Abstract. Although the depth of bioturbation can be estimated on the basis of ichnofabric, the time scale of sediment mixing and irrigation by burrowers that affects carbonate preservation and biogeochemical cycles is difficult to estimate in the stratigraphic record. However, pyrite linings on interior of shells can be a signature of slow mixing and irrigation rate because they indicate that shells of molluscs initially inhabiting oxic sediment zones were immediately and permanently sequestered in reduced microenvironments where molluscan biomass and associated microbial coatings stimulated sulfate reduction and pyrite precipitation. A high abundance of pyrite-lined shells in the stratigraphic record can thus be diagnostic of limited net exposure of labile tissues to O₂ even when the seafloor is inhabited by abundant burrowing infauna as in the present-day northern Adriatic Sea. Here, we reconstruct this sequestration pathway (1) by assessing preservation and postmortem ages of pyrite-lined shells of the hypoxia-tolerant bivalve *Varicorbula gibba* in sediment cores and (2) by evaluating whether an independently-documented decline in bioturbation, driven by eutrophication and seasonal hypoxia during the 20th century, affected the frequency of pyrite-lined shells in the stratigraphic record of the northern Adriatic Sea. First, at prodelta sites with high sedimentation rate, linings of pyrite framboids form rapidly in near-surface sediment zones as they appear already in interiors of shells and in intra-shell conchiolin layers younger than 10 years and occur preferentially in well-preserved and articulated shells with periostracum and relatively high concentrations of amino acids. Second, increments deposited in the early 20th century contain <20% of shells with pyrite at the Po prodelta and 30–40% at the Isonzo prodelta, whereas the late 20th century increments possess 50–80% of shells with pyrite at both locations. At sites with slow sedimentation rate, the frequency of pyrite linings is low (<10–20%). Third, the upcore increase in the frequency of pyrite-lined shells positively correlates with an abrupt increase in maximum shell size and biomass of *V. gibba*. Therefore, the upcore increase in the frequency of pyrite-lined shells indicates that sediment mixing and bioirrigation rates declined during the 20th century, leading to higher sequestration of pyrite-lined shells during the late 20th century. We hypothesize that the permanent preservation of pyrite linings within the shells of *V. gibba* in the subsurface stratigraphic record was allowed by slow recovery of infaunal communities frequently interrupted by seasonal hypoxic events, leading to the dominance of surficial sediment modifiers with low irrigation potential. Abundance of well-preserved shells lined by pyrite exceeding ~10% per assemblage in apparently well-mixed sediments in the deep-time stratigraphic record can be an indicator of short net exposure of shells to O₂ and inefficient bioirrigation. Fine-grained prodelta sediments in the northern Adriatic Sea deposited since the mid-20th century, with high preservation potential of reduced microniches, can represent taphonomic and early-diagenetic analogues of deep-time skeletal assemblages with pyrite linings.

1. Introduction

Slow and shallow bioturbation (including biomixing and bioirrigation, Kristensen et al., 2012) can reflect oxygen depletion, toxicity or other environmental stresses that limit ecosystem functioning and nutrient recycling (Rhoads and Germano, 1986; Nilsson and Rosenberg, 2000; Rosenberg et al., 2001; Solan and Kennedy, 2002). It can be also conditioned by evolutionary

