24 Abstract

25 The flow of carbon through terrestrial ecosystems and the response to climate is a critical but highly uncertain
26 process in the global carbon cycle. However, with a rapidly expanding array of in situ and satellite data, there is an
27 opportunity to improve our mechanistic understanding of the carbon (C) cycle's response to land use and climate
28 change. Uncertainty in temperature limitation on productivity pose a significant challenge to predicting the response
29 of ecosystem carbon fluxes to a changing climate. Here we diagnose and quantitatively resolve environmental
30 limitations on growing season onset of gross primary production (GPP) using nearly two decades of meteorological
31 and C flux data (2000-2018) at a subalpine evergreen forest in Colorado USA. We implement the CARDAMOM
32 model-data fusion network to resolve the temperature sensitivity of spring GPP. To capture a GPP temperature
33 limitation—a critical component of integrated sensitivity of GPP to temperature—we introduced a cold temperature
34 scaling function in CARDAMOM to regulate photosynthetic productivity. We found that GPP was gradually
35 inhibited at temperature below 6.0 °C (± 2.6 °C) and completely inhibited below -7.1 °C (± 1.1 °C). The addition of
36 this scaling factor improved the model's ability to replicate spring GPP at interannual and decadal time scales ($r =$
37 0.88), relative to the nominal CARDAMOM configuration ($r = 0.47$), and improved spring GPP model predictability
38 outside of the data assimilation training period ($r = 0.88$). While cold temperature limitation has an important
39 influence on spring GPP, it does not have a significant impact on integrated growing season GPP, revealing that
40 other environmental controls, such as precipitation, play a more important role in annual productivity. This study

41 highlights growing season onset temperature as a key limiting factor for spring growth in winter-dormant evergreen
42 forests, which is critical in understanding future responses to climate change.

43 1. Introduction

44 Northern hemisphere evergreen forests contribute significantly to terrestrial carbon (C) storage and exchange
45 (Beer et al., 2010; Thurner et al., 2014). High-elevation evergreen forests show increasing gross primary
46 productivity (GPP) with increasing temperature driven in large part by earlier growing seasons (Myneni et al., 1997;
47 Randerson et al., 1999; Forkel et al., 2016; Winchell et al., 2016, Lin et al., 2017). However, the response of gross
48 and net C fluxes to warming remains uncertain, especially in subalpine temperate forests, which can experience
49 freezing temperature while still absorbing large amounts of sunlight; both these factors ultimately influence the
50 timing and magnitude of GPP (Bowling et al. 2018). In particular, warmer springs can also lead to earlier snowmelt,
51 which can reduce spring C uptake through increased surface exposure to colder ablation-period air temperatures
52 (Winchell et al., 2016), and can reduce summer C uptake via drought (Hu et al., 2010). Many subalpine forests in
53 western North America are also highly water limited, with warming and earlier snow melt creating accumulated
54 water deficits, increased drought stress, and growing season C uptake losses (Wolf et al., 2016; Sippel et al., 2017;
55 Buermann et al., 2018, Goulden and Bales, 2019); these factors ultimately make subalpine forest ecosystems
56 sensitive to the direct and indirect effects of climate change and other disturbances, including the effects of droughts,
57 fires and insect infestations (Frank et al., 2014; Knowles et al., 2015). The uncertainty in the temperature sensitivity
58 of springtime GPP, increasing vulnerability to disturbance, and GPP modeling challenges (Anav et al., 2015) create
59 urgency to improve our ability to observe and model these ecosystems to understand how C exchange will be altered
60 in a warming climate.

61 Fortunately, availability of long term ecosystem observations is improving. The expansion of international
62 flux tower networks over the last three decades (e.g. AmeriFlux, FLUXNET, ChinaFLUX, ICOS) has greatly
63 improved C flux sampling across global ecosystems at 1 km scale (Baldocchi 2008; Baldocchi et al., 2018), and the
64 number of spaceborne sensors continues to grow, allowing global estimation of gross primary production (GPP) and
65 net ecosystem C exchange (NEE) over the last decade (e.g. Stavros et al., 2017; Sun et al., 2017; Schimel et al.,
66 2019). While uncertainties in estimating C fluxes from in situ and satellite data remain a challenge, the expanding
67 observational record offers a great opportunity to study the temperature sensitivity of subalpine forests at multiple
68 temporal scales.

69 The range of modeling tools available to quantify and study major C pools under ever growing
70 observational constraints is also increasing. Process-based models, in general terms, use explicit mathematical
71 relationships to mechanistically describe bio-physical processes (Korzukhin et al., 1996; Huxman et al., 2003;
72 Keenan et al., 2012). In contrast, model-data fusion (MDF) is a relatively new tool that alters model parameters to
73 statistically reduce mismatches between observations and model predictions (Raupach et al., 2005; Wang et al.,
74 2009; Keenan et al., 2012). MDF methods can be used to statistically represent the terrestrial C balance by
75 generating optimized state and process variable parameterizations, with uncertainties, which best match the signal
76 and noise in observations (Bloom et al., 2020).

77 Models of varying complexity and assimilation capabilities have been used to study how C exchange varies
78 with temperature in subalpine evergreen ecosystems (e.g., Moore et al., 2008; Scott-Denton et al., 2013; Knowles et
79 al., 2018). Moore et al. (2008) used a simplified ecosystem function model and assimilated C flux data from the
80 Niwot Ridge (US-NR1) subalpine evergreen forest AmeriFlux tower in Colorado to show the importance of accurate
81 meteorological forcing for parameter optimization and the usefulness of assimilating C flux data for determining
82 connections between the C and water cycles. Scott-Denton et al. (2013) integrated meteorological and flux data
83 from 1999-2008 from the same site with an ensemble of more sophisticated Earth System Models (ESM) and
84 showed higher rates of C uptake by the end of the 21st century associated with warming and lengthening growing
85 seasons, and driven by greater increases of spring GPP relative to late season respiration.

86 Interestingly, model and empirical studies of the C flux response to climate at US-NR1 focus on the 2000-
87 2011 period, which saw increasing summer drought coupled with sustained declines in spring temperature and GPP.
88 US-NR1 has since experienced a gradual recovery of spring GPP with increased spring warming throughout 2011-
89 2018 (Figure 1), which begs the question: what is the temperature sensitivity of spring GPP over multiple decades of
90 spring cooling and warming at US-NR1, and how well can data-constrained models reproduce long term variability?
91 To answer this question, we combine a mechanistic ecosystem C model (Data Assimilation Linked Ecosystem
92 Carbon, DALEC2; Williams et al., 2005; Bloom et al., 2016) with the CARbon DATA-MODEL framework
93 (CARDAMOM; Bloom and Williams, 2015; Bloom et al., 2020) driven by observed meteorological forcing and
94 constrained against eddy covariance fluxes at US-NR1, to investigate the temperature sensitivity of this subalpine
95 evergreen forest at seasonal and interannual timescales. We introduce a new cold temperature limitation function,
96 trained on observed temperature, for more realistic simulation of spring GPP onset. The use of high quality and long
97 term (2000-2018) meteorology and partitioned GPP data at US-NR1 to drive and constrain the model enables robust
98 statistical analysis of interannual variability (IAV), and assessment of “model predictability” through training and
99 validation against subsets of data. We also leverage a recent model intercomparison study (Parazoo et al., 2020),
100 driven by site level meteorological data at US-NR1, to provide a model benchmark assessment, and extract any
101 common environmental controls on modeled GPP. Finally, we examine whether decadal flux tower-derived GPP
102 observations are sufficiently robust to match and predict seasonal to annual GPP. Given the complexity of carbon-
103 water cycle interactions during the growing (summer) season in this highly water limited ecosystem, and the
104 relatively weak correlation between tower-derived spring and summer GPP ($r = -0.31$, $p = 0.20$), we focus on spring
105 GPP-temperature interactions, with the aim to resolve just one piece of the larger, complex problem of
106 understanding changes in C uptake in a subalpine evergreen ecosystem.

