climate (Allen et al. 2018; Björklund et al. 2019) but are  
 laborious and expensive to measure directly. As well as undertaking a dendroclimatic assessment of multiple BI parameters  
 in different Australasian, temperature sensitive confers, we also assess the potential for furthering the analysis of wood  
 anatomical parameters in Australasian dendroclimatology. Improving terrestrial based estimates of past temperature in the  
 110 land-limited Southern Hemisphere (Neukom et al. 2014) will only be achieved by enhancing the strength of the calibrated  
 signal that until recently has been characterized solely by low performing ring-width data.

115 **Table 1: Chronology information for the seven Tasmanian and 5 New Zealand sites used in the study (see Figure 1).**

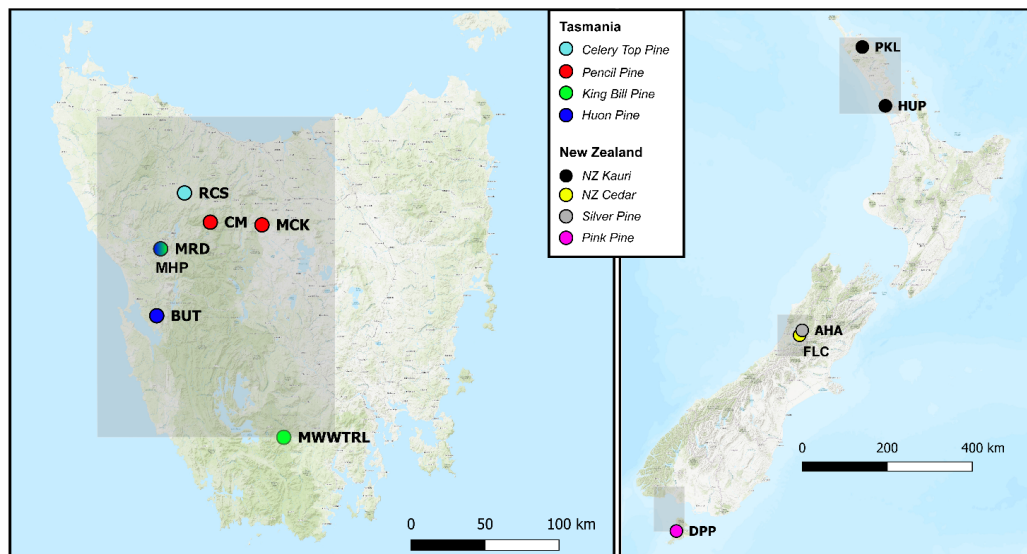

## 2 Data and Methods

Four tree species from Tasmania and New Zealand were targeted for analysis (Figure 1, Table 1) representing species that  
 have not only been used in previous dendrochronological studies, but each has the potential to produce climate proxy records  
 120 more than 1000 years in length. Until recently, RW data were used for most Australasian dendroclimatological studies but  
 calibration results never exceeded 40-45% explained variance (Allen et al. 2018). In Tasmania, the strongest calibration  
 results for summer temperatures had been obtained using high elevation Huon pine (*Lagarostrobos franklinii* - Buckley et al.  
 1997; Cook et al. 2006) although some coherence was also found for Pencil pine (*Athrotaxis cupressoides*) and King Billy

125 pine (*Athrotaxis selaginoides* - Allen et al. 2011; Allen et al. 2017). Celery Top (*Phyllocladus aspleniifolius*) RW data,  
however, express a complex non-linear relationship with climate and has not been used for dendroclimatic reconstruction  
(Allen et al. 2001). By contrast summer temperature calibration experiments performed on measurement series of several  
wood anatomical properties from these same species have shown substantial improvements over RW (Allen et al. 2018), as  
well as the development of hydroclimate reconstructions (Allen et al. 2015a/b). In New Zealand, RW based summer  
temperature reconstructions have been developed from NZ Cedar (*Libocedrus bidwillii* - Palmer and Xiong 2004), Silver  
130 pine (*Manoao colensoi* - Cook et al. 2002, 2006) and Pink pine (*Halocarpus biformis* - D'Arrigo et al. 1996, Duncan et al.  
2010) although ring density (Xiong et al. 1998 – Pink pine) and BI (Blake et al 2020 – Silver pine) measured from  
earlywood cells have produced stronger results. Kauri (*Agathis australis*) is the longest-lived tree species in Australasia  
(Boswijk et al. 2014) and is notable in that it expresses a strong stable relationship with indices of the El Nino Southern  
Oscillation (Cook et al. 2006; Fowler et al. 2012).

135

140 **Figure 1:** Location map (basemap ESRI 2021) of the tree-ring sites used in this study (see Table 1). Also indicated (grey boxes) are  
the regional domains of the gridded CRU TS 4.03 temperature and precipitation data (Harris et al., 2014) used for analyses.  
Tasmania: 145-147°E / 41-43°S; New Zealand: North: 173-175°E / 35-37°S; Central: 167-168°E / 46-47°S; South: 171-172°E / 42-  
43°S.