factors such as the lack of innovations for deep burrowing (Thayer, 1983) or by extinction of burrowers after mass
 40 extinctions (Pruss et al., 2004; Buatois and Mangano, 2011). Estimating the mixing rate and depth on the basis of the
 stratigraphic record thus can be used to assess the response and recovery of benthic ecosystems to stress and disturbances
 and to evaluate long-term trends in ecosystem functioning and biogeochemical cycling (Droser et al., 2002; Canfield and
 Farquhar, 2009; Tarhan et al., 2015; Gougeon et al., 2018; Buatois et al., 2020). The mixing rate, the mixing depth, and the
 sediment accumulation rate represent three parameters that determine the residence time of sedimentary and organic particles
 45 in the mixed layer (Meysman et al., 2003). The residence time determines preservation, recycling and burial efficiency of
 organic matter, carbonates and redox-sensitive minerals because it controls their exposure time to O_2 in near-surface
 sediment zones (Aller, 1994; Hartnett et al., 1998; Meile and van Cappellen, 2005; Boyle et al., 2014; Aller and Cochran,
 2019) and to borers, microbes and undersaturated pore waters in the so-called taphonomic active zone (TAZ; Davies et al.,
 1989; Walker and Goldstein, 1999). If sedimentation rate does not change over a given duration of deposition, dividing the
 50 depth of the mixed layer by sediment accumulation rate can be used to estimate the residence time of particles in the mixed
 layer (Wheatcroft, 1990; Tomašových et al., 2019a). However, first, exposure time to bioirrigation is not a simple function of
 residence time of sedimentary particles in the mixed layer and also depends on the size, life habits and mobility of burrowers
 (Sandnes et al., 2000; Lohrer et al., 2004; Gingras et al., 2008; Renz et al., 2018), with deposit feeders mainly promoting
 mixing and suspension-feeders and chemosymbionts mainly inducing irrigation (Christensen et al., 2000). Second, long-term
 55 estimates of net sediment accumulation rate cannot be interpolated to shorter time scales (Jerolmack and Sadler, 2007) and
 the time scale of mixed-layer formation is similarly confounded by internal temporal variability in bioturbation over shorter
 time scales (Teal et al., 2008). For example, a 20-cm thick layer deposited under 1 cm/y may be mixed (or irrigated)
 instantaneously just in a single year or permanently over 20 years. Both the instantaneous mixing and the slower mixing will
 generate age-homogeneous distribution of sedimentary particles but will differ in recycling and burial efficiency of redox-
 60 sensitive sedimentary particles. Therefore, although the depth of mixing in the stratigraphic record can be estimated on the
 basis of ichnofabric and trace fossils (Droser and Bottjer, 1988; Savrda and Ozalas, 1993), it is unclear whether intense
 mixing, leading to age homogenization, was also associated with efficient irrigation and whether a mixed layer observed in
 the stratigraphic record was mixed instantaneously or whether the ichnofabric developed over yearly, decadal or longer time
 scales. This uncertainty differs from temporally-explicit estimates of O_2 penetration, from estimates of apparent redox
 65 potential discontinuity, or from the estimates of the mixed layer thickness based on ^{234}Th that can be measured in present-
 day environments (Maire et al., 2008; Germano et al., 2011; Gerwing et al., 2018; Solan et al., 2019).

One criterion that can be used to constrain the residence time of particles and their exposure to O_2 in the mixed
 layer in the *ancient* stratigraphic record includes the detection of rapid authigenic mineralization associated with the decay of
 labile organic tissues in the absence of O_2 (Allison, 1988; Briggs et al., 1991, 1996). The lack of bioturbation that **limit** O_2
 70 exposure and **allow** preservation of intact, articulated, multi-element skeletal remains under anaerobic degradation of organic
 matter can induce early pyritization, phosphatization or silicification of organic tissues (Gabbott et al., 2004; Zhu et al.,
 2005; Cai et al., 2012; Saleh et al., 2019; 2020; Schiffbauer et al., 2014; Novek et al., 2016). Early pyritization or
 silicification induced by reactive organics may also generate death masks that stabilize and cement sediment and blanket
 benthic organisms (Gehling, 1999; Strang et al., 2016; Tarhan et al., 2016; Gibson et al., 2018; Liu et al., 2019; Slagter et al.,
 75 **20**). Similar pathways stimulated by the decay of labile organics or further sustained by microbial and mucus-forming
 processes in anaerobic microniches (Emery and Rittenberg, 1952; Jorgensen, 1977; Borkow and Babcock, 2003; Stockdale
 et al., 2010; Anderson et al., 2011; Virtasalo et al., 2010, 2013; Lehto et al., 2014) do not directly replace organic tissues but
 can lead to distinctive clusters of authigenic minerals concentrated in intra-skeletal voids initially filled with organic tissues
 in otherwise well-preserved skeletal remains (Brett et al., 2012a, b). For example, intraskeletal pores (initially containing
 80 labile organic tissues and microbes associated with their decay) lined by framboids or larger pyrite crystals preserved in the