107 2. Materials & Methods

108 2.1. Study Site: Niwot Ridge, CO., USA

109 Our study focuses on an AmeriFlux (<https://ameriflux.lbl.gov/>) core site in Niwot Ridge, Colorado, USA
110 (US-NR1, 40°1'58''N; 105°32'47'' W), where a tower-based eddy covariance system has been continuously
111 measuring the net ecosystem exchange (NEE) of carbon dioxide over a subalpine forest since November 1998. The

112 26 m tall tower is located in a high elevation (3050 m) subalpine site in the Rocky Mountains of Colorado (Monson
113 et al., 2002). Located in an evergreen needleleaf (ENF) ecosystem, the dominant tree species include lodgepole pine
114 (*Pinus contorta*), subalpine fir (*Abies lasiocarpa*), and Engelmann spruce (*Picea engelmannii*) (Turnipseed et al.,
115 2002; Turnipseed et al., 2004). Average annual precipitation is 800 mm, with a majority of precipitation falling in
116 the winter as snow (Greenland, 1989; Knowles et al., 2015), which creates a persistent winter snowpack from
117 November through early June (Bowling et al., 2018).

118 2.2. Observations

119 NEE measurements are screened for calm conditions using the standard u_{star} filtering, gap-filled, and
120 partitioned into GPP and ecosystem respiration based on the relationship between nighttime NEE
121 (photosynthetically active radiation, $\text{PAR} < 50 \mu\text{mol m}^{-2} \text{s}^{-1}$) and air temperature (Reichstein et al., 2005; Wulzler et
122 al., 2018). Monthly averages of GPP based on nighttime partitioning show similar seasonal structure to results found
123 using an alternative daytime partitioning algorithm (Lasslop et al., 2010), so only nighttime partitioned GPP data are
124 reported here. All GPP estimates are processed as half hourly means, then averaged monthly. Details on the flux
125 measurements, data processing and quality control are provided in Burns et al. (2015).

126 2.3. The CARDAMOM Model-Data Fusion System

127 The CARbon DATA-MODEL FraMework (CARDAMOM; Bloom et al., 2016; Yin et al., 2020; Exbrayat et
128 al., 2018; Smallman et al., 2017; Quetin et al., 2020; Lopez-Blanco et al., 2017; Famiglietti et al., 2020; Bloom et
129 al., 2020; amongst others) uses carbon cycle and meteorological observations to constrain carbon fluxes, states and
130 process controls represented in the DALEC2 model of terrestrial C cycling (Williams et al., 2005; Bloom and
131 Williams, 2015). Specifically, CARDAMOM uses a Bayesian model-data fusion approach to optimize DALEC2
132 time-invariant parameters (such as leaf traits, allocation and turnover times) and the “initial” C and H₂O conditions
133 (namely biomass, soil and water states at the start of the model simulation period).

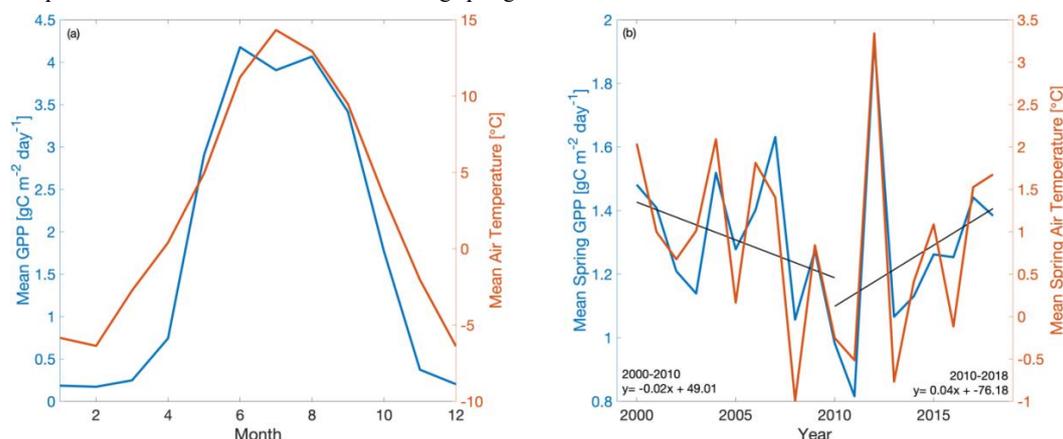

134 The DALEC model (Williams et al., 2005; Rowland et al. 2014; Fox et al., 2009; Richardson et al., 2010;
135 Famiglietti et al., 2020; Bloom & Williams, 2015; amongst others) is a box model of C pools connected via fluxes
136 that has been used to evaluate terrestrial carbon cycle dynamics across a range of ecosystems and spatial scales. In
137 all site, regional, and global applications, DALEC parameters are subject to very broad, but physically realistic, prior
138 distributions, and independently estimated and constrained by available observations at each grid point. Here we use
139 DALEC version 2 (DALEC2; Yin et al., 2020; Quetin et al., 2020; Bloom et al., 2020); gross and net carbon fluxes
140 are determined as a function of 33 parameters, which comprise of 26 time-invariant parameters relating to
141 allocation, turnover times, plant traits, respiration climate sensitivities, water-use efficiency and GPP sensitivity to
142 soil moisture, and 7 parameters describe the initial conditions of live biomass pools (live biomass C, dead organic C
143 and plant-available H₂O). Within DALEC2, GPP estimates are generated in the aggregated canopy model (ACM,
144 Williams et al., 1997); the ACM is derived from simple functional relationships with environmental and plant
145 structural and biochemical information (Williams et al., 1997), that are produced from a sensitivity analysis of GPP
146 estimates from the more comprehensive SPA land surface model scheme (Williams et al., 1996, Williams et al.,

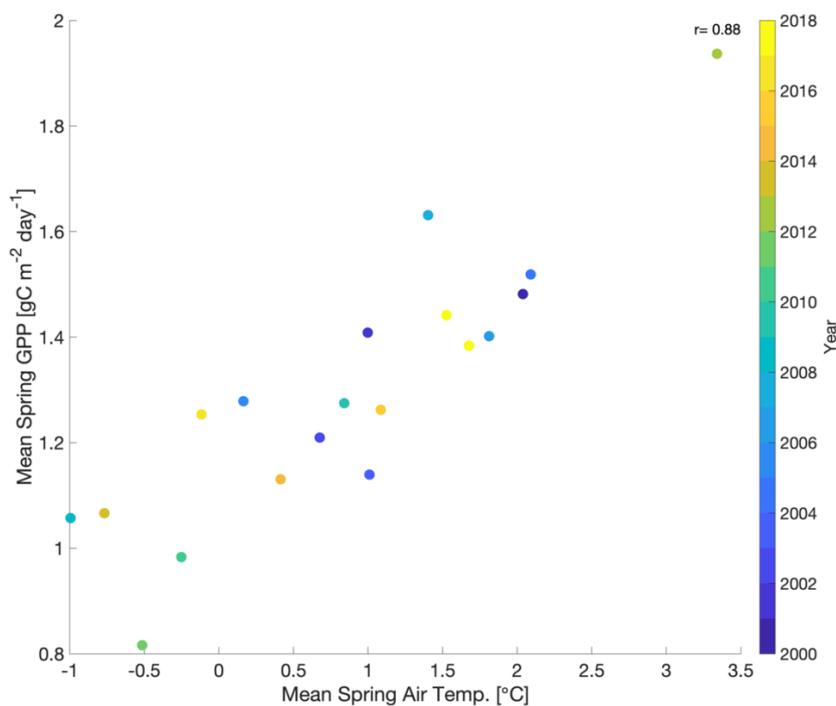

147 2001). ACM GPP estimates are contingent on plant structural and biochemical variables (including LAI, foliar
148 nitrogen and nitrogen-use efficiency) and meteorological forcings (total daily irradiance, maximum and minimum
149 daily temperature, day length, atmospheric CO₂ concentration). In DALEC2, water limitation on ACM is prescribed
150 as a linear response to soil water deficit (Bloom et al., 2020). For more details on the model-data fusion
151 methodology and CARD ensembles, we refer the reader to Appendix A. For a comprehensive overview of
152 DALEC2 model, we refer the reader to Bloom et al., (2020) and references therein.

