Abstract

The flow of carbon through terrestrial ecosystems and the response to climate is a critical but highly uncertain process in the global carbon cycle. However, with a rapidly expanding array of in situ and satellite data, there is an opportunity to improve our mechanistic understanding of the carbon (C) cycle's response to land use and climate change. Uncertainty in temperature limitation on productivity poses a significant challenge to predicting the response of ecosystem carbon fluxes to a changing climate. Here we diagnose and quantitatively resolve environmental limitations on growing season onset of gross primary production (GPP) using nearly two decades of meteorological and C flux data (2000-2018) at a subalpine evergreen forest in Colorado, USA. We implement the CARDAMOM model-data fusion network to resolve the temperature sensitivity of spring GPP. To capture a GPP temperature limitation—a critical component of integrated sensitivity of GPP to temperature—we introduced a cold temperature scaling function in CARDAMOM to regulate photosynthetic productivity. We found that GPP was gradually inhibited at temperature below 6.0 °C (± 2.6 °C) and completely inhibited below -7.1 °C (± 1.1 °C). The addition of this scaling factor improved the model's ability to replicate spring GPP at interannual and decadal time scales ($r = 0.88$), relative to the nominal CARDAMOM configuration ($r = 0.47$), and improved spring GPP model predictability outside of the data assimilation training period ($r = 0.88$). While cold temperature limitation has an important influence on spring GPP, it does not have a significant impact on integrated growing season GPP, revealing that other environmental controls, such as precipitation, play a more important role in annual productivity.

41 This study highlights growing season onset temperature as a key limiting factor for spring growth in winter-dormant
42 evergreen forests, which is critical in understanding future responses to climate change.

43 **1. Introduction**

44 Northern hemisphere evergreen forests contribute significantly to terrestrial carbon (C) storage and exchange
45 (Beer et al., 2010; Thurner et al., 2014). High-latitude and high-elevation evergreen forests show increasing gross
46 primary productivity (GPP) with increasing temperature driven in large part by earlier growing seasons (Myneni et
47 al., 1997; Randerson et al., 1999; Forkel et al., 2016; Winchell et al., 2016, Lin et al., 2017). However, the response
48 of gross and net C fluxes to warming remains uncertain, especially in subalpine temperate forests, which can
49 experience freezing temperature while still absorbing large amounts of sunlight; both these factors ultimately
50 influence the timing and magnitude of GPP (Bowling et al., 2018). In particular, warmer springs can also lead to
51 earlier snowmelt, which can reduce spring C uptake through increased surface exposure to colder ablation-period air
52 temperatures (Winchell et al., 2016), and can reduce summer C uptake via drought (Hu et al., 2010). Many
53 subalpine forests in western North America are also highly water limited, with warming and earlier snow melt
54 creating accumulated water deficits, increased drought stress, and growing season C uptake losses (Wolf et al.,
55 2016; Sippel et al., 2017; Buermann et al., 2018, Goulden and Bales, 2019); these factors ultimately make subalpine
56 forest ecosystems sensitive to the direct and indirect effects of climate change and other disturbances, including the
57 effects of droughts, fires and insect infestations (Keenan et al., 2014; Frank et al., 2014; Knowles et al., 2015). The
58 uncertainty in the temperature sensitivity of springtime GPP, increasing vulnerability to disturbance, and GPP
59 modeling challenges (Anav et al., 2015) create urgency to improve our ability to observe and model these
60 ecosystems to understand how C exchange will be altered in a warming climate.

61 Fortunately, availability of long term ecosystem observations is improving. The expansion of international
62 flux tower networks over the last three decades (e.g. AmeriFlux, FLUXNET, ChinaFLUX, ICOS) has greatly
63 improved C flux sampling across global ecosystems at 1 km scale (Baldocchi 2008; Baldocchi et al., 2018), and the
64 number of spaceborne sensors continues to grow, allowing global estimation of gross primary production (GPP) and
65 net ecosystem C exchange (NEE) over the last decade (e.g. Stavros et al., 2017; Sun et al., 2017; Schimel et al.,
66 2019). While uncertainties in estimating C fluxes from in situ and satellite data remain a challenge, the expanding
67 observational record offers a great opportunity to study the temperature sensitivity of subalpine forests at multiple
68 temporal scales.

69 The range of modeling tools available to quantify and study major C pools under ever growing
70 observational constraints is also increasing. Process-based models, in general terms, use explicit mathematical
71 relationships to mechanistically describe bio-physical processes (Korzukhin et al., 2011; Huxman et al., 2003;
72 Keenan et al., 2012). In contrast, model-data fusion (MDF) is a relatively new tool that alters model parameters to
73 statistically reduce mismatches between observations and model predictions (Raupach et al., 2005; Wang et al.,
74 2009; Keenan et al., 2012). MDF methods can be used to statistically represent the terrestrial C balance by
75 generating optimized state and process variable parameterizations, with uncertainties, which best match the signal
76 and noise in observations (Bloom et al., 2020).

77 Models of varying complexity and assimilation capabilities have been used to study how C exchange varies
78 with temperature in subalpine evergreen ecosystems (e.g., Moore et al., 2008; Scott-Denton et al., 2013; Knowles et
79 al., 2018). Moore et al. (2008) used a simplified ecosystem function model and assimilated C flux data from the
80 Niwot Ridge (US-NR1) subalpine evergreen forest AmeriFlux tower in Colorado to show the importance of accurate
81 meteorological forcing for parameter optimization and the usefulness of assimilating C flux data for determining
82 connections between the C and water cycles. Scott-Denton et al. (2013) integrated meteorological and flux data
83 from 1999-2008 from the same site with an ensemble of more sophisticated Earth System Models (ESM) and
84 showed higher rates of C uptake by the end of the 21st century associated with warming and lengthening growing
85 seasons, and driven by greater increases of spring GPP relative to late season respiration.

86 Interestingly, model and empirical studies of the C flux response to climate at US-NR1 focus on the 2000-
87 2011 period, which saw increasing summer drought coupled with sustained declines in spring temperature and GPP.
88 US-NR1 has since experienced a gradual recovery of spring GPP with increased spring warming throughout 2011-
89 2018 (Fig. 1), which begs the question: what is the temperature sensitivity of spring GPP over multiple decades of
90 spring cooling and warming at US-NR1, and how well can data-constrained models reproduce long term variability?
91 To answer this question, we combine a mechanistic ecosystem C model (Data Assimilation Linked Ecosystem
92 Carbon, or DALEC2; Williams et al., 2005; Bloom et al., 2016) with the CARbon DAta-MODEl fraMework
93 (CARDAMOM; Bloom and Williams, 2015; Bloom et al., 2020) driven by observed meteorological forcing and
94 constrained against eddy covariance fluxes at US-NR1, to investigate the temperature sensitivity of this subalpine
95 evergreen forest at seasonal and interannual timescales. We introduce a new cold temperature limitation function,
96 trained on observed temperature, for more realistic simulation of spring GPP onset. The use of high quality and long
97 term (2000-2018) meteorology and partitioned GPP data at US-NR1 to drive and constrain the model enables robust
98 statistical analysis of interannual variability (IAV), and assessment of “model predictability” through training and
99 validation against subsets of data. We also leverage a recent model intercomparison study (Parazoo et al., 2020),
100 driven by site level meteorological data at US-NR1, to provide a model benchmark assessment, and extract any
101 common environmental controls on modeled GPP. Finally, we examine whether using a decade of flux tower-
102 derived GPP observations to train the model is sufficient to match and predict seasonal to annual patterns in GPP.
103 Given the complexity of carbon-water cycle interactions during the growing (summer) season in this highly water
104 limited ecosystem, and the relatively weak correlation between tower-derived spring and summer GPP ($r = -0.31$, p
105 $= 0.20$), we focus on spring GPP-temperature interactions, with the aim to resolve just one piece of the larger,
106 complex problem of understanding changes in C uptake in a subalpine evergreen ecosystem.

107 2. Materials & Methods

108 2.1. Study Site: Niwot Ridge, CO., USA

109 Our study focuses on an AmeriFlux (<https://ameriflux.lbl.gov/>) core site in Niwot Ridge, Colorado, USA
110 (US-NR1, 40°1'58"N; 105°32'47" W), where a tower-based eddy covariance system has been used to continuously
111 monitor the net ecosystem exchange (NEE) of carbon dioxide over a subalpine forest since November 1998. The 26

112 m tall tower is located in a high elevation (3050 m) subalpine site in the Rocky Mountains of Colorado (Monson et
113 al., 2002). Located in an evergreen needleleaf (ENF) ecosystem, the dominant tree species include lodgepole pine
114 (*Pinus contorta*), subalpine fir (*Abies lasiocarpa*), and Engelmann spruce (*Picea engelmannii*) (Turnipseed et al.,
115 2002; Turnipseed et al., 2004). Average annual precipitation is 800 mm, with a majority of precipitation falling in
116 the winter as snow (Greenland, 1989; Knowles et al., 2015), which creates a persistent winter snowpack from
117 November through early June (Bowling et al., 2018).