stratigraphic record, as observed in interiors of foraminifers, cephalopods, articulated brachiopods or bivalves, demonstrate that reduced microniches were not re-exposed to O₂ by irrigation or exhumed to sediment-water interface (Hudson, 1982; Schieber and Baird, 2001; Hunda et al., 2006; Schieber, 2012; Machain-Castillo et al., 2019). Such microniches thus remained permanently sequestered after their initial formation. However, with the exception of seep environments (Powell et al. 2012) or studies focusing on pyrite infills in burrows (Virtasalo et al., 2010), pyrite-lined skeletal remains are rarely documented or observed in actualistic studies assessing preservation of organisms with durable skeletal elements in Holocene or Anthropocene marine environments (Best and Kidwell, 2000). This rarity may be not surprising because the preservation of pyrite framboids nucleating at the sites of organic decay (initiated in reduced microniches) is limited in habitats affected by physical mixing or bioturbation where most of the sulfide produced by sulfate reducers in microniches is later re-oxidized (Canfield et al., 1993; Wijsman et al., 2002; Canfield and Farquhar, 2009). However, taphonomic and early-diagenetic pathways that affect skeletal remains remain poorly explored in environments affected by eutrophication, stratification and oxygen depletion that can be characterized by high burial efficiency of iron (Carstensen et al., 2014; Lenstra et al., 2019).

The decline in the functioning of marine soft-bottom benthic ecosystems driven by eutrophication and deoxygenation over the past centuries (Schaffner et al., 1992; Valente and Cuomo, 2005; Zillén et al., 2008) thus represents a unique opportunity (1) to assess the nature of pathways that lead to the preservation of pyrite-lined shells (especially the steps associated with the initial formation of microniches and with the subsequent lack of their re-oxidation) and thus can provide a taphonomic and early-diagenetic analogues for pyrite-lined shells in the deep-time stratigraphic record, and (2) to test whether the decline in bioturbation detected in sediment cores over the past decades influenced the frequency of pyrite-lined shells in the stratigraphic record. Here, we focus on Holocene-Anthropocene sediment cores from the northern Adriatic Sea which harbors diverse types of infaunal and epifaunal benthic communities (Fedra et al., 1976; Zuschin et al., 1999; Zuschin and Stachowitsch, 2009). This sea was affected by eutrophication and by an increase in frequency of seasonal hypoxia in the 20th century (Justic, 1991; Degobbi et al., 2000), with frequent mucilage events (Cozzi et al., 2004; Giani et al., 2005; Precali et al., 2005) and several spatially-extensive seasonal anoxic events inducing mass mortality of benthic fauna in the 70s-90s (Stefanon and Boldrin, 1982; Stachowitsch, 1991). Oligotrophization was detected in the northern Adriatic Sea since 1990s (Djakovac et al., 2015), although habitats close to Po prodelta were regularly affected by seasonal hypoxia during the 1977-2008 monitoring (Alvisi and Cozzi, 2016) and hypoxic events were detected in the Gulf of Trieste also in the early 21st century (Kralj et al., 2020). Paleoeological records in sediment cores collected in the Po prodelta and in the Gulf of Trieste showed that the effects of seasonal oxygen depletion (and other changes related to pollution, sediment turbidity and trawling) translated into a 20th century regime shift in the composition of soft-bottom molluscan communities (at 10-30 m water depths, Tomašových et al., 2020).

Pyrite can precipitate rapidly at the location of decay of primary reactive tissues of hosts or at the location of intra-skeletal organic matrices among crystals (we call such pyrite *primary linings*, Boekschoten, 1966; Brown, 1966) but can also form at the location of decay of secondary inhabitants of shells that were exposed to redox fluctuations in the taphonomic active zone for longer (coelobionts, encrusters, or borers; *secondary linings*, Kobluk and Risk, 1977) or can precipitate slowly when H₂S reacts with less reactive iron-bearing minerals (Neumann et al., 2005). However, only primary linings can represent a key evidence of limited exposure time of such shells to O₂ from irrigation prior to their burial below the mixed layer. Here, to assess whether abundant pyrite-lined shells of the hypoxia-tolerant bivalve *Varicorbula gibba* are informative about mixing and irrigation rates and to distinguish primary from secondary linings (and from other types of pyrite associated with skeletal remains that forms over longer time scales), we evaluate (1) the rate of pyrite formation and the depth of its formation (in surface or subsurface sediment zones) on the basis of postmortem age- and depth-frequency

distributions of dated specimens of *V. gibba* in sediment cores, (2) whether pyrite-lined valves possess more frequently a periostracum (or internal conchiolin layer) and higher shell organic content than valves without pyrite (controlling for shell postmortem age), (3) whether the increment-level frequency of pyrite-lined valves correlates negatively with other types of alteration such as disarticulation or bioerosion, (4) whether the frequencies of pyrite-lined valves change upcore within the Holocene-Anthropocene stratigraphic record, and whether they track independently-documented changes in community composition and bioturbation using abundance, shell size, and biomass of the hypoxia-tolerant bivalve *V. gibba*.