153 2.4. Experiment Design

154 In order to develop model experiments that could reliably evaluate temperature-GPP interactions, we first
155 examine the observed environmental controls on tower-derived GPP. We focus on GPP during spring, defined here
156 in the traditional sense as the period from March-May, which encompasses the climatological onset of GPP and
157 transition from dormant winter conditions to peak summer conditions (Fig 1A). Mean spring GPP exhibits large
158 interannual variability (IAV) with both a small decreasing trend from 2000-2010 ($-0.02 \text{ g C m}^{-2} \text{ day}^{-1}$ per year) and
159 increasing trend from 2010-2018 ($0.04 \text{ g C m}^{-2} \text{ day}^{-1}$ per year) (Fig. 1B). Comparison to tower observed
160 temperature data (Fig. 1A and Fig. 2) shows that spring GPP is positively correlated to mean spring temperature
161 (Pearson's linear $r = 0.88$) and summer (June-September) temperature ($r = 0.08$). Mean winter (December-
162 February) precipitation also has a positive correlation with spring GPP, ($r = 0.07$, $p = 0.77$), but it is much smaller
163 than spring temperature. At interannual timescales, mean annual GPP shows a small increasing trend ($0.0072 \text{ g C m}^{-2}$
164 day^{-1} per year) over the time period (Fig. S1), and largest correlation with winter (December – February)
165 precipitation (Pearson's linear $r = 0.63$, Fig. S2) and shortwave irradiance ($r = -0.30$). In contrast, spring
166 temperature shows little correlation with mean annual GPP ($r = -0.03$, $p = 0.91$). It appears that winter precipitation
167 and total irradiance are the dominant drivers in annual productivity, both of which are correlated, while spring
168 temperatures show a first order effect in driving spring GPP.

169
170 **Figure 1.** Time series of (a) mean monthly GPP (blue) and air temperature (orange) and (b) mean spring (March-May) GPP and
171 air temperature at Niwot Ridge (US-NR1) from 2000-2018. GPP data are derived using a nighttime partitioning technique based
172 on tower observations of NEE and air temperature.

191

192

We also find that cold temperature has an important limitation on seasonal GPP at US-NR1. The seasonal cycle of GPP shows peak productivity in early summer (~June) and falling to near-zero values by early winter (November), continuing through late winter (February-March). Comparison of monthly GPP and minimum, maximum and mean monthly temperature shows an initiation of photosynthesis at monthly maximum temperature above 0 °C (Fig. 3a) and monthly minimum temperature above -5 °C (Fig. 3b). The strong dependence of monthly GPP on temperature is consistent with previous findings that temperature is an important driver of spring onset and seasonal variability of GPP in evergreen forests (e.g., Pierrat et al., 2021; Parazoo et al., 2018; Euskirchen et al., 2014; Arneeth et al., 2006). As temperature falls in winter dormant plants, productivity becomes negligible. Productivity is triggered again in spring when sufficient radiation is available for absorption by green needles, and air temperature becomes warm enough to thaw stems, trigger xylem flow and promote access to soil moisture (e.g., Pierrat et al., 2021; Bowling et al., 2018; Ishida et al., 2001). Due to this observed dependence of GPP on temperature at US-NR1, we focus our analysis specifically on spring GPP, where we hypothesize that cold temperature is the dominant control on spring GPP variability.

193
 194 **Figure 3.** Scatter plot of mean monthly GPP vs. a.) mean maximum air temperature, b.) mean minimum air temperature and c.)
 195 mean average air temperature for 2000-2018. Dots are colored with the corresponding month.
 196

197 In the baseline version of CARDAMOM, seasonal GPP in DALEC2 is limited primarily by incoming
 198 shortwave radiation. This light-focused limitation works well for deciduous forests where spring temperature and
 199 sunlight are correlated, as well as high latitude regions where sunlight is limited. However, for reasons discussed
 200 above, this method fails in evergreen forests such as Niwot Ridge whose green canopies are exposed to high sunlight
 201 and below-freezing temperature in spring. As such, we implement a cold temperature scaling factor (g) in DALEC2
 202 (1), to act as a thermostat that regulates evergreen needleleaf carbon uptake phenology. This scaling factor is
 203 developed by analyzing the relationship between monthly minimum & maximum temperature with tower-derived
 204 monthly GPP, where

205
$$\text{If: } T_{min}(t) < T_0 : g = 0 \quad (1)$$

206
$$\text{If: } T_{min}(t) > T_g : g = 1$$

207
$$\text{Else: } g(t) = \frac{(T_{min}(t) - T_0)}{(T_g - T_0)}$$

208
$$\text{GPP}_{cold}(t) = \text{GPP}(t) * g(t) \quad (2)$$

209 where $GPP(t)$ is the nominal ACM-based DALEC2 GPP estimate (see section 2.3) and GPP_{cold} is the corresponding
 210 cold temperature GPP estimate. The temperature thresholds for photosynthesis shutdown (referred to as T_0) and
 211 initiation (referred to as T_g) are added as model parameters in DALEC, bringing the total number of parameters to
 212 35. These 35 DALEC parameters are simultaneously optimized in CARDAMOM. The CARDAMOM Bayesian-
 213 inference probability distributions (see Appendix A) for the T_0 (-7.1 ± 1.1 °C) and T_g (6.0 ± 2.6 °C) parameters used
 214 to define the cold temperature limitation are plotted in Fig S3. We refer to the cold temperature constrained version
 215 of DALEC2 (within CARDAMOM) as DALEC2cold.

216 The baseline (DALEC2) and cold temperature (DALEC2cold) versions of the model are run for the 2000-
 217 2018 period using tower observed, gap-filled, monthly meteorological (MET) drivers (including minimum and
 218 maximum temperature, shortwave radiation, vapor pressure deficit, and precipitation). We conduct four
 219 experiments, summarized in Table 1: experiments using DALEC2 and DALEC2cold within CARDAMOM, where
 220 19 years of GPP data are assimilated (referred to as CARD and CARDcold), and a corresponding pair of
 221 experiments where only the first decade of data (2000-2009) is assimilated (referred to as CARD-Half and
 222 CARDcold-Half) and the second decade of data (2010-2019) is withheld for validation, as a train-test scenario. All
 223 months of GPP data are assimilated into the model, however our analysis focuses on the constraints on spring
 224 (March-May) GPP. These four experiments serve to evaluate the sensitivity of modelled GPP at Niwot Ridge to cold
 225 temperature limitation, parameter optimization, and data assimilation. Specifically, the objective of experiments
 226 “CARD” and “CARDcold” is to determine whether the cold temperature scaling factor improves the representation
 227 of spring GPP variability across the 2000-2018 period; the objective of experiments “CARD-Half” and “CARDcold-
 228 Half” is to cross-validate the predictive skill of CARDcold by assessing whether the addition of a cold temperature
 229 scaling factor, informed by a subset of GPP data, can improve prediction of a withheld subset of GPP data.

230

231 **Table 1.** Summary of CARDAMOM modeling experiments to determine sensitivity of seasonal and interannual spring GPP
 232 variability to cold temperature limitation (CARD vs CARDCold) and ability to perform outside training window (Half).

Experiment Name	Met. Drivers	Time Period	GPP assimilation	Time period considered in assimilation	Uncertainties in GPP	Cold Temp. Limitation
CARD	yes	2000-2018	yes	2000-2018	20%	No
CARD-Half	yes	2000-2018	yes	2000-2009	20%	No
CARDCold	yes	2000-2018	yes	2000-2018	20%	Yes
CARDCold-Half	yes	2000-2018	yes	2000-2009	20%	Yes

233

234 2.5. Comparison to Terrestrial Biosphere Model Ensemble

235 A recent model intercomparison study provides an ideal benchmark for evaluating CARDAMOM
236 simulations (section 2.4). Parazoo et al. (2020) conducted an experiment in which an ensemble of state-of-the-art
237 terrestrial biosphere models (TBMs) were forced by the same observed meteorology at Niwot Ridge from 2000-2018,
238 but with differences in spin-up, land surface characteristics, and parameter tuning. The TBMs are designed to simulate
239 the exchanges of carbon, water, and energy between the biosphere and atmosphere, from global to local scales
240 depending on inputs from meteorological forcing, soil texture, and plant functional type. The experiment is designed
241 primarily to evaluate simulations of solar induced fluorescence (SIF) and GPP, the latter of which we focus on here.
242 We refer the reader to Parazoo et al. (2020) for a more complete description of models, within-model experiments,
243 and between-model differences.