118 **2.2. Observations**

119 NEE measurements are screened for calm conditions using the standard u_{star} filtering, gap-filled, and
120 partitioned into GPP and ecosystem respiration based on the relationship between nighttime NEE
121 (photosynthetically active radiation, $\text{PAR} < 50 \mu\text{mol m}^{-2} \text{s}^{-1}$) and air temperature (Reichstein et al., 2005; Wutzler et
122 al., 2018). Monthly averages of GPP based on nighttime partitioning show similar seasonal structure to results found
123 using an alternative daytime partitioning algorithm (Lasslop et al., 2009), so only nighttime partitioned GPP data are
124 reported here. All GPP estimates are processed as half hourly means, then averaged monthly. Details on the flux
125 measurements, data processing and quality control are provided in Burns et al. (2015).

126 **2.3. The CARDAMOM Model-Data Fusion System**

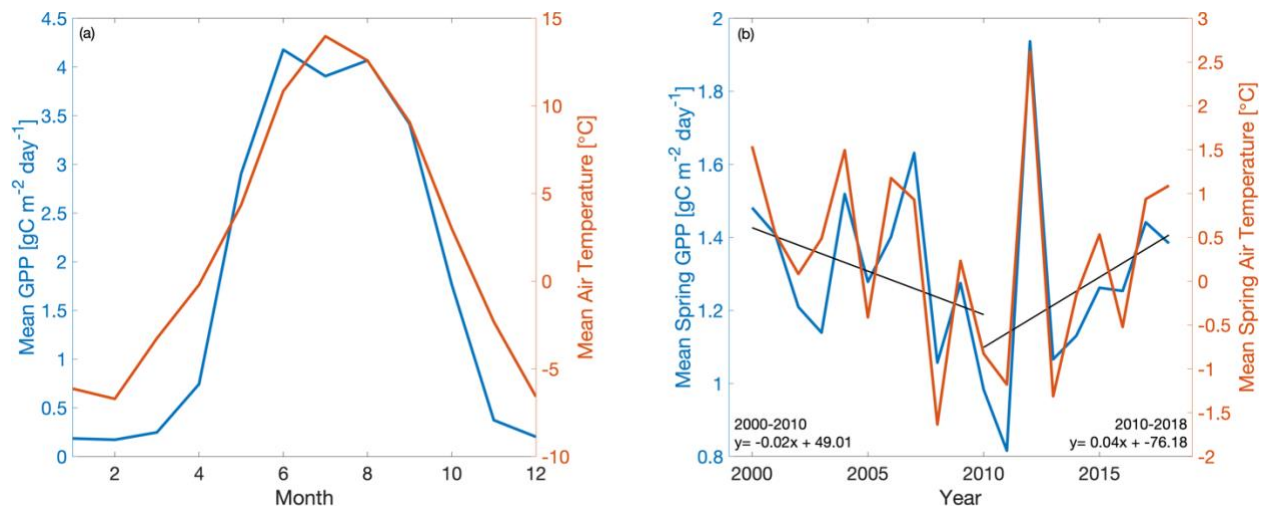

127 The CARbon DATA-MODEL FraMework (CARDAMOM; Bloom et al., 2016; Yin et al., 2020; Exbrayat et
128 al., 2018; Smallman et al., 2017; Quetin et al., 2020; López-Blanco et al., 2019; Famiglietti et al., 2021; Bloom et
129 al., 2020; amongst others) uses carbon cycle and meteorological observations to constrain carbon fluxes, states and
130 process controls represented in the DALEC2 model of terrestrial C cycling (Williams et al., 2005; Bloom and
131 Williams, 2015). Specifically, CARDAMOM uses a Bayesian model-data fusion approach to optimize DALEC2
132 time-invariant parameters (such as leaf traits, allocation and turnover times) and the “initial” C and H₂O conditions
133 (namely biomass, soil and water states at the start of the model simulation period).

134 The DALEC model (Williams et al., 2005; Rowland et al., 2014; Fox et al., 2009; Richardson et al., 2010;
135 Famiglietti et al., 2021; Bloom & Williams, 2015; amongst others) is a box model of C pools connected via fluxes
136 that has been used to evaluate terrestrial carbon cycle dynamics across a range of ecosystems and spatial scales. In
137 all site, regional, and global applications, DALEC parameters are subject to very broad, but physically realistic, prior
138 distributions, and independently estimated and constrained by available observations at each grid point. Here we use
139 DALEC version 2 (DALEC2; Yin et al., 2020; Quetin et al., 2020; Bloom et al., 2020); gross and net carbon fluxes
140 are determined as a function of 33 parameters, including 26 time-invariant parameters relating to allocation, turnover
141 times, plant traits, respiration climate sensitivities, water-use efficiency and GPP sensitivity to soil moisture, and 7
142 parameters describing the initial conditions of live biomass pools (live biomass C, dead organic C and plant-
143 available H₂O). Within DALEC2, GPP estimates are generated in the aggregated canopy model (ACM, Williams et
144 al., 1997); the ACM is derived from simple functional relationships with environmental and plant structural and
145 biochemical information (Williams et al., 1997), that are produced from a sensitivity analysis of GPP estimates from
146 the more comprehensive SPA land surface model scheme (Williams et al., 1996, Williams et al., 2001). ACM GPP

147 estimates are contingent on plant structural and biochemical variables (including LAI, foliar nitrogen and nitrogen-
 148 use efficiency) and meteorological forcing (total daily irradiance, maximum and minimum daily air temperature, day
 149 length, atmospheric CO₂ concentration). In DALEC2, water limitation on ACM is prescribed as a linear response to
 150 soil water deficit (Bloom et al., 2020). For more details on the model-data fusion methodology and CARDAMOM
 151 ensembles, we refer the reader to Appendix A. For a comprehensive overview of the DALEC2 model, we refer the
 152 reader to Bloom et al. (2020) and references therein.

153 2.4. Experiment Design

154 In order to develop model experiments that could reliably evaluate temperature-GPP interactions, we first
 155 examine the observed environmental controls on tower-derived GPP. We focus on GPP during spring, defined here
 156 as the period from March-May, which encompasses the climatological onset of GPP and transition from dormant
 157 winter conditions to peak summer conditions (Fig 1a). Mean spring GPP exhibits large interannual variability (IAV)
 158 with both a small decreasing trend from 2000-2010 ($-0.02 \text{ g C m}^{-2} \text{ day}^{-1}$ per year) and increasing trend from 2010-
 159 2018 ($0.04 \text{ g C m}^{-2} \text{ day}^{-1}$ per year) (Fig. 1b). Comparison to tower observed temperature data (Fig. 1b and Fig. 2)
 160 shows that spring GPP is positively correlated to mean spring air temperature (Pearson's linear $r = 0.89$, $p =$
 161 0.000004) and summer (June-September) air temperature ($r = 0.10$, $p = 0.70$, Fig. S1a). Mean winter (December-
 162 February) precipitation also has a positive correlation with spring GPP, ($r = 0.07$, $p = 0.77$, Fig. S1b), but it is much
 163 smaller than spring temperature. At interannual timescales, mean annual GPP shows a small increasing trend
 164 ($0.0072 \text{ g C m}^{-2} \text{ day}^{-1}$ per year) over the time period (Fig. S2), and largest correlation with winter (December –
 165 February) precipitation (Pearson's linear $r = 0.63$, $p = 0.003$, Fig. S3d) and shortwave irradiance ($r = -0.30$, $p = 0.22$,
 166 Fig. S3f). In contrast, spring temperature shows little correlation with mean annual GPP ($r = -0.02$, $p = 0.92$, Fig.
 167 S3c). It appears that winter precipitation and total irradiance are the dominant drivers in annual productivity, both of
 168 which are correlated, while spring temperature show a first order effect in driving spring GPP.