2. Setting

The northern Adriatic Sea is a relatively low-energy shelf environment with narrow tidal range, with counterclockwise surface circulation, mainly driven by the freshwater input of the River Po (Kemp et al., 1999; Boldrin et al., 2009; Brush et al., 2021). The cyclonic circulation normally deflects nutrient-rich water masses off the Po Delta southwards. However, this circulation slows down during the summer when a local cyclonic gyre can spread such eutrophic waters also towards the eastern Adriatic shelf normally characterized by oligotrophic surface conditions. The decline in circulation leads to the development of a pycnocline, and in combination with high phytoplankton production, to the accumulation of marine snow and mucilages and to bottom-water oxygen depletion in some years across large parts of the northern Adriatic Sea (Stachowitsch, 1991; Penna et al., 1993; Precali et al., 2005). Sediments associated with silt and clay-rich sediments are relatively rich in iron in deltaic environments (3-4%, Spagnoli et al., 2014) and less so in carbonate sediments off Istria (>1.5-3% in the Gulf of Trieste, Faganeli et al., 1991; Faganeli et al., 1994; Dolenc et al., 1998). Iron is bounded mainly by iron oxides or by pyrite (as framboids or foram infillings) that forms 2-5% of the sediments in the Gulf of Trieste (Faganeli and Ogrinc, 2009), and typically less than 1% in Holocene cores on the Po Plain (Amorosi et al., 2002). Biogeochemical studies performed in the 1990s showed that organic-rich sediments at Po prodelta are dominated by anaerobic decomposition of organics (mainly sulfate reduction, Barbanti et al., 1995). In contrast, less-organic rich sites in the NW Adriatic Sea with slower sedimentation display a higher importance of aerobic respiration and iron reduction (Barbanti et al., 1995; Hammond et al., 1999). This gradient in sedimentation rate leads to lower recycling of organic carbon at the Po prodelta and higher recycling at distal sites. A similar situation was also observed in the Gulf of Trieste, with higher burial efficiency of organic carbon and nitrogen at muddy sites at the Isonzo prodelta and higher recycling at sandy sites with slow sedimentation in the southern parts of the Gulf of Trieste (Hines et al., 1997; Faganeli and Ogrinc, 2009).

3. Methods

3.1 Sediment cores

Sediment cores collected at five sites in the northern Adriatic Sea (Fig. 1) described and geochronologically-dated in our former papers were used to assess stratigraphic changes in the proportion of specimens lined with pyrite. Two sites are located at the Po prodelta (Po 3 and Po 4 at 21 m, Tomašových et al., 2018), one site in the northern Gulf of Trieste, in the Bay of Panzano at 12 m at the Isonzo prodelta (Gallmetzer et al., 2017; Tomašových et al., 2017), one site in the southern Gulf of Trieste off Piran at 23 m (Mautner et al., 2018; Tomašových et al., 2019), and one site on the southern tip of Istria at Brijuni at 44 m (Schneidl et al., 2018). Sediment cores collected in 2013 are ~1.5 m long and were initially split into 2 cm-thick increments in the upper 20 cm and into 5 cm-thick increments below. The core diameter was 9 cm at the site Brijuni and 16 cm at sites Po, Panzano, and Piran. All increments were sieved with 1 mm and, with some exceptions (at Piran), all

160 individuals of *Varicorbula gibba* were picked from residues. At Piran, the increments between 10 to 35 cm were split into quarters and increments between 35 to 45 cm were split to half owing to high shell abundance (Gallmetzer et al., 2019)