244 The most important model differences worth noting here include the representation of stomatal-conductance,
245 canopy absorption of incoming radiation, and limiting factors for photosynthesis. We analyze a subset of the models
246 which were run for multiple years, including SiB3 and SiB4 (Simple Biosphere model versions 3 and 4, respectively),
247 ORCHIDEE (Organizing Carbon and Hydrology in Dynamic Ecosystems), BEPS (Boreal Ecosystems Productivity
248 Simulator), and CLM4.5 and CLM5.0 (Community Land Model Versions 4.5 and 5.0, respectively). We also analyze
249 within-model experiments in SiB3 and ORCHIDEE to isolate effects related to prescription of leaf area index (LAI;
250 monthly varying in SiB3-exp1, fixed at 4.0 m²/m² in SiB3-exp2), temperature and water stress (ORCHIDEE-exp1
251 includes temperature stress; ORCHIDEE-exp2 accounts for temperature and water stress), and data assimilation
252 (ORCHIDEE-exp3, in which a subset of model parameters controlling photosynthesis and phenology are optimized
253 against global OCO-2 SIF data, Bacour et al., 2019). Finally, we note that not all model simulations span the entire
254 observed record (2000-2018). While our analysis focuses on the long term record from 2000-2018, we provide
255 multiple comparison to ensure consistency of time period: (1) IAV from 2001-2018 for SiB3, SiB4, ORCHIDEE, and
256 CLM4.5; (2) IAV from 2012-2018 for SiB3, SiB4, ORCHIDEE, CLM4.5, and CLM5.0, (3) Seasonal variability from
257 2015-2018 for all models. We refer to the ensemble of models and within model experiments collectively as TBM-
258 MIP.

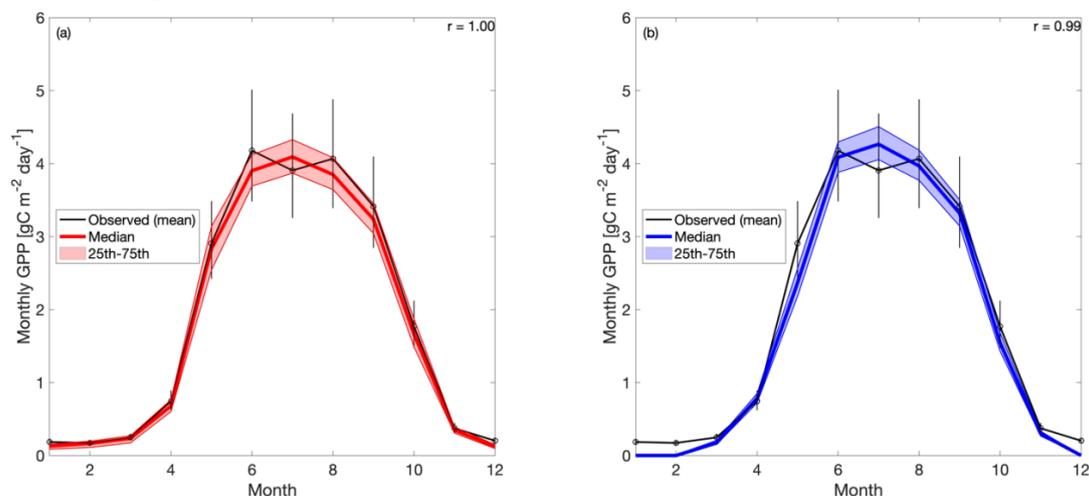

259 3. Results & Discussion

260 3.1. Evaluation of CARDAMOM 2000–2018 GPP

261 When the 19 years of tower-derived GPP data are assimilated into both versions of the model, the mean
262 seasonal cycle is accurately replicated (Fig. 4). The Pearson's r values for CARD (Fig. 4a) and CARDcold (Fig. 4b)
263 are almost equal ($r = 1.0$ and 0.99) with minimal increases in root mean square error (RMSE) and mean bias error
264 (MBE) for CARDcold (RMSE = $0.24 \text{ g C m}^{-2} \text{ day}^{-1}$ and $0.23 \text{ g C m}^{-2} \text{ day}^{-1}$, MBE = $0.06 \text{ g C m}^{-2} \text{ day}^{-1}$ and 0.19 g C
265 $\text{m}^{-2} \text{ day}^{-1}$ for CARD and CARDcold, respectively). Assimilating only the first decade of GPP data (Half
266 experiments) does not drastically alter model performance (Fig. S4), with only slight changes in RMSE and MBE

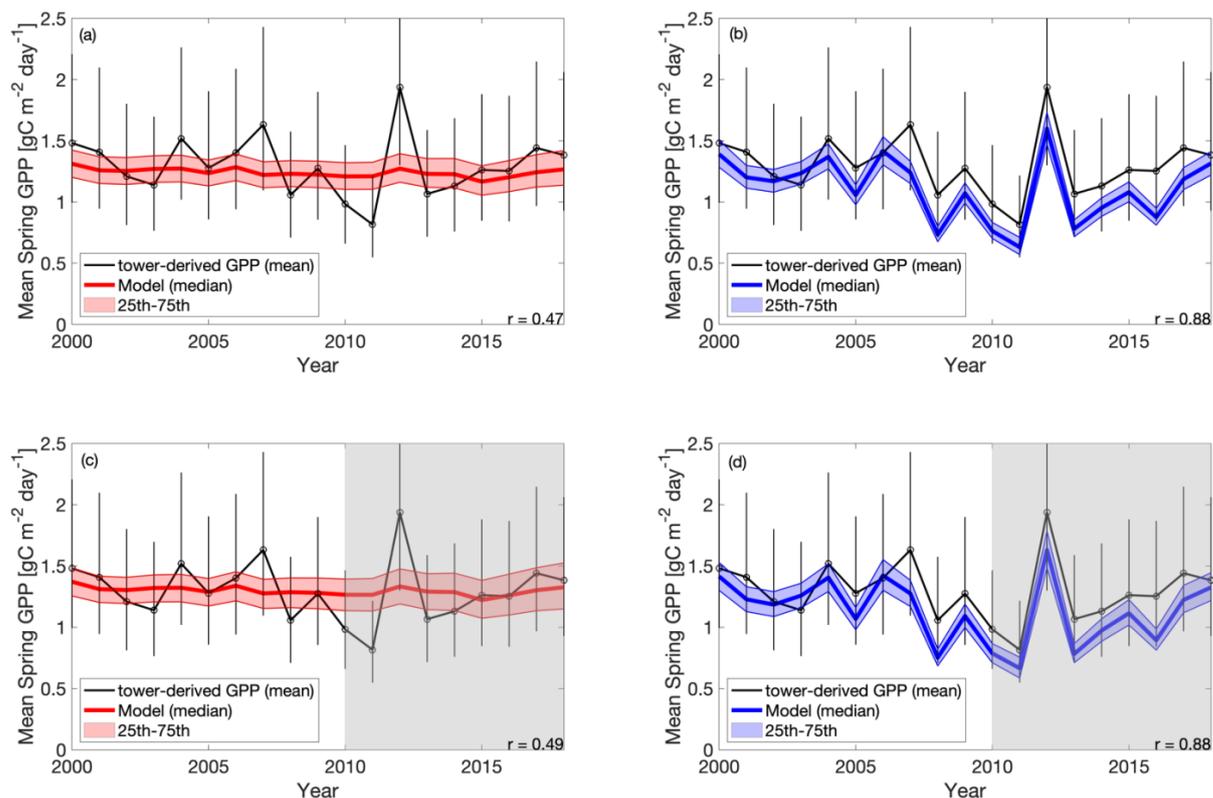

267 ($\Delta\text{RMSE} = 0.008 \text{ g C m}^{-2} \text{ day}^{-1}$, $\Delta\text{MBE} = 0.03 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARD-Half, $\Delta\text{RMSE} = -0.003 \text{ g C m}^{-2} \text{ day}^{-1}$,
268 $\Delta\text{MBE} = 0.02 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARDcold-Half).