In this study, we utilised tree cores sampled over the past three decades and prepared for RW measurement. Considering the  
145 focus of this study is to assess the potential of BI parameters for enhancing dendroclimatic reconstruction, and the fact that  
the samples were already mounted, no resin extraction was performed except for the Silver pine AHA site (see Blake et al.  
2020 for details). As many of the species are resinous by nature, this immediately imposes a potential problem for measuring  
reflectance data, because any inhomogeneous resin-related discolouration will impact intensity values (Rydval et al., 2014;  
Björklund et al., 2014, 2015; Wilson et al. 2017b; Reid and Wilson 2020). Consequently, as the high frequency signal will  
150 only be minimally affected by discolouration (Wilson et al. 2017a), all analyses for this proof-of-concept study will utilise  
only the high pass fraction of the chronologies.

The mounted samples were re-sanded using fine grade (> 600 grit) sandpaper to remove decadal markings. Samples were  
scanned at multiple institutions using different scanners and a range of resolutions from 1200 to 3200 DPI. RW and BI data  
155 were generated using Coorecorder (Cybis 2016, <http://www.cybis.se/forfun/dendro/index.htm>) except for AHA  
(WinDendro – see Blake et al. 2020). Despite many of the samples being substantially older, most samples were measured  
only back into the 17<sup>th</sup> or 18<sup>th</sup> centuries (with site MHP (Table 1) being an exception), providing enough data to ensure  
robust calibration and validation over the instrumental period and to allow comparison with a temperature reconstruction  
from Tasmania based on wood anatomy (Allen et al. 2018). Parameters generated for analysis were RW, EWB and LWB.  
160 The LWB data were not inverted as is the norm in Northern Hemisphere studies using data generated in Coorecorder  
(Rydval et al. 2014).

Perhaps the greatest limitation for light reflectance-based data is that any colour changes that do not represent year-to-year  
changes in wood anatomical features such as lumen size and cell wall thickness will impose a colour-related bias in the  
165 intensity measurements. Examples of non-anatomically related colour changes are those associated with the  
heartwood/sapwood transition, sections of highly resinous wood, or fungal staining. Björklund et al. (2014) proposed a  
potential procedure that could correct for such colour changes. This procedure subtracts the LWB reflectance value from the  
EWB data producing a delta parameter (hereafter referred to as Delta BI - DB). Theoretically, DB should correct for  
common colour change biases between heartwood and sapwood and even resinous zones within the wood. To date, DB has  
170 been utilised successfully in only a few studies (Björklund et al., 2014, 2015; Wilson et al., 2017b; Fuentes et al. 2018; Blake  
et al. 2020; Reid and Wilson 2020). As no resin extraction was performed (except site AHA, Table 1) and all the species  
used for this study express a colour change from heartwood to sapwood, DB data will also be examined to explore its  
dendroclimatic potential.

175 For some species, the heartwood/sapwood transition colour change is very sharp and pronounced in reflectance values  
(Figure A1), and inflexible detrending options could impose a systematic bias in the resultant detrended indices. As an  
extreme example, the heartwood/sapwood transition of the EWB raw mean non-detrended chronology for the CM Pencil

180 pine site (Figure A2) cannot be tracked well with cubic smoothing splines (Cook and Peters 1981) of 200, 100 or even 50  
years respectively. This is not surprising given that the smoothing spline, operating as a symmetric digital filter, is not well  
suited for dealing with abrupt changes in time series such as that observed in the CMewb chronology. In fact, the bias of low  
(pre-transition) and high (post-transition) index values are only minimised when a flexible 20-year spline is used because it  
better adapts to the observed discontinuity. However, this adaptability comes at the cost of losing potentially valuable >20-  
year variability in the time series. This is clearly undesirable and better ways of modelling and removing such discontinuities  
without the unwanted loss of lower-frequency variability are needed. Although less flexible splines could be used for other  
185 species with a slower or minimal colour change from heartwood to sapwood (Figure A1), a consistent approach to  
detrending was deemed prudent and therefore a 20-year spline was used for all datasets.

The mean interseries correlation statistic (R<sub>BAR</sub>) is utilised to assess how many series are needed to attain an Expressed  
Population Signal value of 0.85 (Wigley et al. 1984; Wilson and Elling 2004). Previous research has shown that the common  
190 signal expressed by BI data can be rather weak (Wilson et al. 2014, 2017a/b, 2019; Kaczka et al. 2018; Wiles et al. 2019).  
We explore this phenomenon further with this multi-parameter/species network by using the coefficient of variation to help  
understand relative internal variance and co-variance of the parameter chronologies.

The climate signal expressed in the individual chronologies was initially explored using simple correlation analysis against  
195 monthly gridded (see Figure 1 for locations) CRUTS 4.03 temperature and precipitation data (Harris et al. 2014) for the  
periods 1902-1995, 1902-1950 and 1951-1995. 1902 was the initial start year as correlations were performed over 20 months  
including the previous growing season while 1995 reflects the final common year for all tree-ring datasets (Table 1).  
Correlations with monthly precipitation were weak, variable and temporally unstable for all species/parameter chronologies  
and the results are presented in the Appendix but not discussed further (see Figure A4a-d).