Although these sites are located at similar water depths, they differ in their proximity to clastic input from rivers, grain size, net sedimentation rate, sediment organic enrichment and iron content. Stratigraphic profiles in grain size and in concentrations of CaCO₃, TOC and TN, and Fe concentrations (in 63 µm sediment fraction, documented in Gallmetzer et al., 2017; Mautner et al., 2018; Schnedl et al., 2018) show that the three prodelta sites are exclusively muddy and rich in iron (~3%) whereas the two locations off Istria are sandy, iron-poor (1-2%), and rich in carbonate skeletal material (molluscs, echinoderms, bryozoans, coralline algae) (Fig. 2). The two Po cores are characterized by high sedimentation rate (1-2 cm/y), the Panzano core was deposited under intermediate sedimentation rate (0.2-0.4 cm/y), and the Piran and Brijuni sites are sediment-starved (<0.01 cm/y). The thickness of the surface well-mixed layer, based on homogeneity of shell ages (amino acid racemization calibrated by ¹⁴C) and the vertical extent of uniform or irregular segments of profiles in ²¹⁰Pb excess (data described by Gallmetzer et al., 2017, 2019; Tomašových et al., 2017, 2018, 2019), is ~16-20 cm at Po and at Brijuni, 6 cm at Panzano, 8 cm at Piran (where a coarse skeletal shell bed occurs at 8-35 cm below the seafloor), and 20 cm at Brijuni (where a sandy mud overlies a coarse bryozoan-rich molluscan muddy sand). Owing to geographic differences in net sedimentation rates, these estimates apply to the depths that are fully-mixed at decadal (Po and Panzano) and millennial time scales (Piran and Brijuni). Some incomplete mixing also occurs below these depths (Tomašových et al., 2018). The cores at Piran and Brijuni are mixed by bioturbation but can be subdivided to units deposited during the transgressive systems tract (TST), maximum flooding zone (MFZ), highstand systems tract (HST, prior to the 20th century), and the uppermost zones that contain a mixture of late-highstand and 20th century sediments (Fig. 2). The core at Panzano captures about 500 years and the 20th century sediments occur in the upper 35 cm. The cores at Po consist of sediments deposited during the early and the late 20th century (and the earliest 21st century), as described by Gallmetzer et al. (2017), Tomašových et al. (2018, 2019), Mautner et al. (2018), and Schnedl et al. (2018).

We target specimens of the bivalve *V. gibba* because this species tends to be common in all cores and its intrinsic attributes with tightly-closed valves can favor the formation of reduced microniches (Fig. 3). The shells of this species consist of two unequal-sized valves that are formed by an outer (with a cross-lamellar structure) and an inner (with a cross-lamellar and complex cross-lamellar structure) layer (Fig. 3A). Both valves possess one or more conspicuous internal, 10-100 µm-thick conchiolin layers (Fig. 3B-C), with embedded aragonite nodules (< 5 µm) (Lewy and Samtleben, 1979; Kardon, 1998). The internal conchiolin layer in the right valve terminates on the internal surface in a groove between the pallial line and the ventral margin (Fig. 3). First, the margin of the left valve is pressed on this edge of the conchiolin layer in the groove so that the left valve is almost perpendicular relative to the right valve. Second, the external periostracum of the left valve overlaps with the ventral external margin of the right valve. These traits allow a tight closure of articulated valves. Although the conchiolin in the internal layers is more refractory and insoluble (Krampitz et al., 1983) than labile organics initially lining the interior of valves, the internal conchiolin layers within valves can be also prone to the decay under reducing conditions.

195 3.2 Age distributions of pyrite-lined valves

D/L values and concentrations of eight amino acids (aspartic, glutamic, serine, alanine, valine, phenylalanine, isoleucine, and leucine) in valves of *V. gibba* were measured at Northern Arizona University using reverse-phase high-pressure liquid chromatography (RP-HPLC) and the procedures of Kaufman and Manley (1998). These data were measured in 252 valves