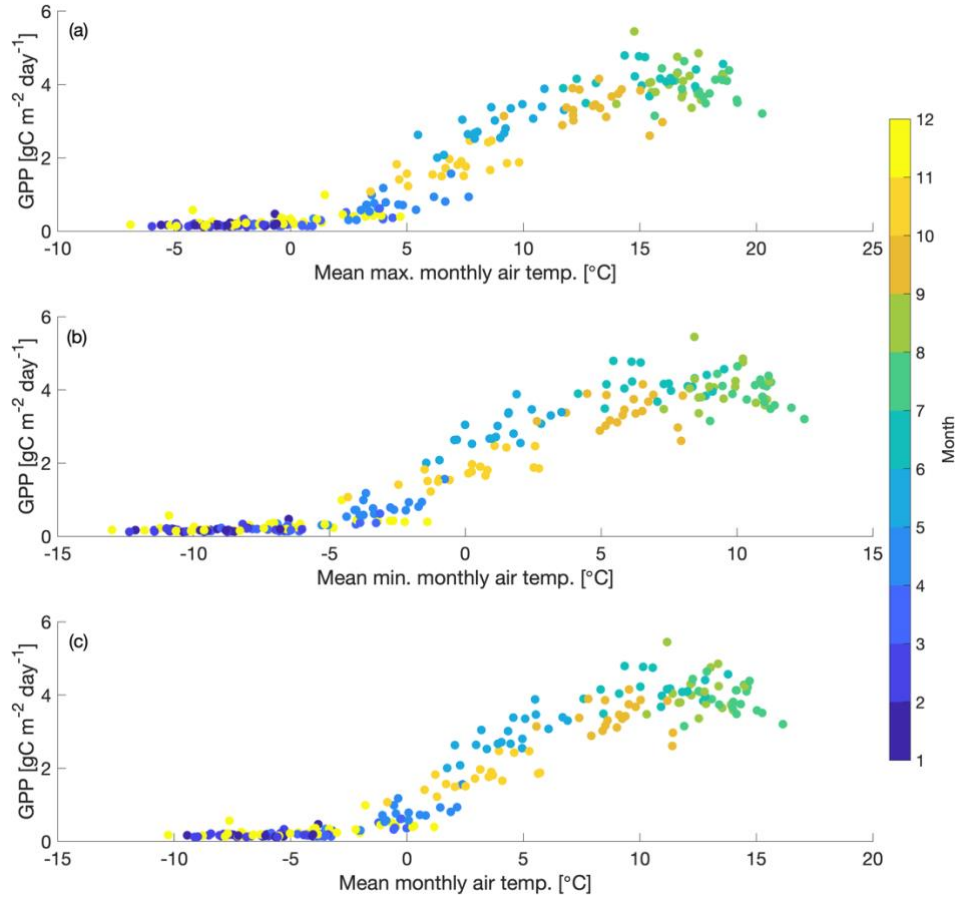

169
 170 **Figure 1.** Time series of (a) mean monthly GPP (blue) and air temperature (orange) and (b) mean spring (March-May) GPP and
 171 air temperature at Niwot Ridge (US-NR1) from 2000-2018. GPP data are derived using a nighttime partitioning technique based
 172 on tower observations of NEE and air temperature.
 173

174
 175 **Figure 2.** Scatterplot of mean spring (March-May) GPP with mean spring air temperature with the color bar showing the
 176 corresponding year (2000-2018). ‘r’ is Pearson’s correlation coefficient.
 177

178 We also find that cold temperature has an important limitation on seasonal GPP at US-NR1. The seasonal
 179 cycle of GPP shows peak productivity in early summer (around June) and falling to near-zero values by early winter
 180 (November), continuing through late winter (February-March). Comparison of monthly GPP and minimum,
 181 maximum, and mean monthly air temperature shows an initiation of photosynthesis at monthly maximum air
 182 temperature above 0 °C (Fig. 3a) and monthly minimum air temperature above -5 °C (Fig. 3b). The strong
 183 dependence of monthly GPP on temperature is consistent with previous findings that temperature is an important
 184 driver of spring onset and seasonal variability of GPP in evergreen forests (e.g., Pierrat et al., 2021; Parazoo et al.,
 185 2018; Euskirchen et al., 2014; Arneth et al., 2006). As temperature falls in winter dormant plants, productivity
 186 becomes negligible. Productivity is triggered again when spring air temperature becomes warm enough to thaw
 187 stems, trigger xylem flow and promote access to soil moisture (e.g., Pierrat et al., 2021; Bowling et al., 2018; Ishida
 188 et al., 2001). Due to this observed dependence of GPP on temperature at US-NR1, we focus our analysis
 189 specifically on spring GPP, where we hypothesize that cold temperature is the dominant control on spring GPP
 190 variability.
 191

202
203

In the baseline version of CARDAMOM, seasonal GPP in DALEC2 is limited primarily by incoming shortwave radiation. This light-focused limitation works well for deciduous forests where spring temperature and sunlight are correlated, as well as high latitude regions where sunlight is limited. However, for reasons discussed above, this method fails in evergreen forests such as Niwot Ridge whose green canopies are exposed to high sunlight and below-freezing temperature in spring. As such, we implement a cold temperature scaling factor (g) in DALEC2 Eq. (1), to act as a thermostat that regulates evergreen needleleaf carbon uptake phenology. This scaling factor is developed by analyzing the relationship between monthly minimum & maximum air temperature with tower-derived monthly GPP, where

$$\text{If: } T_{min}(t) < T_0 : g = 0 \quad (1)$$

$$\text{If: } T_{min}(t) > T_g : g = 1$$

$$\text{Else: } g(t) = \frac{(T_{min}(t) - T_0)}{(T_g - T_0)}$$

$$GPP_{cold}(t) = GPP(t) * g(t) \quad (2)$$

208
209
210

$T_{min}(t)$ is the observed minimum temperature at Niwot Ridge at time t , $GPP(t)$ is the nominal ACM-based DALEC2 GPP estimate (see section 2.3) and GPP_{cold} is the corresponding cold temperature GPP estimate. Equation (2) may represent changes in plant hydraulics and photosynthetic activity due to changing temperature in the spring. As

211 temperature increases, evergreen stems slowly thaw, which enables the trees to access available soil moisture and
212 slowly reactivate their carbon and water exchange processes (Mayr et al., 2014; Bowling et al., 2018). Temperature
213 also impacts the reactivation of photosynthetic activity after winter dormancy (Öquist and Huner, 2003; Tanja et al.,
214 2003). For example, fluctuating temperature in the spring has been shown to limit and sometimes reverse the
215 activation of biochemical processes needed for photosynthesis recovery (Ensminger et al., 2004). Exposure to cold
216 temperature, when combined with increased irradiance in the spring, can also damage evergreen trees (Öquist and
217 Huner, 2003; Yang et al., 2020), therefore disrupting CO₂ assimilation. These processes may be approximated by
218 this cold temperature scaling factor added to CARDAMOM. The temperature thresholds for photosynthesis
219 shutdown (referred to as T₀) and initiation (referred to as T_g) are added as model parameters in DALEC2, bringing
220 the total number of parameters to 35. These 35 DALEC parameters are simultaneously optimized in CARDAMOM.
221 The CARDAMOM Bayesian-inference probability distributions (see Appendix A) for the T₀(-7.1 ± 1.1 °C) and T_g
222 (6.0 ± 2.6 °C) parameters used to define the cold temperature limitation are plotted in Fig S4. We refer to the cold
223 temperature constrained version of DALEC2 (within CARDAMOM) as DALEC2cold.

224 The baseline (DALEC2) and cold temperature (DALEC2cold) versions of the model are run for the 2000-
225 2018 period using tower observed, gap-filled, monthly meteorological (MET) drivers (including minimum and
226 maximum air temperature, shortwave radiation, vapor pressure deficit, and precipitation). We conduct four
227 experiments, summarized in Table 1: experiments using DALEC2 and DALEC2cold within CARDAMOM, where
228 19 years of GPP data are assimilated (referred to as CARD and CARDcold), and a corresponding pair of
229 experiments where only the first decade of data (2000-2009) is assimilated (referred to as CARD-Half and
230 CARDcold-Half) and the second decade of data (2010-2019) is withheld for validation, as a train-test scenario. All
231 months of GPP data are assimilated into the model, however our analysis focuses on the constraints on spring
232 (March-May) GPP. These four experiments serve to evaluate the sensitivity of modeled GPP at Niwot Ridge to cold
233 temperature limitation and parameter optimization. Specifically, the objective of experiments “CARD” and
234 “CARDcold” is to determine whether the cold temperature scaling factor improves the representation of spring GPP
235 variability across the 2000-2018 period; the objective of experiments “CARD-Half” and “CARDcold-Half” is to
236 cross-validate the predictive skill of CARDcold by assessing whether the addition of a cold temperature scaling
237 factor, informed by a subset of GPP data, can improve prediction of a withheld subset of GPP data.

Table 1. Summary of CARDAMOM modeling experiments to determine sensitivity of seasonal and interannual spring GPP variability to cold temperature limitation (CARD vs CARDCold) and the ability to perform outside training window (Half).