200 Principal component analysis (PCA) was used on varying subsets of chronologies for each region (i.e. all chronologies of the  
same parameter, or all parameters from a single species) to reduce the data to a few modes of common variance. Principal  
components that had both an eigenvalue > 1.0 and correlated significantly (95% C.L.) with the target instrumental data were  
entered into a stepwise multiple regression and calibrated against a range of seasonal temperatures. For New Zealand, the  
205 three CRU TS 4.03 grid boxes (Figure 1) were averaged to create a country wide mean series. This was justified as the three  
inter-grid box mean correlation values between all tested seasons was 0.93 (STDEV = 0.01) suggesting there is a strong  
common signal between North Island and southern South Island. PCA was also utilised to ascertain the optimal season for  
dendroclimatic calibration using the full chronology network for each country as well as exploring seasonal differences  
between parameters and species. Analyses were performed over the common period of all tree-ring and climate data (1901-  
210 1995) as well as early (1901-1950) and late (1951-1995) period calibration and verification. The Coefficient of Efficiency  
(CE - Cook et al., 1994) was used to validate the regression-based climate estimates.

### 3 Results and Discussion

#### 3.1 Chronology variability and signal strength

Wilson et al. (2014), using temperature sensitive spruce samples from British Columbia, noted lower mean coefficient of variation (CV) values for LWB (0.05) compared to RW (0.28) and MXD (0.19). Common signal strength was strongest for the MXD data (RBAR = 0.42) while RW and LWB were similar (0.30). For the Australasian detrended data, overall, RW data express higher relative variance (mean CV = 0.13) followed by DB (0.07), LWB (0.03) and EWB (0.02 – Figure 2a). The range in values for RW (0.09 – 0.17) and DB (0.04 – 0.13) are greater than LWB (0.02 – 0.06) although there is overlap in the range of DB and LWB. The EWB data express a significantly narrower range (0.01 – 0.02). RBAR values for the four different parameter groups generally return a stronger common signal for RW (mean = 0.33) compared with EWB (0.14), LWB (0.16), and DB (0.15 – Figure 2b). Therefore, following traditional methodologies to assess signal strength, more BI series are needed than RW to attain a robust chronology. On average, to attain an EPS value of at least 0.85 (Wigley et al. 1984), 14 series would be needed for RW, while 44, 47 and 58 series would be needed for EWB, LWB and DB respectively. This weaker common signal of the BI parameters has been noted before (Wilson et al. 2014, 2017a/b, 2019; Kaczka et al. 2018; Wiles et al. 2019; Blake et al. 2020) and is also noted in wood anatomical data from Tasmania (Allen et al. *in prep*). The common signal is particularly weak for Celery Top and Kauri (EWB) and Pink pine and Kauri (LWB and DB – see Table A1 for detailed values).

230

Figure 2: A: Coefficient of variation (CV) of the 20-year spline detrended chronologies; B: mean inter-series correlation (RBAR) of the 20-year spline detrended series. Horizontal dashed lines denote the number of series needed for that particular RBAR value to attain an EPS of 0.85; C: Scatter plot of CV versus RBAR with linear regression.

235

A scatter plot of the CV and RBAR data (Figure 2c) suggests that the common signal expressed by these chronologies is partly a function of the relative variance of the time-series ( $r = 0.72$ ,  $p < 0.001$ ). Although the range in RBAR values for the EWB and LWB data suggests some uncertainty in this observation (see also Table A1), the implication of these results is that the relatively low variation of values around the mean for the BI parameters suggests that any anomalous colour staining on the wood that does not reflect the true wood properties being measured could have a large impact on the chronology common signal. However, it should be emphasised that a weak common signal and low EPS value does not necessarily result in a weak climate signal (Buras 2017).