from Po 3, in 243 valves from Po 4, in 311 valves from Panzano, and in 232 valves from Piran, and were presented with age
 200 calibrations of aspartic acid D/L by ^{14}C -dated valves by Tomašových et al. (2017, 2018) and Mautner et al. (2018). To
 constrain the rate and the location of pyrite formation on the basis of postmortem age data, we evaluated (1) whether valves
 of the same postmortem age (binned to 10 years at Po stations and to 50 years at Panzano), with and without pyrite linings,
 differ in their mean stratigraphic depth or whether pyrite-lined valves are located deeper, (2) whether the rate of valve-loss
 from the mixed layer (by burial or by disintegration) differs between valves with and without pyrite linings, and 3) whether
 205 valves of the same age with and without pyrite linings differ in their content of amino acids. We assess the differences in
 depth and age between valves with and without pyrite by comparing their mean values and 95% bootstrapped confidence
 intervals. We estimate loss rates of valves from the mixed layer by fitting age distributions of valves with and without pyrite
 linings from Po and Panzano to a simple model with temporally-constant loss rate that can be well-fitted by the exponential
 distribution (disintegration-burial model) and to a more complex model where loss rate declines with postmortem age at
 210 some sequestration rate and the resulting age distributions are heavy-tailed, typically caused by exhumation of older valves
 to sediment surface (Tomašových et al., 2014). We use the Akaike Information Criterion corrected for small sample size to
 assess the relative fit of these two models. The higher support for the disintegration-burial model can indicate that the both
 types of valves undergo a simple, temporally-constant loss from the mixed layer. We use independent estimates of net
 sedimentation rate based on ^{210}Pb data to assess whether this loss-rate parameter corresponds to disintegration or burial. The
 215 higher support for the more complex model could indicate that pyrite-lined valves were exhumed from deeper zones to the
 mixed layer.

3.3 Taphonomic scoring

To assess the nature and types of pyrite linings, we evaluated preservation of all specimens of *V. gibba* at light-microscope
 220 scale at 10-20x magnification. We investigated several specimens with scanning electron microscope (SEM) and with
 backscattered electrons (BSE), using electron probe microanalyzer at 100-1,000x magnification. The chemical composition
 of pyrite and iron oxides was validated with energy-dispersive X-ray spectroscopy. All valves of *V. gibba* that were dated by
 amino-acid racemization at four sites (Po 3, Po 4, Panzano M28, and Piran M53) were scored. At Po 3 (replicate cores M12,
 M13 and M14), Po 4 (cores M20 and M21), Panzano (cores M28 and M29), all additional specimens were scored under a
 225 light microscope. At Brijuni, all specimens of *V. gibba* from every second increment were scored. Nine alteration variables
 were scored on specimens of *V. gibba* at light-microscope magnification (10-20x): (1) pyrite presence (black grains and
 framboids on interior valve surfaces), (2) loss of periostracum and/or of the internal conchiolin layer (if either external
 periostracum and/or internal conchiolin layer are visible, conchiolin is scored as being preserved), (3) disarticulation, (4)
 internal fine-scale surface dissolution, (5) internal bioerosion (generated by algae and sponges, excluding predatory drilling),
 230 (6) external encrustation, (7) intense surface wear (loss of external ornamentation), and (8) penetrative dark gray staining
 (induced by nanopyritic inclusions that fill valve microporosity).

3.4 Geographic and stratigraphic differences in the frequency of pyrite-lined valves

To evaluate stratigraphic and geographic changes in preservation of *V. gibba* at the increment scale, we compute relative
 235 frequencies of specimens with a given alteration relative to the total number of specimens in 4 cm (pooling 2 cm increments
 in the upper 20 cm in each core) and 5 cm-thick increments at five stations. The frequency of disarticulated shells is
 computed as the number of all articulated specimens in a given increment divided by the minimum number of individuals

(i.e., the sum of articulated shells plus the higher number of left or right valves). Although the estimates of disarticulation are biased upward owing to disarticulation that takes place during sieving, we assume that this bias affects all increments equally. All increments were plotted and analyzed in stratigraphic analyses. However, the downcore stratigraphic profiles reflect (1) downcore changes in early-diagenetic conditions within the mixed layer driven by vertical changes in O₂ penetration and by the extent of iron and sulfate reduction and (2) chronological changes in biogeochemical processes (e.g., driven by eutrophication-induced changes in organic input and in O₂ exposure of sedimentary particles). Therefore, assuming that preservation of valves below the mixed layer is permanent, our inferences about chronological changes in preservation are based on the subsets of stratigraphic profiles below the mixed layer (and on increments with more than 10 scored individuals). In analyses assessing bivariate and multivariate relationships among all alteration variables, we extracted the increments located below the mixed layer with more than 10 specimens, and measured Spearman rank correlations between per-increment frequencies of pyrite-lined valves on one hand and other types of alteration on the other hand. We use principal coordinate analysis to investigate (1) geographic differences in preservation of *V. gibba* among all sites and (2) differences in preservation of *V. gibba* between the late 20th century increments (that primarily capture the main eutrophication phase) and increments that are older (corresponding to the early 20th century at the Po prodelta and the 16-19th centuries at the Isonzo prodelta) at the three prodelta sites with high sediment accumulation rates.