Experiment Name	Met. Drivers	Time Period	GPP assimilation	Time period considered in assimilation	Uncertainties in GPP	Cold Temp. Limitation
CARD	yes	2000-2018	yes	2000-2018	20%	No
CARD-Half	yes	2000-2018	yes	2000-2009	20%	No
CARDCold	yes	2000-2018	yes	2000-2018	20%	Yes
CARDCold-Half	yes	2000-2018	yes	2000-2009	20%	Yes

250

251 **2.5. Comparison to Terrestrial Biosphere Model Ensemble**

252 A recent model intercomparison study provides an ideal benchmark for evaluating CARDAMOM
 253 simulations (section 2.4). Parazoo et al. (2020) conducted an experiment in which an ensemble of state-of-the-art
 254 terrestrial biosphere models (TBMs) were forced by the same observed meteorology at Niwot Ridge from 2000-2018,
 255 but with differences in spin-up, land surface characteristics, and parameter tuning. The TBMs are designed to simulate
 256 the exchanges of carbon, water, and energy between the biosphere and atmosphere, from global to local scales
 257 depending on inputs from meteorological forcing, soil texture, and plant functional type (PFT). The experiment was
 258 designed primarily to evaluate simulations of solar induced fluorescence (SIF) and GPP, the latter of which we focus
 259 on here. We refer the reader to Parazoo et al. (2020) for a more complete description of models, within-model
 260 experiments, and between-model differences.

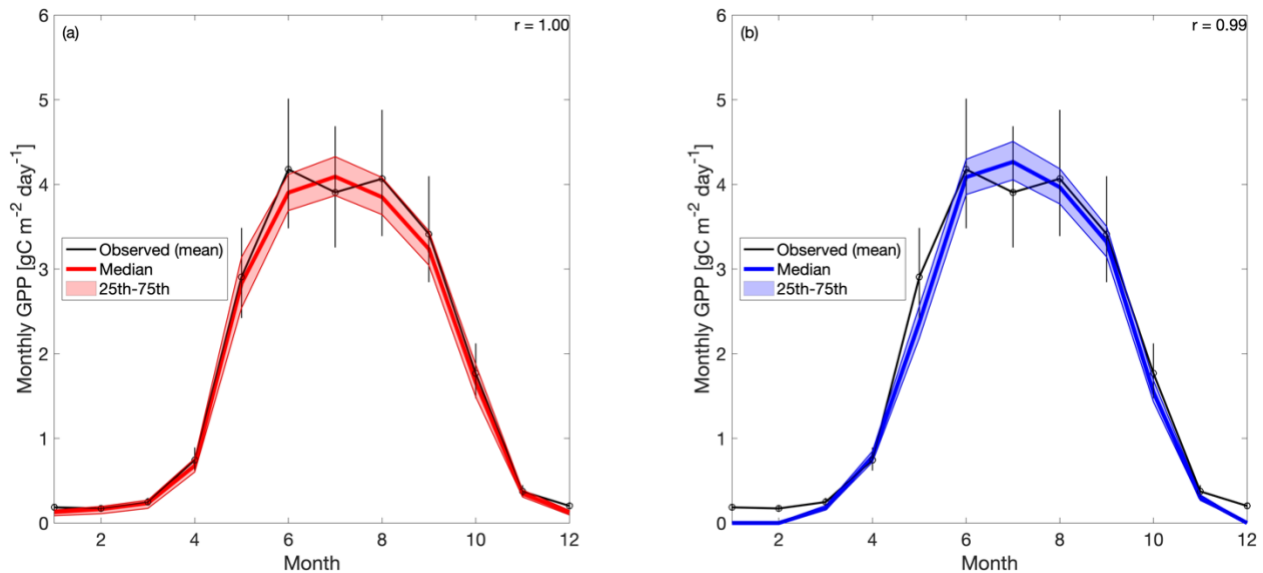

261 The most important model differences worth noting here include the representation of stomatal conductance,
 262 canopy absorption of incoming radiation, and limiting factors for photosynthesis. We analyze a subset of the models
 263 which were run for multiple years, including SiB3 and SiB4 (Simple Biosphere model versions 3 and 4, respectively),
 264 ORCHIDEE (Organizing Carbon and Hydrology in Dynamic Ecosystems), BEPS (Boreal Ecosystems Productivity
 265 Simulator), and CLM4.5 and CLM5.0 (Community Land Model Versions 4.5 and 5.0, respectively). We also analyze
 266 within-model experiments in SiB3 and ORCHIDEE to isolate effects related to prescription of leaf area index (LAI;
 267 monthly varying in SiB3-exp1, fixed at 4.0 m²/m² in SiB3-exp2), temperature and water stress (ORCHIDEE-exp1
 268 includes temperature stress; ORCHIDEE-exp2 accounts for temperature and water stress), and data assimilation
 269 (ORCHIDEE-exp3, in which a subset of model parameters controlling photosynthesis and phenology are optimized
 270 against global OCO-2 SIF data, Bacour et al., 2019). Most of the TBM model experiments were run with default
 271 parameters (BEPS, CLM50, SiB3, SiB4, ORCHIDEE-exp1 and exp2). The other experiments were optimized in the
 272 following ways: either a) parameters were hand-tuned based on the US-NR1 data (CLM45) or b) the parameters were
 273 optimized using OCO-2 SIF data (ORCHIDEE-exp3). For more details on the parameterization of the TBM-SIF

274 experiments, we refer the reader to Parazoo et al. (2020). The use of these models provides insight into the spread in
 275 model structures and the use of their default parameters. Finally, we note that not all model simulations span the entire
 276 observed record (2000-2018). While our analysis focuses on the long-term record from 2000-2018, we provide
 277 multiple comparisons to ensure consistency of time period: (1) IAV from 2001-2018 for SiB3, SiB4, ORCHIDEE,
 278 and CLM4.5; (2) IAV from 2012-2018 for SiB3, SiB4, ORCHIDEE, CLM4.5, and CLM5.0, and (3) seasonal
 279 variability from 2015-2018 for all models. We refer to the ensemble of models and within model experiments
 280 collectively as TBM-MIP.