### 3.2 Climate response

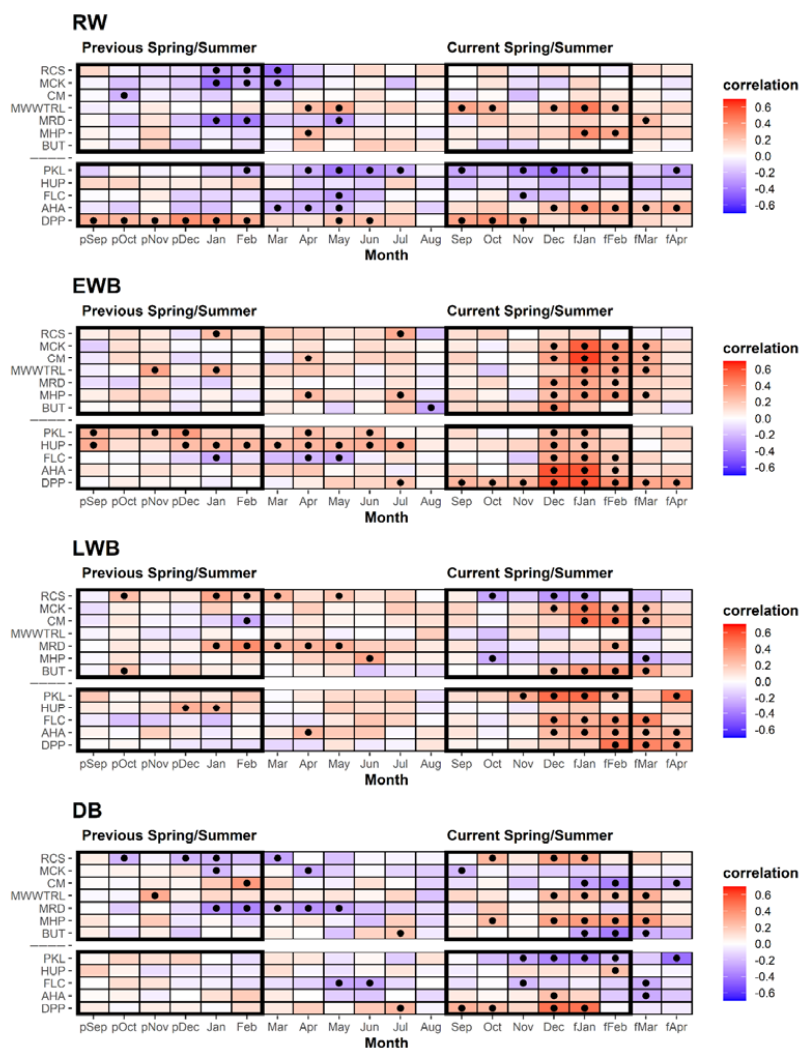

The strength of correlations between the RW chronologies and mean monthly temperatures varies across species. Over the full period (Figure 3), the Tasmanian MWWTRL and MHP sites express significant positive correlations with September-February and January-February respectively, which are broadly time stable (Figure A3a). RCS, MCK and MRD show inverse correlations with late summer temperatures of the previous year. Of the New Zealand sites, PKL (Kauri) has negative correlations for many months from winter through to the summer, while AHA and DPP correlate positively with December-April and September- November.

Correlations between the EWB chronologies and mean temperatures are surprisingly consistent for most sites although correlations for RCS and BUT are weak. Almost all site chronologies correlate positively with the summer months for the current season – December through to March (Tasmania) and December-February (New Zealand). Some sites express narrower (MMWTRL, MRD, PKL, and HUP) or wider response windows (DPP - Figure 3). Although these relationships appear generally time stable, the Tasmanian sites correlate more strongly with the narrower January-February season for 1902-1950 compared to the later post 1951 period (Figure A3b). Significant correlations with winter and prior year temperatures are weaker and less consistent than for current spring/summer. Overall, the EWB results are extremely encouraging.

Significant relationships between LWB and summer and early Autumn temperatures are generally noted, although the results are less consistent than those for EWB. Both RCS (Celery Top) and high elevation Huon pine (MHP) express negative correlations that are in line with MXD/temperature relationships noted in the Northern Hemisphere. Excluding MMWTRL and HUP, that do not have any significant correlations with temperature in the growing season, all the other species express positive correlations with summer and early autumn temperatures. This antithetic behaviour is not a new observation and has been noted by Drew et al. (2013), O'Donnell et al. (2016), Blake et al. (2020) for latewood wood anatomical parameters and LWB data, but these new results suggest that this physiological phenomenon is not based on a chance occurrence of a single species and is consistent between a number of Australasian conifer tree species (Pencil pine, Huon pine (low elevation), Kauri, NZ Cedar, Silver pine and Pink pine). Blake et al. (2020) explained the inverse LWB relationship as a reduction in the

duration of secondary cell wall thickening in warmer years. Such “emergent” surprising results (Cook and Pederson 2011)  
 270 clearly need further research and testing.

275 **Figure 3: Correlation response function analysis results for the different TR parameter chronologies with CRU TS temperatures. Analysis undertaken over the 1902-1995 period (see supplementary figure S3 for correlations for split periods 1902-1950, 1951-1995). Black dots denoted correlations significant at the 95% C.L.**

The DB chronologies express a range of responses to temperature that are all generally weaker than for EWB and LWB (Figure 3). Significant positive correlations with summer temperatures are found for RCS, MMWTRL, MHP, and DPP. HUP and AHA also express some weak positive summer temperature coherence. Negative correlations are noted for CM, BUT, PKL and FLC. However, many of these correlations are not temporally stable when compared over the 1902-1950 and 1951-1995 periods (Figure A3d). Current theory suggests that DB should perform well when EWB and LWB parameters are weakly correlated and express different earlier and later seasonal climate response (Björklund et al., 2014). However, the results herein indicate that this simple hypothesis does not consistently apply in this multi-species study. For example, the EWB and LWB data for the Pink pine DPP site express different early and late seasonal responses with temperatures (Figure 3), but still show a reasonably high inter-parameter correlation (0.60, Table A2). However, the DB data still expresses a significant and strong response with summer temperatures, although marginally weaker than the EWB response. On the other hand, DB for the Pencil pine sites (MCK and CM) behaves more like conifers in the Northern Hemisphere (Björklund et al., 2014; Wilson et al. 2017b), with significant correlations noted for both EWB and LWB with summer temperatures, but, likely due to the high inter-parameter correlation (0.57 and 0.68), the DB data express weak, or even inverse correlations with summer temperatures. Overall, the DB results are mixed and disappointing. This parameter theoretically could minimise the colour bias of the darker to lighter colour heartwood/sapwood transition (Figure A1) but, for the data used herein, this appears not to be the case. These results suggest that alternative approaches to using DB may need to be explored to minimise the impact of the heartwood/sapwood change noted in most of the species used in this study.