269
270 **Figure 4.** Tower-derived average monthly GPP (black line) and modeled GPP seasonal cycles at US-NR1, averaged for 2000-
271 2018, for a.) CARD and b.) CARDcold experiments. The half-assimilation experiments (CARD-Half and CARDcold-Half) can
272 be found in the supplement (Fig S4). Model outputs include the median value of each experiment (bold color line) with the 25th-
273 75th percentiles of the ensembles (shaded area). The median is plotted instead of the mean to avoid impact of outlier ensemble
274 members (N = 4000). Error bars = tower-derived GPP multiplied/divided by $\exp(\sqrt{\log(2)^2 * n}/n)$, n=# of years in average (n
275 = 19). 'r' is the Pearson's coefficient.

276
277 The cold experiments exhibit an improved fit to the observed IAV in spring productivity (Fig. 5), relative to
278 CARD, ($r = 0.47$, $\text{std} = 0.03 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARD; $r = 0.88$, $\text{std} = 0.27 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARDcold). CARDcold
279 also has slightly reduced RMSE ($-0.01 \text{ g C m}^{-2} \text{ day}^{-1}$) and larger MBE ($0.13 \text{ g C m}^{-2} \text{ day}^{-1}$). Similar to the seasonal
280 cycle analysis, the assimilation of only the first decade of GPP data (Half experiments) has minimal impact on
281 model performance ($\Delta\text{RMSE} = 0.007 \text{ g C m}^{-2} \text{ day}^{-1}$, $\Delta\text{MBE} = 0.06 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARD-Half, and $\Delta\text{RMSE} =$
282 $0.02 \text{ g C m}^{-2} \text{ day}^{-1}$, $\Delta\text{MBE} = 0.02 \text{ g C m}^{-2} \text{ day}^{-1}$ for CARDcold-Half). We find less agreement between modelled and
283 tower-derived GPP IAV in summer for both CARD and CARDcold (CARD $r = 0.32$, $\text{std} = 0.11 \text{ g C m}^{-2} \text{ day}^{-1}$;
284 CARDcold $r = 0.05$, $\text{std} = 0.10 \text{ g C m}^{-2} \text{ day}^{-1}$; Fig. S5). While there is little variation in RMSE between the half and
285 full-assimilation experiments, RMSE is larger for summer than spring GPP (average RMSE = $0.23 \text{ g C m}^{-2} \text{ day}^{-1}$ for
286 spring model outputs, average RMSE = $0.35 \text{ g C m}^{-2} \text{ day}^{-1}$ for summer model outputs). Model agreement is further
287 reduced when considering annual average GPP (Fig. S6, Table S2). Although the cold temperature limitation
288 improves IAV slightly, it is still small compared to observed variability ($\text{std} = 0.14 \text{ g C m}^{-2} \text{ day}^{-1}$). Correlations to
289 tower-derived GPP at the annual scale are small for both CARD and CARDcold ($r = 0.19$ and $r = 0.22$, Fig. S6a-b).
290 Overall, the cold temperature limitation substantially improves agreement between the model and tower-derived
291 spring GPP, with slight reductions in performance for summer and annual GPP.

292

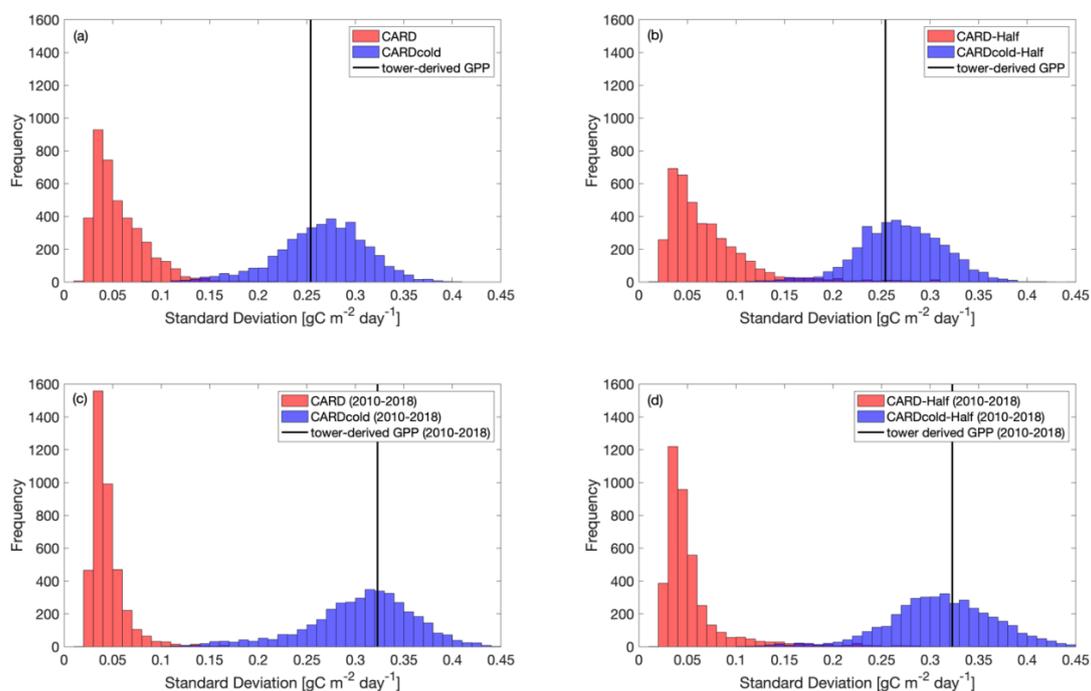

293
 294 **Figure 5.** Tower-derived (black line) mean spring (March-May) GPP with model interquartile range (shaded area) and median
 295 (bold color line) spring GPP outputs for a.) CARD, b.) CARDcold, c.) CARD-Half, and d.) CARDcold-Half experiments. The
 296 grey regions indicate no data assimilation (i.e. testing window). Model experiments are the same as in Figure 4. Uncertainty =
 297 $\exp(\sqrt{\log(2)^2 * n})/n$, n = # of months in average ($n = 3$).
 298

299 The standard deviation in tower-derived mean spring GPP (March-May) is approximately $0.25 \text{ g C m}^{-2} \text{ day}^{-1}$
 300 ¹. The addition of the cold temperature limitation improves the model's ability to match the IAV of mean spring
 301 GPP (Fig. 6a-b). An examination of all modeled scenarios for CARD and CARDcold (i.e. all 4000 DALEC2
 302 simulations), shows that the cold temperature limitation produces spring IAV values much closer to what is
 303 observed in the tower-derived GPP data. Only 0.3% of CARD ensembles produces mean spring IAV values within
 304 20% of the tower-derived spring GPP standard deviation ($0.25 \pm 0.05 \text{ g C m}^{-2} \text{ day}^{-1}$), whereas 69% of CARDcold
 305 ensembles have standard deviation values within the same range. Interestingly, assimilating only the first ten years
 306 of GPP data (Half experiments, Fig. 6b) slightly increases the number of ensemble members with standard
 307 deviations within the mentioned range for both CARD-Half (2.4%) and CARDcold-Half (70%). It is promising to
 308 see that despite not assimilating the 2010-2018 GPP data into the model, CARDcold-Half is still able to match
 309 average spring IAV of the full data record.