281 3. Results & Discussion

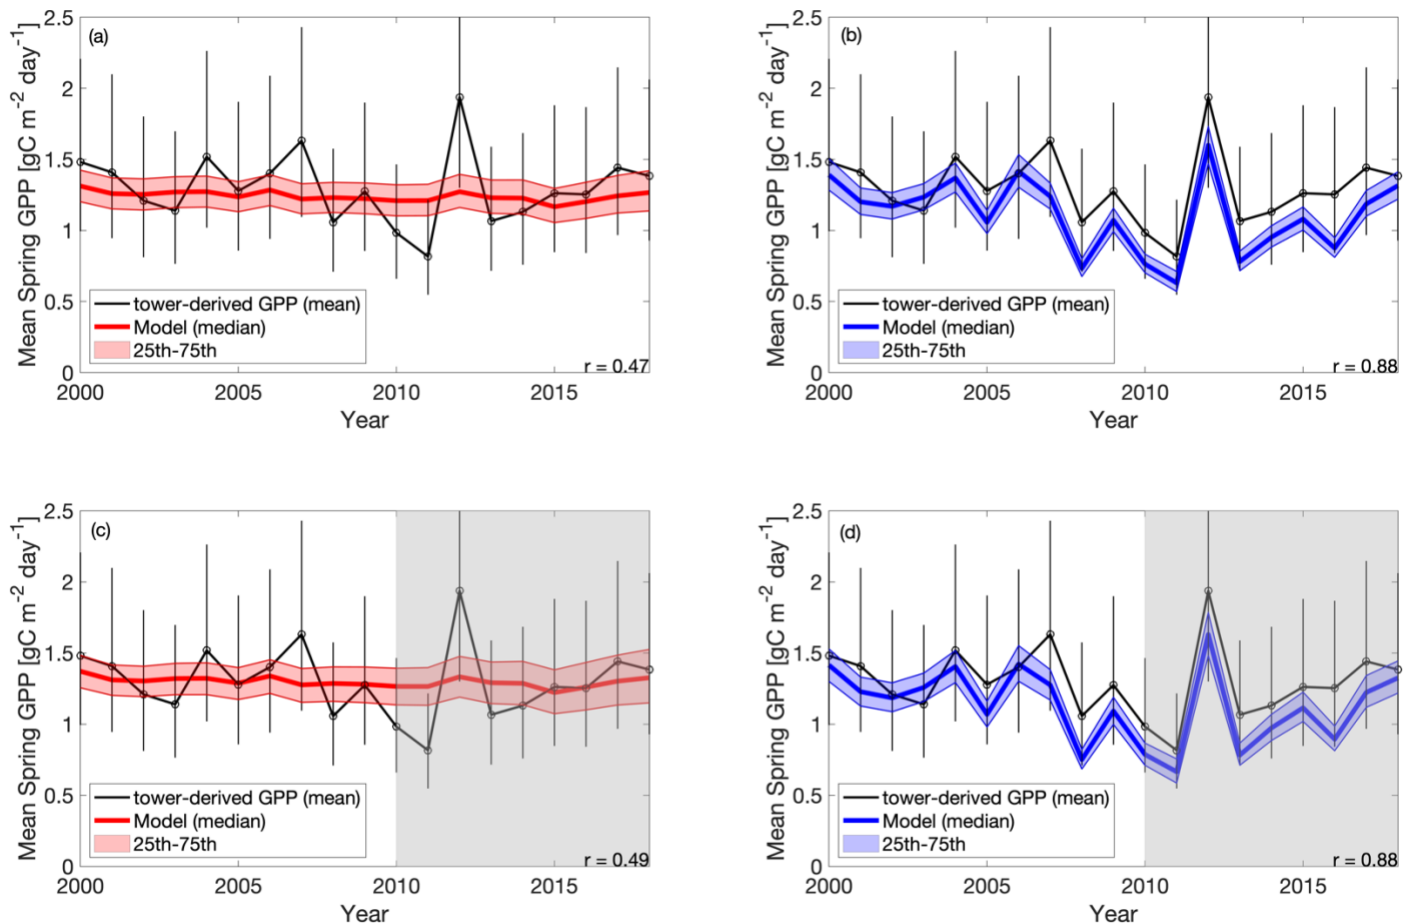

282 3.1. Evaluation of CARDAMOM 2000–2018 GPP

283 When the 19 years of tower-derived GPP data are assimilated into both versions of the model, the mean
 284 seasonal cycle is accurately replicated (Fig. 4). The Pearson’s r values for CARD (Fig. 4a) and CARDcold (Fig. 4b)
 285 are almost equal ($r = 1.0$ and 0.99) with minimal increases in root mean square error (RMSE) and mean bias error
 286 (MBE) for CARDcold (RMSE = $0.24 \text{ g C m}^{-2} \text{ day}^{-1}$ and $0.23 \text{ g C m}^{-2} \text{ day}^{-1}$, MBE = $0.06 \text{ g C m}^{-2} \text{ day}^{-1}$ and 0.19 g C
 287 $\text{m}^{-2} \text{ day}^{-1}$ for CARD and CARDcold, respectively). Assimilating only the first decade of GPP data (Half
 288 experiments) does not drastically alter model performance (Fig. S5), with only slight changes in RMSE and MBE
 289 ($\Delta\text{RMSE} = 0.008 \text{ g C m}^{-2} \text{ day}^{-1}$, $\Delta\text{MBE} = 0.03 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARD-Half, $\Delta\text{RMSE} = -0.003 \text{ g C m}^{-2} \text{ day}^{-1}$,
 290 $\Delta\text{MBE} = 0.02 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARDcold-Half).

291
 292 **Figure 4.** Tower-derived average monthly GPP (black line) and modeled GPP seasonal cycles at US-NR1 for 2000-2018, for a.)
 293 CARD and b.) CARDcold experiments. The half-assimilation experiments (CARD-Half and CARDcold-Half) can be found in
 294 the supplement (Fig S5). Model outputs include the median value of each experiment (bold color line) with the 25th-75th
 295 percentiles of the ensembles (shaded area). The median is plotted instead of the mean to avoid impact of outlier ensemble
 296 members ($N = 4000$). Error bars = tower-derived GPP multiplied/divided by $\exp(\sqrt{\log(2)^{2*n}}/n)$, $n = \#$ of years in average (n
 297 $= 19$). ‘ r ’ is the Pearson’s coefficient.
 298

299 The cold experiments exhibit an improved fit to the observed IAV in spring productivity (Fig. 5), relative to
 300 CARD, ($r = 0.47$, $\text{std} = 0.03 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARD; $r = 0.88$, $\text{std} = 0.27 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARDcold). CARDcold
 301 also has slightly reduced RMSE ($-0.01 \text{ g C m}^{-2} \text{ day}^{-1}$) and larger MBE ($0.13 \text{ g C m}^{-2} \text{ day}^{-1}$). Similar to the seasonal
 302 cycle analysis, the assimilation of only the first decade of GPP data (Half experiments) has minimal impact on
 303 model performance ($\Delta\text{RMSE} = 0.007 \text{ g C m}^{-2} \text{ day}^{-1}$, $\Delta\text{MBE} = 0.06 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARD-Half, and $\Delta\text{RMSE} =$
 304 $0.02 \text{ g C m}^{-2} \text{ day}^{-1}$, $\Delta\text{MBE} = 0.02 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARDcold-Half). We find less agreement between modeled and
 305 tower-derived GPP IAV in summer for both CARD and CARDcold (CARD $r = 0.32$, $\text{std} = 0.11 \text{ g C m}^{-2} \text{ day}^{-1}$;
 306 CARDcold $r = 0.05$, $\text{std} = 0.10 \text{ g C m}^{-2} \text{ day}^{-1}$; Fig. S6). While there is little variation in RMSE between the half and
 307 full-assimilation experiments, RMSE is larger for summer than spring GPP (average RMSE = $0.23 \text{ g C m}^{-2} \text{ day}^{-1}$ for
 308 spring model outputs, average RMSE = $0.35 \text{ g C m}^{-2} \text{ day}^{-1}$ for summer model outputs). Model agreement is further
 309 reduced when considering annual average GPP (Fig. S7, Table S2). Although the cold temperature limitation
 310 improves IAV slightly, it is still small compared to observed variability (mean annual $\text{std} = 0.14 \text{ g C m}^{-2} \text{ day}^{-1}$).
 311 Correlations to tower-derived GPP at the annual scale are small for both CARD and CARDcold ($r = 0.19$ and $r =$
 312 0.22 , Fig. S7a-b). Overall, the cold temperature limitation substantially improves agreement between the model and
 313 tower-derived spring GPP, with slight reductions in performance for summer and annual GPP.
 314

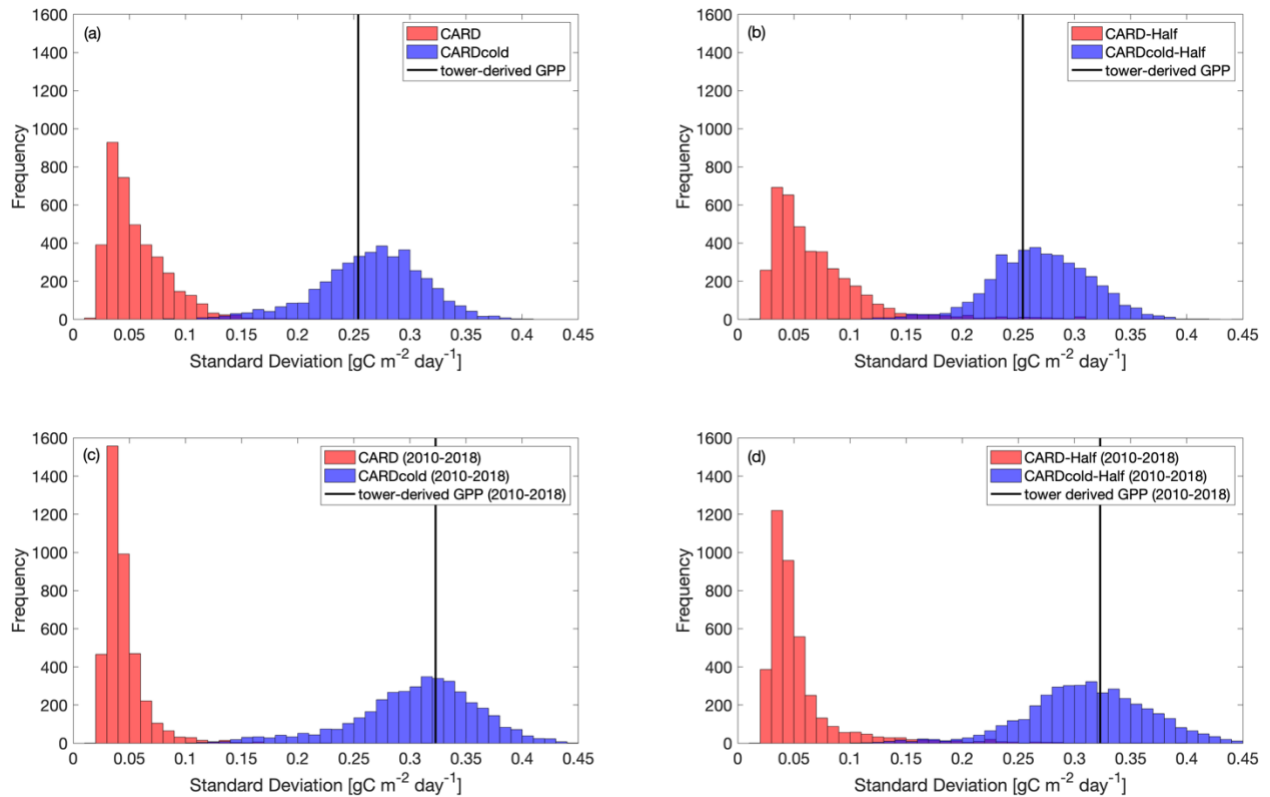

315
 316 **Figure 5.** Tower-derived (black line) mean spring (March-May) GPP with model interquartile range (shaded area) and median
 317 (bold color line) spring GPP outputs for a.) CARD, b.) CARDcold, c.) CARD-Half, and d.) CARDcold-Half experiments. The