### 3.3 Parameter and species-specific principal component calibration tests

The previous section detailed that temperature is the predominant climate signal expressed across species and parameters in these chronologies from Tasmania and New Zealand (Figures 3, A3a-d). Only weak coherence with precipitation was found (Figure A4a-d). To further explore the climate response, principal component regression calibration (1901-1995) experiments with seasonal temperature were performed to ascertain which combination of BI parameters and species express the strongest climate signal and therefore should be the focus for future research – including refined BI measurement and/or wood anatomical measurement.

For Tasmania, the PCA identifies 3, 2, 2 and 2 significant principal components for RW, EWB, LWB and DB respectively. Each BI parameter PC regression explains > 40% of the temperature variance while RW is substantially poorer at 21% (Figure 4a). Both EWB and LWB explain 43% of the December-February and January-March variance respectively - these seasons being biologically logical with respect to the earlier seasonal start for EWB and later end for LWB. Despite the site-specific DB data correlating with temperature more weakly than EWB and LWB (Figure 3), their multivariate combination calibrates better (48%) with January-March temperatures. Although this is an encouraging result as DB may theoretically

correct for colour related biases, the mix of positive and negative zero order correlations with temperature (Figure 3) suggest  
 310 that some caution will be needed if such data are used to capture more secular scale information.

Figure 4: PC regression calibration (1901-1995) experiments for both parameters (A) and species (B). A range of temperature seasonal targets are used with the strongest seasonal calibrations highlighted with circles.

315

For New Zealand, PCA identifies 3, 2, 2 and 3 significant principal components for RW, EWB, LWB and DB respectively. EWB calibrates very strongly (55%) with December-January temperatures while LWB explains 40% of the broader December-April season (Figure 4a). Alone, RW explains 28% of the temperature variance but for a broad September-April season which reflects the variable site-specific responses of PKL, AHA and DPP (Figure 3). The DB data calibrate poorly explaining only 19% of the December-January temperature variance.

320

Of all the species tested, Tasmanian Pencil pine returns the strongest calibration (47%) with January-February temperatures (Figure 4b) although New Zealand Silver pine and Pink pine also calibrate reasonably with 41% (December-January) and 42% (September-January). It should be noted that two Pencil pine sites were used (Table 1) compared to only one each for  
325 Silver pine and Pink pine which likely will influence these results. Of the species models (Figure 4b), King Billy pine, Huon pine and Kauri explain 30% (December-February), 34% (January-February) and 33% (November-April) respectively of the temperature variance with New Zealand cedar still showing some reasonable coherence (26%) for December-March. Celery Top is the weakest species explaining only 10% of the December-January temperature variance.

### 3.4 Region wide calibration and validation

330 A multi-site, multi-species approach to dendroclimatology can improve overall calibration even if some of the sampled sites and species are not located close to climate limited treeline ecotones (Alexander et al. 2019). Herein we have an opportunity to pool all the data for each country to create a combined multi-species and multi-parameter reconstruction. As the optimal season for calibration varies as a function of species and parameter (Figure 4), initial PC regression experiments using all chronologies from each of the two regions was performed. For each of these models, all PCs with an eigenvalue > 1.0 were  
335 entered into the regression model. January-February (JF) temperature was identified as the overall optimal season for Tasmania while December-January (DJ) provided the strongest calibration for New Zealand. Forcing all variables into the PC regression model also provides an opportunity to identify the importance of each species parameter towards the development of regional reconstructions. The beta weights (Cook et al. 1994) from the regression modelling (Table 2) clearly show the strong influence of the EWB parameters in the multiple regression model, especially from Pencil pine  
340 (MCK and CM) and Silver pine (AHA) although strong beta weights are also noted for King Billy pine (MDR), Huon pine (MHP) and Pink pine (DPP). Other parameters that provide useful information in the modelling are RW (King Billy pine (MWWTRL) and Huon pine (MHP)), LWB (Pencil pine (MCK, CM), Huon pine (BUT) and Kauri (PKL)) and DB (Huon pine (MHP) and Pink pine DPP)). These results are consistent with the correlation response function analysis (Figure 3), but it must be emphasised that the results shown in Table 2 are related to specific seasons (JF for Tasmania and DJ for New  
345 Zealand) and may not reflect the optimal season for individual species or parameters (Figure 4).