3.5 Relationship with ecosystem indices

To assess whether shell preservation responds to the ecosystem shift in the 20th century, we rank correlate the frequencies of pyrite-lined valves on one hand with several indicators of community states typical of the eutrophication phase (marked by high abundance and size of the hypoxia-tolerant bivalve *V. gibba*) on the other hand, including (1) absolute (per 0.02 m² and 5 cm-thick increments) and (2) proportional abundances of *V. gibba* (relative to the total molluscan abundance), (3) maximum shell size of *V. gibba* (measured by the 95th percentile of length distributions per increment), and (4) its population-level biomass index based on the sum of biovolumes of all specimens that were preserved (assuming that rates of disintegration did not vary during the deposition of cores). We use the per-individual biomass-biovolume regression equation of Stanton and Powell (1985) to compute the specimen-level estimates of biomass on the basis of shell length and height of *V. gibba*. Absolute abundances of *V. gibba* at Brijuni were multiplied by a factor of 3.2 to correct for the smaller core diameter at Brijuni. Although absolute and proportional abundances are affected by between-core variability in time averaging and in net sedimentation rate, trends in proportional and absolute abundance within cores can be robust because sedimentation rates remained relatively constant during the deposition of individual cores.

4. Results

4.1 Preservation of pyrite and valves at light-microscope scales

The preservation of *V. gibba* valves varies from well-preserved valves with periostracum (Fig. 4A-B; 4A-B) or without periostracum (Fig. 4C-D), with well-preserved pallial line and the internal conchiolin groove (pl and clg in Fig. 4), to valves with signs of fine-scale dissolution and delaminated into two distinct valve layers (originally separated by the internal conchiolin layer, Fig. 4E-F and 4G-H). This delamination is a characteristic signature of *V. gibba* preservation driven by the decay of internal conchiolin layer at all stations (Fig. 4E-H, 5C-H). The internal conchiolin layer (icl) located ventrally below the pallial line can be exposed in fragments (Fig. 4I) or in delaminated valves (Fig. 4F). The interiors of valves at Po and Panzano are frequently lined by dispersed pyrite microcrystals, by individual pyrite framboids, or by aggregates of pyrite

framboids whereas pyrite-lined valves are rare at Piran and Brijuni, especially in valves with periostracum and internal conchiolin. Pyrite framboids are randomly dispersed on valve interiors (Fig. 4J-K), are arranged in filamental strings (Fig. 4L), and form continuous (Fig. 4M-N) or patchy internal linings (Fig. 4O-P). Framboids are rare on exteriors.

280 Pyrite linings can be associated with internal fine-scale dissolution and can co-occur with reddish grains of Fe oxides at all sites. However, the dissolution of valves at Po and Panzano is minor, and is still associated with some surviving portions of periostracum or conchiolin layer. Specimens from Piran and Brijuni are bored and dissolved but are rarely lined by pyrite framboids (Fig. 5). In contrast to pristine valves without any framboids on interiors (Fig. 6A), the pyrite linings can be detected in thin sections as linings formed by framboids dispersed on interior valve surfaces (black grains in Fig. 6B-D) 285 and in the conchiolin layer (Fig. 6E). Valves at Piran and Brijuni contain dispersed framboids that are mainly concentrated in borings or are associated with secondary sediment fillings of borings (Fig. 6F). Some relatively pristine valves from Po and Panzano show a blueish-colored staining on the interior and exterior, still with well-preserved external ornamentation (Fig. 4Q-T). In contrast, gray-stained valves at Piran and Brijuni are worn, degraded by bioerosion, and affected by internal encrustation (Fig. 5). In thin sections, macroborings produced by sponges are very rare in valves from Po and Panzano, and 290 bioerosion is primarily limited to simple borings that are few microns thick. In contrast, valves from Piran and Brijuni exhibit dense borings (Fig. 6F).