310 We also consider the IAV in spring GPP for just the second half of the data record (2010-2018). IAV of
 311 tower-derived spring GPP increases slightly in 2010-2018 ($0.32 \text{ g C m}^{-2} \text{ day}^{-1}$). Once again, the cold temperature
 312 limitation enables CARDAMOM to match spring GPP IAV (Fig. 6c-d). 0.03% of CARD ensembles produce mean

313 spring IAV values within 20% of the tower-derived spring GPP standard deviation for the 2010-2018 period ($0.32 \pm$
314 $0.06 \text{ g C m}^{-2} \text{ day}^{-1}$), whereas 76% of CARDcold ensembles have standard deviation values within the same range.
315 For the Half experiments, 0.6% of CARD and 75% of CARDcold ensembles have IAV values within 20% of the
316 standard deviation for 2010-2018. Overall, CARDcold produces a less biased distribution of IAV values (relative to
317 both assimilated and withheld observations), whereas CARD is more skewed towards smaller IAVs, which indicates
318 that the cold temperature limitation enables a mechanistic and statistical improvement in capturing the interannual
319 variability of spring GPP.
320

321
322 **Figure 6.** Histograms comparing standard deviation in mean spring GPP across all ensembles ($N=4000$) for CARD (red bars) and
323 CARDcold (blue bars) experiments with a.) full assimilation, b.) half assimilation, c.) full assimilation for the second decade
324 (2010-2018), and d.) half assimilation for the second decade (2010-2018). Black line indicates standard deviation in tower-
325 derived mean spring GPP (std = $0.25 \text{ gC m}^{-2} \text{ day}^{-1}$ for full period, std = $0.32 \text{ gC m}^{-2} \text{ day}^{-1}$ for 2010-2018).
326

327 3.2. Temperature controls on springtime GPP

328 The added value of the DALEC2 cold temperature limitation for modelling mean spring (March-May) GPP
329 is logically due to large fluctuations in spring temperature at Niwot Ridge. The cold temperature limitation allows
330 DALEC2-CARDAMOM to match the IAV of spring tower-derived GPP closely. Furthermore, the cold temperature
331 limitation enables the model to match tower spring IAV in the second half of the time period (2010-2018) when only
332 the first ten years of GPP data are assimilated (2000-2009). This indicates that the cold temperature limitation is
333 able to estimate spring GPP outside of its training window and could be useful at other sites where data availability

334 is limited. Future work will include evaluating the cold temperature limitation at other sites to ensure that it is
335 applicable beyond Niwot Ridge, for example using forecast skill metrics proposed by Famiglietti et al. (2020).
336 Temperature-induced spring onset of GPP is driven by two general processes (1) initiation of bud burst and
337 leaf expansion leading to increasing LAI, and/or (2) initiation of photosynthetic activity (photosynthetic efficiency
338 i.e. GPP per unit LAI) due to temperature-induced changes in plant hydraulics (Ishida et al., 2001; Pierrat et al.,
339 2021) or kinetics of the photosynthetic machinery (e.g. Medlyn et al., 2002). In-situ LAI measurements suggest that
340 the LAI at Niwot Ridge is relatively constant across the season, which is somewhat expected given the dominant
341 tree species at the site. Hence, the temperature-induced onset of GPP is likely due to the latter process, increased
342 photosynthetic efficiency, as supported by the measurements (Fig. 2), although small changes in LAI are still
343 feasible given uncertainties in the measurements. The inclusion of the cold-temperature limitation scaling factor in
344 the model, a semi-empirical process, leads to a substantial improvement in model representation of GPP at the site.
345 Further development may look to identify the relative roles of increased LAI and increased photosynthetic efficiency
346 at Niwot Ridge and other evergreen needleleaf sites, as changes in GPP can lead to changes in carbon allocation to
347 LAI, among other plant carbon pools.

348 With the inclusion of the cold-temperature limitation on GPP and its application in CARDAMOM we
349 provide a data-constrained estimate of the climate-sensitivity of the Niwot Ridge forest to spring temperatures.
350 Posterior estimates indicate that GPP is gradually inhibited below $6.0\text{ °C} \pm 2.6\text{ °C}$ (T_g) and completely inhibited
351 below $-7.1\text{ °C} \pm 1.1\text{ °C}$ (T_0). The gradual limitation of GPP by temperature has been observed on hourly and daily
352 timescales in other cold-weather ecosystems, such as Alaskan conifers (Parazoo et al., 2018) and Canadian spruce
353 e(Pierret et al., 2020). This has been connected to the triggering of transpiration and water flow from xylem into
354 leaves (Ishida et al., 2001). However, both biotic (carotenoid/chlorophyll ratios) and abiotic (canopy airspace)
355 factors together regulate GPP response to meteorological forcings, and further process-oriented investigations are
356 required to resolve the emergent response of GPP to temperature. For now, this is a useful metric for climate-
357 sensitivity of spring GPP, at least in the absence of long-term adaptations. Furthermore, over the 19 year observation
358 period investigated here the use of a temporally constant T_0 and T_g yields significantly improved suggesting that
359 much of the variability can be attributed to climate-driven changes, not interannual variation in vegetation
360 parameters. As temperature continues to increase due to climate change (particularly in the early growing season),
361 productivity at US-NR1 could increase as a result and therefore increase carbon uptake, with productivity peaking
362 earlier in the year (e.g., Xu et al., 2016). However, these spring gains in GPP have been shown to not offset the
363 losses of carbon due to summer droughts (e.g., Buermann et al., 2013; Knowles et al., 2018). It is also unclear how
364 the long-term stress of increased temperature could affect forest productivity directly.

365 This study focuses on the relationship between temperature and GPP and its usefulness on model
366 predictions of spring GPP, but an important component that cannot be ignored is the confounding effect of water
367 availability on GPP. Future changes in winter precipitation are more uncertain, therefore limiting our ability to
368 analyze how precipitation changes will alter future productivity. While precipitation observations are analyzed to
369 discern any major connections between GPP and meteorological controls, an analysis of how precipitation affects
370 model predictability is not included in this study. The combined results, including the cold temperature limitation

371 and train-test data assimilation experiments, suggest that other factors besides spring temperature, most notably
372 winter and summer precipitation (Fig. 2) and resulting soil water limitation, also have important impacts on summer
373 GPP. We therefore highlight the need to jointly resolve spring-time temperature limitations in conjunction with
374 water stress limitations in future efforts to understand the integrated role of environmental forcings on interannual
375 GPP variability. Furthermore, this analysis does not consider how winter precipitation as snowfall versus rainfall
376 affected productivity, or how resulting changes to winter snowpack could alter productivity long-term. Since annual
377 average GPP appears to be more dependent on winter precipitation/snowpack, future work will include improving
378 model predictability of late season productivity and quantifying temperature-water effects on carbon uptake. The
379 definition of the seasons could also alter the connections drawn between seasonal temperature, precipitation and
380 productivity.