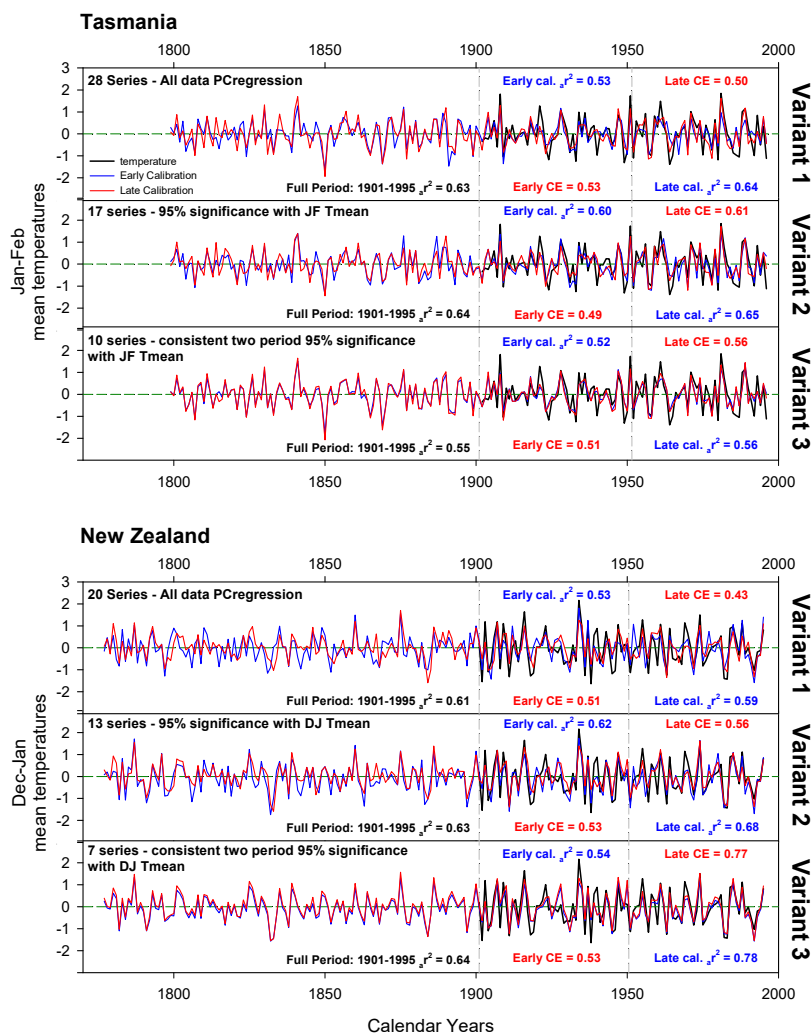

350 **Table 2: PC regression calibration (1901-1995) beta weights using all parameter and species data. The Tasmanian modelling was against January-February temperatures while New Zealand was with December-January.**

For the final countrywide calibration and validation experiments, three PC regression approaches were used, each reflecting more stringent screening procedures; (1) as already detailed above - all data entered into PCA and PCs with an eigenvalue > 1.0 that correlated significantly (95%) with the instrumental target were entered as possible candidates into a stepwise multiple regression; (2) same as (1) but chronologies were initially screened for significant correlation with the full period instrumental target before PCA; (3) similar to previous variants, but significant correlations between the chronologies and the instrumental target for both the 1901-1950 and 1951-1995 periods were required.

360 For Tasmania, the initial 28 parameter chronologies were reduced to 17 and 10 respectively via the two more stringent screening procedures while the 20 initial chronologies from New Zealand were reduced to 13 and 7 respectively (Figure 5). Full period (1901-1995) calibration is excellent for all versions with the Tasmanian variants 1 and 2 expressing 63-64% of the JF temperature variance, reducing to 55% for variant 3. The New Zealand data return similarly good results with 61-64% of the DJ temperature variance being explained by all variants. Split period calibration and validation is equally good for all variants with the Tasmanian variants explaining 52-65% of the variance for all early/late period calibration while CE ranges from 0.49-0.61. Similar results are obtained for New Zealand with calibration ar2 and CE ranging from 0.53-0.78 and 0.43-

0.77 respectively. For both countries, calibration and validation was marginally stronger for the later 1951-1995 period which might suggest some degree of uncertainty in the instrumental period in the early part of the 20th century.