318 grey regions indicate no data assimilation (i.e. testing window). Model experiments are the same as in Figure 4. Uncertainty =
319 $\exp(\sqrt{\log(2)^{2*n}/n})$, n=# of months in average (n = 3).
320

321 The standard deviation in tower-derived mean spring GPP (March-May) is approximately 0.25 g C m⁻² day⁻¹.
322 ¹. The addition of the cold temperature limitation improves the model's ability to match the IAV of mean spring
323 GPP (Fig. 6a-b). An examination of all modeled scenarios for CARD and CARDcold (i.e. all 4000 DALEC2
324 simulations), shows that the cold temperature limitation produces spring IAV values much closer to what is
325 observed in the tower-derived GPP data. Only 0.3% of CARD ensembles produces mean spring IAV values within
326 20% of the tower-derived spring GPP standard deviation (0.25 ± 0.05 g C m⁻² day⁻¹), whereas 69% of CARDcold
327 ensembles have standard deviation values within the same range. Interestingly, assimilating only the first ten years
328 of GPP data (Half experiments, Fig. 6b) slightly increases the number of ensemble members with standard
329 deviations within the mentioned range for both CARD-Half (2.4%) and CARDcold-Half (70%). It is promising to
330 see that despite not assimilating the 2010-2018 GPP data into the model, CARDcold-Half is still able to match
331 average spring IAV of the full data record.

332 We also consider the IAV in spring GPP for just the second half of the data record (2010-2018). IAV of
333 tower-derived spring GPP increases slightly in 2010-2018 (0.32 g C m⁻² day⁻¹). Once again, the cold temperature
334 limitation enables CARDAMOM to match spring GPP IAV (Fig. 6c-d). 0.03% of CARD ensembles produce mean
335 spring IAV values within 20% of the tower-derived spring GPP standard deviation for the 2010-2018 period ($0.32 \pm$
336 0.06 g C m⁻² day⁻¹), whereas 76% of CARDcold ensembles have standard deviation values within the same range.
337 For the Half experiments, 0.6% of CARD and 75% of CARDcold ensembles have IAV values within 20% of the
338 standard deviation for 2010-2018. This improvement in matching IAV is also observed when considering mean
339 annual GPP (Fig. S8), but is much smaller than the improvements made for spring GPP. Overall, CARDcold
340 produces a less biased distribution of IAV values (relative to both assimilated and withheld observations), whereas
341 CARD is more skewed towards smaller IAVs, which indicates that the cold temperature limitation enables a
342 mechanistic and statistical improvement in capturing the interannual variability of spring GPP.
343

344
 345 **Figure 6.** Histograms comparing standard deviation in mean spring GPP across all ensembles ($N=4000$) for CARD (red bars) and
 346 CARDcold (blue bars) experiments with a.) full assimilation, b.) half assimilation, c.) full assimilation for the second decade
 347 (2010-2018), and d.) half assimilation for the second decade (2010-2018). Black line indicates standard deviation in tower-
 348 derived mean spring GPP (std = $0.25 \text{ gC m}^{-2} \text{ day}^{-1}$ for full period (a-b), std = $0.32 \text{ gC m}^{-2} \text{ day}^{-1}$ for 2010-2018 (c-d)).
 349

350 3.2. Temperature controls on springtime GPP

351 The added value of the DALEC2 cold temperature limitation for modeling mean spring (March-May) GPP
 352 is logically due to large fluctuations in spring temperature at Niwot Ridge. The cold temperature limitation allows
 353 DALEC2-CARDAMOM to match the IAV of spring tower-derived GPP closely. Furthermore, the cold temperature
 354 limitation enables the model to match tower spring IAV in the second half of the time period (2010-2018) when only
 355 the first ten years of GPP data are assimilated (2000-2009). This indicates that the cold temperature limitation is
 356 able to estimate spring GPP outside of its training window and could be useful at other sites where data availability
 357 is limited. Future work will include evaluating the cold temperature limitation at other sites to ensure that it is
 358 applicable beyond Niwot Ridge, for example using forecast skill metrics proposed by Famiglietti et al. (2021).

359 Temperature-induced spring onset of GPP is driven by two general processes: (1) initiation of bud burst
 360 and leaf expansion leading to increasing LAI, and/or (2) initiation of photosynthetic activity (photosynthetic
 361 efficiency i.e., GPP per unit of LAI) due to temperature-induced changes in plant hydraulics (Ishida et al., 2001;
 362 Pierrat et al., 2021) or kinetics of the photosynthetic machinery (e.g., Medlyn et al., 2002). In situ LAI
 363 measurements suggest that the LAI at Niwot Ridge is relatively constant across the season, which is somewhat
 364 expected given the dominant tree species at the site. Hence, the temperature-induced onset of GPP is likely due to

365 the latter process, increased photosynthetic efficiency, as supported by the measurements (Figs. 1-2), although small
366 changes in LAI are still feasible given uncertainties in the measurements. The inclusion of the cold temperature
367 limitation scaling factor in the model, a semi-empirical process, leads to a substantial improvement in model
368 representation of GPP at the site. Further development may also look to identify the relative roles of increased LAI
369 and increased photosynthetic efficiency at Niwot Ridge and other evergreen needleleaf sites, as changes in GPP can
370 lead to changes in carbon allocation to LAI, among other plant carbon pools.

371 Temperature is important in both the reactivation of photosynthetic activity in the spring and the wind
372 down of productivity in the fall (Flynn and Wolkovich, 2018; Stinziano and Way, 2017). Therefore, we anticipate
373 that the cold temperature scaling function may also improve our ability to model fall productivity. However, other
374 factors such as water availability and photoperiod must also be considered (Bauerle et al., 2012; Stinziano et al.,
375 2015). Future studies at Niwot Ridge and other sites should investigate the role of these factors (temperature, water,
376 photoperiod) in regulating fall GPP and how we can represent these processes in CARDAMOM.

377 With the inclusion of the cold temperature limitation on GPP and its application in CARDAMOM, we
378 provide a data-constrained estimate of the climate sensitivity of the Niwot Ridge forest to spring temperature.
379 Posterior estimates indicate that GPP is gradually inhibited below $6.0\text{ }^{\circ}\text{C} \pm 2.6\text{ }^{\circ}\text{C}$ (T_g) and completely inhibited
380 below $-7.1\text{ }^{\circ}\text{C} \pm 1.1\text{ }^{\circ}\text{C}$ (T_0). The gradual limitation of GPP by temperature has been observed on hourly and daily
381 timescales in other cold-weather ecosystems, such as Alaskan conifers (Parazoo et al., 2018) and Canadian spruce
382 (Pierrat et al., 2021). This has been connected to the triggering of transpiration and water flow from xylem into
383 leaves (Ishida et al., 2001). However, both biotic (e.g., carotenoid/chlorophyll ratios) and abiotic (e.g., openness of
384 canopy) factors together regulate GPP response to meteorological forcings, and further process-oriented
385 investigations are required to resolve the emergent response of GPP to temperature. For now, this is a useful metric
386 for climate-sensitivity of spring GPP, at least in the absence of long-term adaptations. Furthermore, over the 19 year
387 observation period investigated here the use of a temporally constant T_0 and T_g yields significantly improved GPP
388 estimates, suggesting that much of the variability can be attributed to climate-driven changes, not interannual
389 variation in vegetation parameters. As temperature continues to increase due to climate change (particularly in the
390 early growing season), productivity at US-NR1 could increase as a result and therefore increase carbon uptake, with
391 productivity peaking earlier in the year (e.g., Xu et al., 2016). However, these spring gains in GPP have been shown
392 to not offset the losses of carbon due to summer droughts (e.g., Buermann et al., 2013; Knowles et al., 2018). It is
393 also unclear how the long-term stress of increased temperature could affect forest productivity directly.