381 3.3. Model intercomparison and implications for GPP models

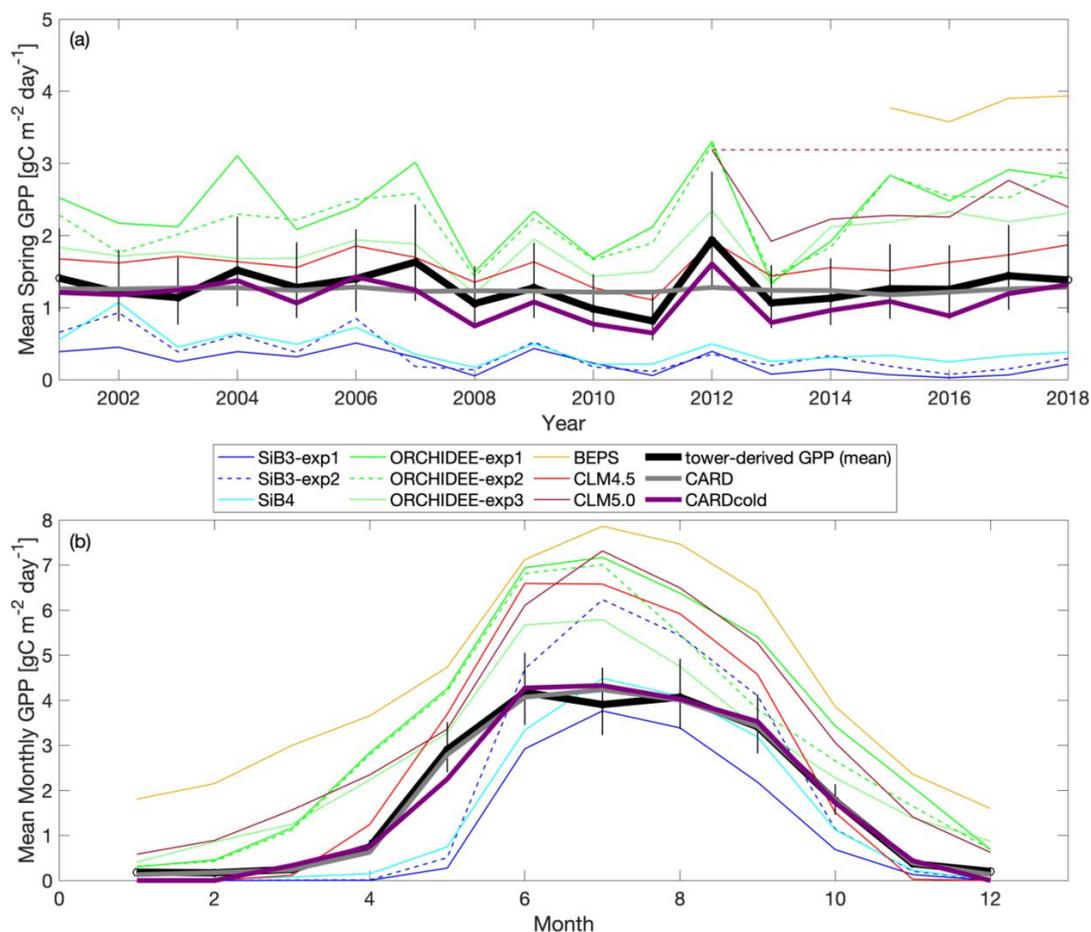

382 Here, we evaluate DALEC2-CARDAMOM against mean spring GPP estimates from TBM-MIP models
383 (Section 2.5 and Parazoo et al. 2020). It is important to remind the reader that the CARDAMOM runs have a
384 significant advantage over the TBM-MIP models in this analysis, as CARDAMOM is trained on US-NR1 GPP data.
385 While TBM-MIP models use tower-observed meteorological inputs, prescribe tower-specific and time-invariant
386 structural properties such as LAI observed at US-NR1 (SiB3-exp2 & CLM4.5), and use data assimilation of global
387 remote sensing data to constrain globally-representative plant functional types (ORCHIDEE-exp3), they are not
388 directly constrained by time-varying carbon fluxes at the tower. As such, we emphasize that our model comparison
389 is not a competition, but rather an attempt to discern common environmental controls in model performance of
390 simulating the magnitude and seasonal-to-interannual variability of spring GPP at an evergreen needleleaf site.

391 There is a wide range in performance of TBM-MIPs in representing the magnitude and IAV or tower-
392 derived spring GPP (Figure 7a). Pearson's r correlations range from 0.25 to 0.82 (mean $r = 0.6$, Table 2) from 2001-
393 2018, with the same models showing slightly improved performance over the second decade (mean $r = 0.73$ from
394 2012-2018). ORCHIDEE-exp1 and CLM4.5 show consistently high performance over all three periods analyzed,
395 with CLM5.0 excelling from 2012-2018, and BEPS from 2015-2018 (Table S1). CLM4.5 also shows smallest mean
396 bias of the TBM-MIP models (RMSE ~ 0.35), and high agreement in the magnitude of spring GPP variability (1-
397 sigma standard deviation = $0.21 \text{ g C m}^{-2} \text{ day}^{-1}$ for CLM4.5, vs $0.25 \text{ g C m}^{-2} \text{ day}^{-1}$ observed). While acknowledging
398 the advantage of data assimilation, it is promising to see that CARDAMOM (with the addition of the cold
399 temperature limitation) is able to perform comparably to the TBM-MIP models. In particular, CARDcold is well
400 correlated in the direction ($r = 0.88$) and magnitude (1-sigma ~ 0.26) of interannual variability, as well as overall
401 magnitude of spring GPP (low RMSE and MBE).

402 The range of performance across within-model experiments reveals important processes, and uncertainty of
403 process representation, in driving the magnitude and variability of spring GPP. For example, the ORCHIDEE data
404 assimilation experiment (exp3) shows consistently and substantially lower overall correlation (e.g., $r = 0.59$ from
405 2001-2018) than corresponding free running experiments (exp 1 and 2, $r = 0.78$ - 0.82), but has reduced RMSE and
406 MBE (RMSE = $0.63 \text{ g C m}^{-2} \text{ day}^{-1}$ vs 1 - $1.14 \text{ g C m}^{-2} \text{ day}^{-1}$). Likewise in SiB3, prescribing an empirically-based but

407 fixed-in-time LAI (exp2) reduces mean bias, but degrades variability ($r = 0.25$) compared to time-variable LAI
 408 (exp1) prescribed from satellite data ($r = 0.50$).
 409
 410

411
 412
 413 **Figure 7.** Comparison of TBM-MIP models to CARD and CARDcold experiments for a.) mean spring GPP and b.) monthly
 414 GPP. Note that fill values are ignored when calculating mean annual values for TBM-MIP experiments. Uncertainty =
 415 $\exp(\sqrt{\log(2)^2 \cdot n/n})$, where $n = \#$ years in average ($n = 19$).
 416

417 There is also large variability in the modeled seasonal cycle (Fig. 7b) and mean annual GPP (Fig. S7). For
 418 mean annual GPP estimates, Pearson’s r values are reduced for all models (Table S2). Once again, ORCHIDEE-
 419 exp2 and ORCHIDEE-exp3 stand out with some of the higher correlations ($r = 0.60$ and $r = 0.64$) and p -values
 420 below 5% significance level. Furthermore, ORCHIDEE-exp3 (temperature stress with SIF data assimilation) has
 421 the lowest RMSE and MBE of the model set. SiB3-exp2 (fixed LAI) has a standard deviation closest to
 422 “observations” ($0.14 \text{ gC m}^{-2} \text{ day}^{-1}$), and the smallest RMSE and MBE of the TBM models.

423 Most TBM-MIP models capture the shape of the seasonal cycle at Niwot Ridge. For the 2015-2018 period,
 424 all models have Pearson's r values larger than 0.91, with p -values much smaller than a 5% significance level (Table
 425 S3). With the help of data assimilation, CARDcold accurately captures the seasonal cycle at Niwot Ridge with
 426 reduced error (RMSE = 0.22 g C m⁻² day⁻¹, MBE = 0.07 g C m⁻² day⁻¹), and data assimilation experiments in
 427 ORCHIDEE-exp3 show reduced bias relative to free running experiments. The cold temperature limitation has little
 428 impact on the modeled mean seasonal cycle or mean annual GPP estimates in CARDAMOM, and appears to be
 429 most valuable for improving spring GPP variability.

430

431 **Table 2.** Pearson's linear r , R-squared, p -value, standard deviation, root mean square error (RMSE), and mean bias error (MBE)
 432 for TBM-MIP and all CARDAMOM experiments to Niwot Ridge tower-derived mean spring (March-May) GPP. Open values
 433 reflect statistics for the 2001-2018 period, while values in parentheses represent the 2012-2018 period. All relevant statistics are
 434 calculated at 5% significance level. *BEPs statistics are not included in this table as this model only has GPP estimates for 2015-
 435 2018.

model	r-value	R-squared	p-value ($\alpha = 0.05$)	RMSE (gC m ⁻² d ⁻¹)	MBE (gC m ⁻² d ⁻¹)	standard deviation (gC m ⁻² d ⁻¹)
CARD-Half	0.47 (0.55)	0.22 (0.30)	0.05 (0.20)	0.24 (0.26)	-0.005 (0.06)	0.03 (0.04)

CLM5.0	(0.96)	(0.92)	(0.00)	(1.09)	(-1.08)	(0.42)

436

437 In summary, TBM-MIP experiments reveal several key factors that can improve or degrade estimates of
 438 spring GPP at Niwot Ridge. For example, adapting model parameters to needleleaf species based on hand-tuning to
 439 tower data and formal data assimilation methods (CLM4.5 and ORCHIDEE-exp3, respectively) improves the
 440 overall magnitude of spring GPP. Likewise, prescribing LAI to a constant value of 4.0 m²/m² based on tower
 441 measurements (SiB3-exp1) improves spring GPP magnitude, while prescribing time variable LAI based on MODIS
 442 data improves year-to-year variability (SiB3-exp2). SiB4, which has prognostic rather than prescribed phenology,
 443 represents a compromise in magnitude and variability when looking at the entire record (2001-2018), but is one of
 444 the top performers across all TBM-MIP models over the most recent period (2012-2018).