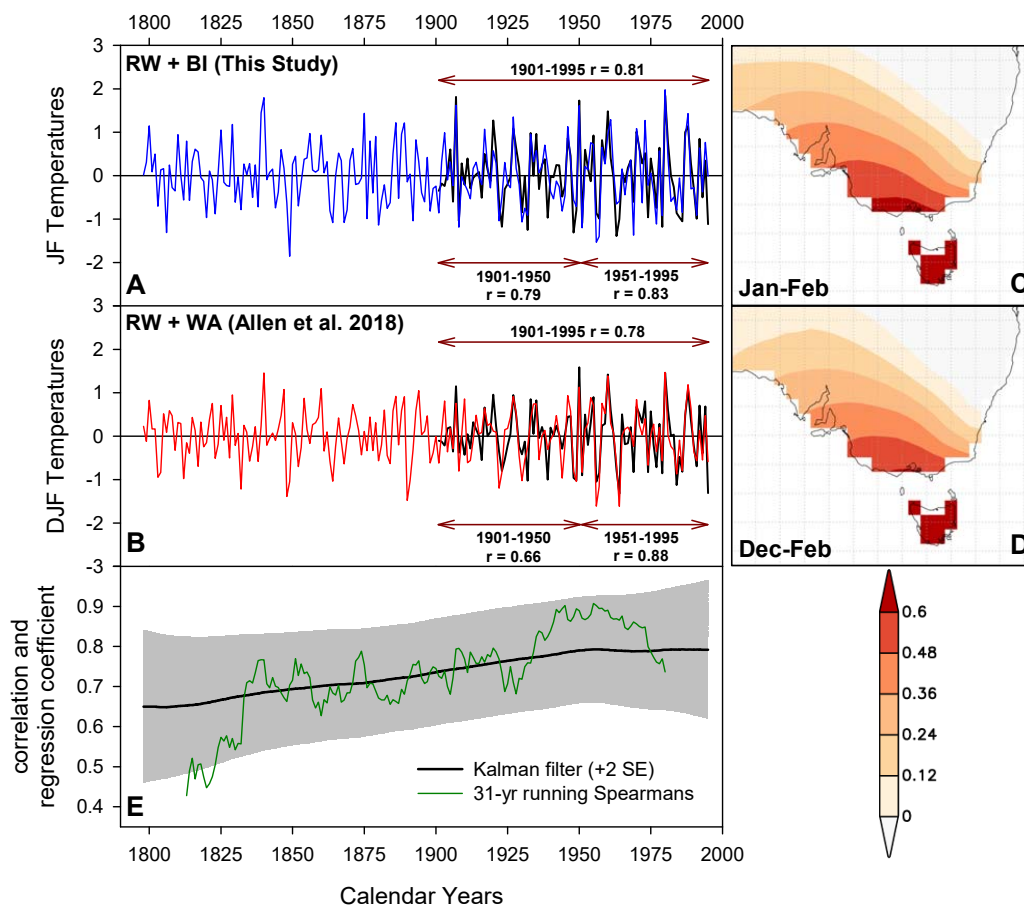

370

Figure 5: Principal component regression results using all data (Variant 1), full period (1901-1995) screened data (Variant 2), and two period screening (Variant 3). Split period calibration and validation performed over 1901-1950 and 1951-1995.

375

380

Figure 6: A: Variant 2 (full period screened) Tasmanian JF temperature RW+BI parameter-based reconstruction with CRU TS temperature data. Pearson's correlation shown for 1901-1995, 1901-1950 and 1951-1995 period; B: As A, but for Allen et al. (2018) RW+WA based Tasmanian DJF temperature reconstruction. These data have also been high pass filtered using a 20-year cubic smoothing spline; C + D: Spatial correlations (1841-1995) between each reconstruction and linearly detrended Berkeley gridded data for the Jan-Feb and Dec-Feb seasons respectively; E: Running 31-year Spearman's rank correlation and Kalman filter analysis (Visser and Molenaar 1988).

385 Overall, the temperature reconstruction experiments for both Tasmania and New Zealand (Figure 5) return excellent results  
with overall calibration  $r^2$  values well in excess of 0.60. Although no wood anatomical data exists yet for New Zealand,  
Allen et al. (2018) recently produced a range of PC regression based Tasmanian summer temperature reconstructions from a  
network of 58 chronologies using RW, mean tracheid radial diameter, mean cell wall thickness, mean density and microfibril  
angle. These variables were measured using the SilviScan system (Evans, 1994) from the same four Tasmanian tree species  
390 used herein. Strong calibration results explaining 50-60% of the temperature variance and robust validation were also noted  
in their analyses. We compare our full period screened temperature reconstruction (Variant 2, Figure 5) with a high-pass  
filtered (20-year spline) version of Allen et al's (2018) "Berkeley all-data" reconstruction variant (Figure 6). Both  
reconstructions correlate similarly with the CRU TS temperature data (1901-1995: RW/BI  $r = 0.81$  (JF) and RW/WA  $r =$   
0.78 (DJF) – Figure 6a/b) although the BI based reconstruction expresses a slightly more stable response with temperatures  
395 over the 1901-1950 and 1951-1995 periods ( $r = 0.79$  and  $0.83$  vs  $0.66$  vs  $0.88$ ). However, as the BI based reconstruction was  
calibrated against these CRU TS data, this slight difference may simply reflect the optimised PC regression fit to one  
instrumental dataset over another. Equivalent split period correlations using the Berkeley temperature data (Rohde et al.  
2013), as used by Allen et al. (2018), are  $0.82/0.86$  (RW/BI) and  $0.77-0.90$  (RW/WA).

400 Correlation with the Berkeley data over the 1841-1900 period, shows that coherence is weaker but similar between Allen et  
al's (2018) and this study ( $0.54$  and  $0.66$ ). The spatial representation of the reconstructed temperature signal in both datasets  
is almost identical when using linearly detrended Berkeley gridded temperature data (Rohde et al. 2013) even when  
including data back to 1841 (Figure 6c/d). Both reconstructions are strongly correlated with each other (Pearson's  $r = 0.75$ ,  
1798-1995) although this coherence weakens back in time as evidenced by both a running 31-year Spearman's rank  
405 correlation and Kalman filter (Visser and Molenaar 1988), showing a peak coherence in the 20th century that decreases back  
towards the early part of the 19th century (Figure 6e). This likely represents the decrease in sample replication through time  
in some BI based datasets (MWWTRL and BUT) used in this study (Figure A1). Overall, the BI data, at least for Tasmania,  
basically express the same high frequency signal as the WA data used in Allen et al. (2018) and the results herein suggest  
that BI parameters could provide excellent proxies of past growing season temperatures. However, for their potential to be  
410 truly realised, the heartwood/sapwood colour bias needs to be overcome.