394 This study focuses on the relationship between temperature and GPP and its usefulness on model
395 predictions of spring GPP, but an important component that cannot be ignored is the confounding effect of water
396 availability on GPP. Future changes in winter precipitation are more uncertain, therefore limiting our ability to
397 analyze how precipitation changes will alter future productivity. While precipitation observations are analyzed to
398 discern any major connections between GPP and meteorological controls, an analysis of how precipitation affects
399 model predictability is not included in this study. The combined results, including the cold temperature limitation
400 and train-test data assimilation experiments, suggest that other factors besides spring temperature, most notably
401 winter and summer precipitation (Fig. S3) and resulting soil water limitation, also have important impacts on

402 summer GPP. We therefore highlight the need to jointly resolve springtime temperature limitation in conjunction
403 with water stress limitations in future efforts to understand the integrated role of environmental forcings on
404 interannual GPP variability. Furthermore, this analysis does not consider how winter precipitation as snowfall
405 versus rainfall affects productivity, or how resulting changes to winter snowpack could alter productivity long-term.
406 Since annual average GPP appears to be more dependent on winter precipitation/snowpack (Pearson's linear $r =$
407 0.63 , Fig. S3a), future work will include improving model predictability of late season productivity and quantifying
408 temperature-water effects on carbon uptake. The definition of the seasons could also alter the connections drawn
409 between seasonal temperature, precipitation and productivity.

410 3.3. Model intercomparison and implications for GPP models

411 Here, we evaluate DALEC2-CARDAMOM against mean spring GPP estimates from TBM-MIP models
412 (Section 2.5 and Parazoo et al. 2020). It is important to remind the reader that the CARDAMOM runs have a
413 significant advantage over the TBM-MIP models in this analysis, as CARDAMOM is trained on US-NR1 GPP data.
414 While TBM-MIP models use tower-observed meteorological inputs, prescribe tower-specific and time-invariant
415 structural properties such as LAI observed at US-NR1 (SiB3-exp2 and CLM4.5), and use data assimilation of global
416 remote sensing data to constrain globally representative plant functional types (ORCHIDEE-exp3), they are not
417 directly constrained by time-varying carbon fluxes at the tower. As such, we emphasize that our model comparison
418 is not a strict assessment of performance, but rather an attempt to learn how model simulation of GPP at an
419 evergreen needleleaf site can be improved.

420 There is a wide range in performance of TBM-MIPs in representing the magnitude and IAV of tower-
421 derived spring GPP (Figure 7a). Pearson's r correlations range from 0.25 to 0.82 (mean $r = 0.6$, Table 2) from 2001-
422 2018, with the same models showing slightly improved performance over the second decade (mean $r = 0.73$ from
423 2012-2018). ORCHIDEE-exp1 and CLM4.5 show consistently high performance over all three periods analyzed,
424 with CLM5.0 excelling from 2012-2018, and BEPS from 2015-2018 (Table S1). CLM4.5 also shows the smallest
425 mean bias of the TBM-MIP models (RMSE ~ 0.35), and high agreement in the magnitude of spring GPP variability
426 (1-sigma standard deviation = $0.21 \text{ g C m}^{-2} \text{ day}^{-1}$ for CLM4.5, vs $0.25 \text{ g C m}^{-2} \text{ day}^{-1}$ observed). While
427 acknowledging the advantage of data assimilation, it is promising to see that CARDAMOM (with the addition of the
428 cold temperature limitation) is able to perform comparably to the TBM-MIP models. In particular, CARDcold is
429 well correlated in the direction ($r = 0.88$) and magnitude (1-sigma ~ 0.26) of interannual variability, as well as overall
430 magnitude of spring GPP (low RMSE and MBE).

431 The range of performance across within-model experiments reveals important processes, and uncertainty of
432 process representation, in driving the magnitude and variability of spring GPP. For example, the ORCHIDEE data
433 assimilation experiment (exp3) shows consistently and substantially lower overall correlation (e.g., $r = 0.59$ from
434 2001-2018) than corresponding free running experiments (exp 1 and 2, $r = 0.78$ - 0.82), but has reduced RMSE and
435 MBE (RMSE = $0.63 \text{ g C m}^{-2} \text{ day}^{-1}$ vs $1.14 \text{ g C m}^{-2} \text{ day}^{-1}$). Likewise in SiB3, prescribing an empirically-based but
436 fixed-in-time LAI of $4.0 \text{ m}^2/\text{m}^2$ (exp2) reduces mean bias, but degrades variability ($r = 0.25$) compared to time-
437 variable LAI (exp1) prescribed from satellite data ($r = 0.50$).

438
439

440
441
442
443
444
445

Figure 7. Comparison of TBM-MIP models to CARD and CARDcold experiments for a.) mean spring GPP for 2000-2018 and b.) monthly GPP from 2015-2018. Note that fill values are ignored when calculating mean annual values for TBM-MIP experiments. Uncertainty = $\exp(\sqrt{\log(2)^2 * n/n})$, where $n = \#$ years in average ($n = 19$).

446 There is also large variability in the modeled seasonal cycle (Fig. 7b) and mean annual GPP (Fig. S9). For
447 mean annual GPP estimates, Pearson's r values are reduced for all models (Table S2). Once again, ORCHIDEE-
448 exp2 and ORCHIDEE-exp3 stand out with some of the higher correlations ($r = 0.60$ and $r = 0.64$) and p -values
449 below 5% significance level. Furthermore, ORCHIDEE-exp3 (temperature stress with SIF data assimilation) has
450 the lowest RMSE and MBE of the model set. SiB3-exp2 (fixed LAI) has a standard deviation closest to
451 "observations" ($0.14 \text{ gC m}^{-2} \text{ day}^{-1}$), and the smallest RMSE and MBE of the TBM models.

452 Most TBM-MIP models capture the shape of the seasonal cycle at Niwot Ridge. For the 2015-2018 period,
453 all models have Pearson's r values larger than 0.91, with p -values much smaller than a 5% significance level (Table

454 S3). With the help of data assimilation, CARDcold accurately captures the seasonal cycle at Niwot Ridge with
 455 reduced error (RMSE = 0.22 g C m⁻² day⁻¹, MBE = 0.07 g C m⁻² day⁻¹), and data assimilation experiments in
 456 ORCHIDEE-exp3 show reduced bias relative to free running experiments. The cold temperature limitation has little
 457 impact on the modeled mean seasonal cycle or mean annual GPP estimates in CARDAMOM, and appears to be
 458 most valuable for improving spring GPP variability.

459

460 **Table 2.** Pearson's linear r, R-squared, p-value, standard deviation, root mean square error (RMSE), and mean bias error (MBE)
 461 for TBM-MIP and all CARDAMOM experiments to Niwot Ridge tower-derived mean spring (March-May) GPP. Open values
 462 reflect statistics for the 2001-2018 period, while values in parentheses represent the 2012-2018 period. All relevant statistics are
 463 calculated at 5% significance level. *BEPs statistics are not included in this table as this model only has GPP estimates for 2015-
 464 2018.

model	r-value	R-squared	p-value ($\alpha = 0.05$)	RMSE (gC m ⁻² d ⁻¹)	MBE (gC m ⁻² d ⁻¹)	standard deviation (gC m ⁻² d ⁻¹)

465

466 In summary, TBM-MIP experiments reveal several key factors that can improve or degrade estimates of
 467 spring GPP at Niwot Ridge. For example, adapting model parameters to needleleaf species based on hand-tuning to
 468 tower data and formal data assimilation methods (CLM4.5 and ORCHIDEE-exp3, respectively) improves the
 469 overall magnitude of spring GPP. Likewise, prescribing LAI to a constant value of 4.0 m²/m² based on tower
 470 measurements (SiB3-exp2) improves year-to-year variability, while prescribing time variable LAI based on MODIS
 471 data improves spring GPP magnitude (SiB3-exp1). SiB4, which has prognostic rather than prescribed phenology,
 472 represents a compromise in magnitude and variability when looking at the entire record (2001-2018), but is one of
 473 the top performers across all TBM-MIP models over the most recent period (2012-2018).

474 We did not directly consider changes in canopy structural or biophysical characteristics in our
 475 CARDAMOM experiments. In CARDAMOM, LAI is a prognostic quantity (a function of foliar C and leaf carbon
 476 mass per area). In the absence of LAI observational constraints, CARDAMOM LAI is indirectly informed by the
 477 constraints of time-varying GPP on DALEC2 parameters (see section 2.3). Our results suggest that additional
 478 improvements are possible with careful consideration of in situ measured vegetation parameters.