445

446 We did not directly consider changes in canopy structural or biophysical characteristics in our
 447 CARDAMOM experiments. In CARDAMOM, LAI is a prognostic quantity (a function of foliar C and leaf carbon
 mass per area). In the absence of LAI observational constraints, CARDAMOM LAI is indirectly informed by the

448 constraints of time-varying GPP on DALEC2 parameters (see section 2.3). Our results suggest that additional
449 improvements are possible with careful consideration of in-situ measured vegetation parameters.

450 TBM-MIP experiments also offer insight on important environmental controls and process representation.
451 Air temperature is an effective constraint of spring GPP onset (CLM4.5, ORCHIDEE-exp1), but which can be
452 degraded when large scale data assimilation does not account for local- to regional- vegetation characteristics in
453 parameter optimization (e.g., ORCHIDEE-exp3). Water availability appears to be a secondary but still important
454 driver of spring GPP. While acknowledging the numerous differences between CLM4.5 and CLM5.0, we find it
455 important to note that plant hydraulic water stress (CLM5.0) shows improved IAV performance (high correlation
456 and reduced error) over simplified soil moisture stress functions (CLM4.5). This result further supports efforts to
457 closely analyze seasonal GPP to locate different environmental controls for future model improvements.

458 While further experiments are needed, these results demonstrate the value of (1) site-level data assimilation
459 for local scale prediction of GPP magnitude and variability, (2) global data assimilation for reducing magnitude
460 biases, and (3) process formulation for accounting for sensitivity to temperature limitation and water stress. Overall,
461 these results are encouraging for model-data fusion systems which have developed the capacity to bring together
462 temporally and spatially resolved functional and structural vegetation components such as LAI, SIF, soil organic
463 matter, and above- and below-ground biomass (e.g., Bacour et al., 2019; Smith et al., 2020; Bloom et al., 2020).
464 Joint assimilation of these datasets, coupled with observed meteorological forcing, has potential to introduce more
465 emergent constraints of vegetation change with respect to environmental change, thus improving overall estimates of
466 productivity. Future work will assess the joint impact of SIF, ET, LAI, and biomass data as effective constraints on
467 light use and water use efficiency (Smith et al., 2019), which is expected to improve the ability of CARDAMOM to
468 use light with respect to increasing biomass subject to longer growing seasons and heat and water stress.

469 4. Conclusions

470 Despite mechanistic advances in ecosystem modeling, it is still a challenge to simulate temporal variations
471 in GPP. In an attempt to dissect the environmental controls on GPP in an evergreen needleleaf ecosystem, we
472 analyzed the impact of temperature on spring (March-May) productivity by implementing a cold temperature GPP
473 limitation within a model-data fusion system (DALEC2-CARDAMOM). The cold weather GPP limitation allows
474 for improved model estimates of productivity at Niwot Ridge, specifically CARDAMOM's ability to match the
475 interannual variability observed in tower-derived mean spring GPP. Furthermore, CARDAMOM is able to match
476 spring interannual variability between model and tower data outside of the training period. When compared to
477 TBM-MIP models, controls that appear to impact model performance include the inclusion of water stress (e.g. soil
478 moisture) and vegetation parameters (e.g. prescription of LAI). The fact that the cold temperature limitation does not
479 improve CARDAMOM's annual GPP estimates suggests that other controls (i.e. winter precipitation) drive GPP
480 variability in other parts of the year, most likely summer (June-September). The cold temperature limitation may
481 prove useful in understanding future changes in spring productivity due to changes in temperature in important
482 ecosystems, such as the Western U.S.

483 Appendices

484 Appendix A: Model-Data Fusion Methodology

485 The DALEC2 model parameter values and state variable initial conditions (henceforth \mathbf{x}) are optimized
486 using a Bayesian inference approach, where the posterior probability distribution of \mathbf{x} given observations \mathbf{O} , $p(\mathbf{x}|\mathbf{O})$,
487 can be expressed as

$$488 \quad p(\mathbf{x}|\mathbf{O}) \propto p(\mathbf{x})L(\mathbf{x}|\mathbf{O}) \quad (\text{A1})$$

489 Where $p(\mathbf{x})$ is the prior probability distribution of \mathbf{x} , and $L(\mathbf{x}|\mathbf{O})$ is the likelihood of the DALEC parameters
490 and initial conditions given observations \mathbf{O} . We define the likelihood function as

$$491 \quad L(\mathbf{x}|\mathbf{O}) = e^{-\frac{1}{2}\sum_i \left(\frac{m_i(\mathbf{x}) - o_i}{\sigma}\right)^2} + e^{-\frac{1}{2}\sum_a \left(\frac{m'_a(\mathbf{x}) - o'_a}{\sigma'}\right)^2}, \quad (\text{A2})$$

492
493 where for monthly timestep i , $m_i(\mathbf{x})$ and o_i represent monthly modelled GPP (based on parameters \mathbf{x}) and
494 flux-tower GPP observation, respectively. Following model-data fusion efforts with a spectrum of temporal modes
495 of variability (Desai 2010, Quetin et al., 2020 and Bloom et al., 2020), we extend the cost function to include mean
496 annual model and tower-derived GPP, $m_a(\mathbf{x})$ and o_a respectively) for year = a , which allows the GPP cost function
497 to be sensitive to both seasonal and inter-annual components of the flux tower GPP signal. We log-transform
498 modelled and tower-derived GPP values (as done in Bloom & Williams, 2015 and Bloom et al., 2016), which is
499 preferable for characterize model-data residuals between strictly positive quantities (such as GPP). For lack of better
500 uncertainty estimates on monthly and annual flux tower GPP accuracy—including lack of knowledge on GPP error
501 characteristics at monthly timescales, error covariance between individual GPP estimates, model structural error
502 impacts on GPP—we conservatively prescribed uncertainty factor of $\sigma = 2$ for monthly values (roughly ~75%), and
503 $\sigma' = 1.2$ (~18%) for annual values; in general we found that these values led to robust agreements between flux
504 tower and DALEC2 GPP variability (model-data mismatch metrics are reported in section 3 of the manuscript).

505 For all model experiments, we sample the probability of $p(\mathbf{x}|\mathbf{O})$, the posterior probability distribution of
506 initial conditions \mathbf{x} given observations \mathbf{O} , we use four Metropolis-Hastings Markov Chain Monte Carlo (MHMCMC;
507 Haario et al. 2001) for 10^8 iterations; we subsample 1000 parameter vectors \mathbf{x} , from the latter 50% of each chain (in
508 total 1000 samples x 4 chains = 4000 samples). We test for convergence in the MHMCMC estimates of \mathbf{x} using a the
509 Gelman-Rubin convergence diagnostic to measure convergence between the four chains.

510 Data Availability

511 The Ameriflux US-NR1 data was obtained from: <https://ameriflux.lbl.gov/sites/siteinfo/US-NR1> (Blanken et al.,
512 2020). The US-NR1 data used in this study, as well as the CARDAMOM and TBM-MIP outputs are publicly
513 available and provided in .nc file format at <http://doi.org/10.5281/zenodo.4928097>.

514 **Code Availability**

515 The CARDAMOM code used in this study is available here: <https://github.com/CARDAMOM->
516 [framework/CARDAMOM_v2.2](https://github.com/CARDAMOM-)

517 **Author Contributions**

518 SGS, NCP and AAB designed and performed the research. AJN, BR, CB, FM, IB, YZ, BQ, and MS contributed
519 model simulations. DRB, SPB, and PDB contributed observational data. All authors contributed to the writing of
520 the paper.

521 **Supplement**

522 **Competing Interests**

523 The authors declare that they have no conflict of interest.

524 **Acknowledgements**

525 The US-NR1 AmeriFlux site has been supported by the U.S. DOE, Office of Science through the AmeriFlux
526 Management Project (AMP) at Lawrence Berkeley National Laboratory under Award Number 7094866. A portion
527 of this research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under contract
528 with NASA. Funding from the NASA Earth Science Division Arctic Boreal Vulnerability Experiment (ABoVE) is
529 acknowledged. We acknowledge the MEASUREs program. DRB and BMR were supported by the NASA CMS
530 (NNX16AP33G) and the NSF Macrosystems Biology and NEON-Enabled Science (1926090) Programs. The
531 National Center for Atmospheric Research (NCAR) is sponsored by NSF.