#### 4 Conclusions and future research directions

In this study, we measured a range of blue intensity parameters from eight conifer species from Tasmania and New Zealand  
to ascertain whether the use of EWB, LWB and/or DB can improve upon previous RW-only based dendroclimatic  
reconstructions that explain about 40-45% of the temperature variance. No attempt to remove resins was made for this proof-  
415 of-concept study. Therefore, due to the impact on reflectance-based parameters of resins and heartwood/sapwood colour

changes on the wood, we detrended the chronologies and climate data using a very flexible spline (20-years) to focus only on the high frequency signal. Metrics denoting signal strength (RBAR and EPS) indicated a very weak common signal in the BI parameters (mean RBAR range 0.14 – 0.16, Figure 2b) compared to the RW data (mean RBAR = 0.33) which appeared to be partly related to the relative variance in these datasets. The EWB data in particular exhibit very low variability which may mean that any colour variation in the wood that does not reflect true year-to-year wood anatomical variance may have a large impact on such data, thus weakening the common signal.

Despite the weak common signal expressed by the BI parameters, the climate signal extant in these data is very strong, especially EWB. When all parameters are combined using PC regression, depending on the period used, 52-78% of the summer temperature variance can be explained (Figure 5). This is generally greater than the norm for Northern Hemisphere based MXD/BI related temperature reconstructions (Wilson et al. 2016), although admittedly, the results in this study are focussed only on the high frequency fraction of the data. These strong calibration results are driven mainly by EWB data from Pencil pine, Huon pine and King Billy pine (Tasmania) and Silver pine, Pink pine and cedar (New Zealand) although useful information was also identified in LWB (Pencil pine, low elevation Huon pine, Kauri and cedar), DB (high elevation Huon pine and Pink pine) and RW (high elevation Huon pine – Table 2). However, the relationship of LWB for most species with summer temperatures is opposite in sign to that observed in the Northern Hemisphere and further study is needed to assess the physiological processes leading to this inverse relationship in these particular Southern Hemisphere conifers.

The similarity of the Tasmanian multi-TR-proxy reconstruction with a reconstruction heavily dependent on wood anatomical data (Allen et al. (2018) - Figure 6) clearly highlights that the BI and WA data express similar wood properties. This is a highly encouraging result for the utilisation of BI as it is quicker and cheaper to produce than WA data. However, the “elephant in the room” is whether robust low frequency information can be extracted from BI based parameters or is it an analytical methodology that ultimately will be relevant only for decadal and higher frequencies. It is unlikely that the heartwood/sapwood colour change (both sharp and gradual – Figure A1), expressed by most of the tree species used in this study, can be fully removed by resin extraction alone. Some success at overcoming heartwood/sapwood colour bias using DB has been shown for some Northern Hemisphere conifer species (Björklund et al., 2014, 2015; Wilson et al., 2017b; Fuentes et al. 2018; Reid and Wilson 2020), but the DB results detailed herein (Table 2, Figures 2- 4) suggest that DB may not always provide a robust solution to the issue.

Other statistical approaches have been used to overcome the colour bias using either contrast adjustments (Björklund et al., 2015; Fuentes et al., 2018) or band-pass approaches where the low frequency signal is derived from the RW data and the high frequency is driven by the BI data (Rydval et al., 2017) but further experimentation is needed. We hypothesise that relatively sharp changes in colour intensity measures related to the heartwood/sapwood transition can be viewed conceptually in a similar way to how endogenous disturbances affect ring-width parameters over time (Cook 1987). Similar

450 to the progress in developing growth release detection methods to reconstruct canopy disturbance histories of forests  
(Altman 2020, Trotsiuk et al. 2018), radial growth averaging (Lorimer and Frelich 1989) or time series methods  
(Druckenbrod et al., 2013; Rydval et al. 2016) could be used to identify and remove the colour bias signature resulting from  
the change in physiology from heartwood to sapwood. However, to facilitate such signal processing methods, more studies  
are needed to directly compare both MXD and WA with BI data to understand the secular trend biases in these light  
455 reflectance parameters. At the very least, the results detailed herein clearly show that BI parameters can be used to identify  
those species that should be targeted for more costly and time-consuming analytical methods such as wood anatomical  
measurements.

Table A1: Mean RW, EWB, LWB and DB values for the raw chronologies. Coefficient of variation (CV) and mean inter-series correlation (RBAR) are calculated from the 20-year spline detrended chronologies. n-EPS reflects the number of series needed to attain an EPS values of 0.85 related to the RBAR value (Wilson and Elling 2004).

## 7 Author contribution

RW: Project conception

RW, KA, PB, SB, GB, BB, EC, RD, AF, PK, JP: Sample collection and image acquisition

RW, KA, SB, MG: Data generation

510 All: Paper writing, final methodological design, comment and editing

## 8 Competing interests

The authors declare that they have no conflict of interest

## 9 Acknowledgements

515 RW was funded through the University of Melbourne Dyason Fellowship in 2014 to undertake preliminary analyses for this study. Permission to obtain samples from the Tasmanian sites was provided by Parks and Wildlife Tasmania through several different permits over multiple years. KA was supported by Australian Research Council grants DP1201040320 and LP12020811 to PB