479 TBM-MIP experiments also offer insight on important environmental controls and process representation.
480 Air temperature is an effective constraint of spring GPP onset (CLM4.5, ORCHIDEE-exp1, Figure 7 and Table 2),
481 but which can be degraded when large scale data assimilation does not account for local- to regional- vegetation
482 characteristics in parameter optimization (e.g., ORCHIDEE-exp3, Table 2). Water availability appears to be a
483 secondary but still important driver of spring GPP. While acknowledging the numerous differences between
484 CLM4.5 and CLM5.0, we find it important to note that plant hydraulic water stress (CLM5.0) shows improved IAV
485 performance (high correlation, Table 2) over simplified soil moisture stress functions (CLM4.5). This result further
486 supports efforts to closely analyze seasonal GPP to locate different environmental controls for future model
487 improvements.

488 Our study of the controls of cold temperature on GPP has important implications for modeling seasonal
489 productivity. First, future work must evaluate cold temperature limitation at other sites across an array of ecosystem
490 types. Additionally, it is important to determine if the temperature thresholds of photosynthesis initiation and
491 cessation are similar across locations, or unique to ecosystem type and/or site. Previous studies have had mixed
492 results, supporting both the use of customized temperature threshold parameters dependent on the site (Tanja et al.,
493 2003; Chang et al., 2020) or for a general parameter across multiple sites or biome type (Bergeron et al., 2007).
494 These differences could be due to variations in other variables (e.g., soil temperature, irradiance, etc.) and/or
495 physiological differences in the vegetation species. Identifying how photosynthesis temperature thresholds vary
496 across space and ecosystem type would be beneficial in improving model performance in simulating productivity.
497 Our model intercomparison study also provide insights on how we may improve our ability to model seasonal GPP.
498 For example, in Fig. 7b, we see that the ORCHIDEE model growing season starts too early. In the photosynthesis
499 module of ORCHIDEE, the temperature-dependency of parameters are described by Arrhenius or modified
500 Arrhenius functions following Medlyn et al. (2002) and Kattge and Knorr (2007). In general, the functions are used
501 to estimate the potential rates of Rubisco activity and electron transport based on temperature, as these rates are
502 needed to determine photosynthetic capacity (Medlyn et al., 2002). The lowest temperature for productivity
503 mentioned in these studies are 5°C and 11°C, respectively. Additionally, there is a test at the start of the
504 photosynthesis subroutine that prevents the computation of photosynthesis if the mean temperature over the last 20
505 days falls below -4°C. For our study, the only ORCHIDEE experiment that uses specific data related to the plant
506 functional type of this site (OCO-2 SIF data for US-NR1) is ORCHIDEE-exp3. This experiment improves the
507 general behavior of the modeled GPP seasonal cycle but does not improve ORCHIDEE's ability to capture the start
508 of the growing season. So with the future evaluation of cold temperature limitation at other sites and further study of
509 the potential temperature-influenced bias in the model, then ORCHIDEE (and other process-based models) may
510 need to improve its photosynthesis temperature-dependency for cold plant functional types. Therefore, we
511 recommend implementing a cold temperature GPP limitation in a process-based model to confirm its ability to
512 improve model performance. If we identify (1) how photosynthesis initiation and shutdown varies with temperature
513 and location, and (2) apply a cold temperature limitation successfully in a process-based model, then we could
514 expand our analyses to answer bigger Earth science questions. For example, we could use Earth System Model
515 temperature trends to determine how changing temperature will impact GPP in the future.

516 While further experiments are needed, these results demonstrate the value of (1) site level data assimilation
517 for local scale prediction of GPP magnitude and variability, (2) global data assimilation for reducing magnitude
518 biases, and (3) process formulation for accounting for sensitivity to temperature limitation and water stress. Overall,
519 these results are encouraging for model-data fusion systems which have developed the capacity to bring together
520 temporally and spatially resolved functional and structural vegetation components such as LAI, SIF, soil organic
521 matter, and above- and below-ground biomass (e.g., Bacour et al., 2019; Smith et al., 2020; Bloom et al., 2020).
522 Joint assimilation of these datasets, coupled with observed meteorological forcing, has potential to introduce more
523 emergent constraints of vegetation change with respect to environmental change, thus improving overall estimates of
524 productivity. Future work will assess the joint impact of SIF, ET, LAI, and biomass data as effective constraints on
525 light use and water use efficiency (Smith et al., 2020), which is expected to improve the ability of CARDAMOM to
526 use light with respect to increasing biomass subject to longer growing seasons and heat and water stress.

527 4. Conclusions

528 Despite mechanistic advances in ecosystem modeling, it is still a challenge to simulate temporal variations
529 in GPP. In an attempt to dissect the environmental controls on GPP in an evergreen needleleaf ecosystem, we
530 analyzed the impact of temperature on spring (March-May) productivity by implementing a cold temperature GPP
531 limitation within a model-data fusion system (DALEC2-CARDAMOM). The cold weather GPP limitation allows
532 for improved model estimates of mean spring productivity at Niwot Ridge, specifically CARDAMOM's ability to
533 match the interannual variability observed in tower-derived mean spring GPP. Furthermore, CARDAMOM is able
534 to match spring interannual variability between model and tower data outside of the training period. When
535 compared to TBM-MIP models, controls that appear to impact model performance include the inclusion of water
536 stress (e.g., soil moisture) and vegetation parameters (e.g., prescription of LAI). The fact that the cold temperature
537 limitation does not improve CARDAMOM's annual GPP estimates suggests that other controls (i.e. winter
538 precipitation) drive GPP variability in other parts of the year, most likely summer (June-September). The cold
539 temperature limitation may prove useful in understanding future changes in spring productivity due to changes in
540 temperature in other ecosystems as well.

541 Appendices

542 Appendix A: Model-Data Fusion Methodology

543 The DALEC2 model parameter values and state variable initial conditions (henceforth \mathbf{x}) are optimized
544 using a Bayesian inference approach, where the posterior probability distribution of \mathbf{x} given observations \mathbf{O} , $p(\mathbf{x}|\mathbf{O})$,
545 can be expressed as

$$546 p(\mathbf{x}|\mathbf{O}) \propto p(\mathbf{x})L(\mathbf{x}|\mathbf{O}) \quad (\text{A1})$$

547 Where $p(\mathbf{x})$ is the prior probability distribution of \mathbf{x} , and $L(\mathbf{x}|\mathbf{O})$ is the likelihood of the DALEC parameters
548 and initial conditions given observations \mathbf{O} . We define the likelihood function as

549
$$L(\mathbf{x}|\mathbf{o}) = e^{-\frac{1}{2}\sum_i \left(\frac{m_i(\mathbf{x})-o_i}{\sigma}\right)^2} + e^{-\frac{1}{2}\sum_a \left(\frac{m'_a(\mathbf{x})-o'_a}{\sigma'}\right)^2}, \quad (\text{A2})$$

550

551 where for monthly timestep i , $m_i(\mathbf{x})$ and o_i represent monthly modeled GPP (based on parameters \mathbf{x}) and
 552 flux-tower GPP observation, respectively. Following model-data fusion efforts with a spectrum of temporal modes
 553 of variability (Desai 2010, Quetin et al., 2020 and Bloom et al., 2020), we extend the cost function to include mean
 554 annual model and tower-derived GPP, $m'_a(\mathbf{x})$ and o'_a respectively) for year = a , which allows the GPP cost function
 555 to be sensitive to both seasonal and inter-annual components of the flux tower GPP signal. We log-transform
 556 modeled and tower-derived GPP values (as done in Bloom & Williams, 2015 and Bloom et al., 2016), which is
 557 preferable for characterize model-data residuals between strictly positive quantities (such as GPP). For lack of better
 558 uncertainty estimates on monthly and annual flux tower GPP accuracy—including lack of knowledge on GPP error
 559 characteristics at monthly timescales, error covariance between individual GPP estimates, model structural error
 560 impacts on GPP—we conservatively prescribed uncertainty factor of $\sigma = 2$ for monthly values (roughly ~75%), and
 561 $\sigma' = 1.2$ (~18%) for annual values; in general we found that these values led to robust agreements between flux
 562 tower and DALEC2 GPP variability (model-data mismatch metrics are reported in section 3 of the manuscript).

563 For all model experiments, we sample the probability of $p(\mathbf{x}|\mathbf{o})$, the posterior probability distribution of
 564 initial conditions \mathbf{x} given observations \mathbf{o} , we use four Metropolis-Hastings Markov Chain Monte Carlo (MHMCMC;
 565 Haario et al. 2001) for 10^8 iterations; we subsample 1000 parameter vectors \mathbf{x} , from the latter 50% of each chain (in
 566 total 1000 samples x 4 chains = 4000 samples). We test for convergence in the MHMCMC estimates of \mathbf{x} using a the
 567 Gelman-Rubin convergence diagnostic to measure convergence between the four chains.