4.2 Preservation of pyrite at 100-1,000x magnification

On one hand, BSE images show that pyrite framboids preserved on the interiors of well-preserved valves vary in shape, size 295 (5-10 μm) and packing, ranging from densely- and regularly-packed microcrystals within spherical framboids up to loosely and irregularly-packed microcrystals within irregularly-shaped framboids (Fig. 7A-G). They coalesce into continuous agglomerations at some places. Framboids also partly fill pores between aragonite nodules (arrows in Fig. 7I) within the conchiolin layer (that is $\sim 10\text{-}100\text{ }\mu\text{m}$ thick) where they can be partly altered by Fe oxide rims (Fig. 7H-I). Larger euhedral pyrite crystals were not observed on valve interiors. At Piran and Brijuni, pyrite framboids located in borings (secondary 300 linings) occur within strongly bored and stained valves (Fig. 7L). On the other hand, in addition to framboidal pyrite that forms primary or secondary linings, another type of pyrite preservation can be detected at high magnification and is characteristic of stained valves. The valves that are stained show disseminated or dispersed inclusions of nanopyrite ($< 1\text{ }\mu\text{m}$) in BSE images. These inclusions are located in nanoscale-dissolution pits and microborings located in the inner or the outer layer; they are not located on valve surfaces or within the conchiolin layer (Fig. 7J-L).

305 SEM images show that pyrite framboids on surfaces of non-bored or unworn valves at Po and Isonzo prodeltas are attached to the original interior surface (primary linings). Dispersed microcrystals uniformly cover inner, well-preserved and smooth surface or fill irregularities close to the groove around the termination of the internal conchiolin layers (Fig. 8A-D). Dispersed microcrystals and subspherical to spherical framboids consisting of microcrystals co-occur together and can be distributed across the whole interior surfaces in clusters (Fig. 8E), in strings (Fig. 8F) and locally co-occur with Fe oxides 310 and gypsum (Fig. 8F). Pristine valves show no or weak bioerosion by larger borers (sponges), although they can be penetrated by simple non-branching borings with micrometric diameters. In contrast, pyrite framboids are rare on interiors of valves that are affected by dense borings produced by sponges, forming complicated galleries, with or without sediment infill (Fig. 8G-H). SEM and BSE observations show that pyrite framboids directly attached to interior surfaces of well-preserved and weakly-bored valves represent primary linings, whereas pyrite framboids occurring on highly-altered valves 315 are located in borings and represented secondary linings.

4.3 Age and depth distributions

Age distributions of valves with and without pyrite linings show right-skewed shapes in the mixed layer at prodelta sites, with median age equal to 7-10 (without pyrite) and 7-18 years (with pyrite linings) at Po (in the upper 20 cm) and to 11 (without pyrite) and 15 years (with pyrite linings) at Panzano (in the upper 6 cm), respectively (Fig. 9A-F). They are dominated by recentmost cohorts younger than 10 years. In the mixed layer, valves with and without pyrite linings exhibit the same distribution shape well-fitted by the exponential distribution, with similar loss-rate parameters within each site (Fig. 9A-F). Therefore, the model with constant burial and disintegration outperforms or is equally efficient than more complex sequestration models both for valves with and without pyrite in the mixed layer at Po and Panzano (black lines in Fig. 9A-F, Table A1). The time to valve loss from the mixed layer is similar to ^{210}Pb -based estimates of sediment accumulation (1-2 cm/y at Po and 0.2 cm at Panzano), indicating that loss rates primarily correspond to burial rates. The pyrite framboids thus form at yearly scales and valves with and without pyrite linings are buried below the mixed layer at comparable rates. Age distributions of *V. gibba* valves without pyrite linings in the mixed layer at Piran are right-skewed but fat-tailed and contain valves that are older than 1,000 years (median age = 1,100 years; only one 140 years-old valve was lined by pyrite, figure not shown). At the scale of the whole cores, median age of pyrite-lined valves and valves without pyrite are also comparable at Po (27 and 33 years with and without pyrite, respectively) and Panzano (100 and 124 years with and without pyrite linings, respectively) (Fig. 9G-L). However, the whole-core age distributions of valves show signs of multimodality, and the frequency with pyrite-lined valves peaks at 1986 AD at Po and at 1963 AD at Panzano. Equally-old pyrite-lined valves and valves without pyrite tend to be located at similar depths within the mixed layer (Fig. 9M-O). The mean depth of valves younger than 10 years is 20 cm for specimens both with and without pyrite at Po, and pyrite-lined valves are located deeper (at 60 cm) than valves without pyrite (at 40 cm) in the 20-year cohort.

4.4 Preservation of pyrite-lined valves relative to other types of alteration

Controlling for postmortem age, valves lined by pyrite contain higher concentrations of amino acids than valves without pyrite at Po and Panzano (Fig. 10). Median concentrations of amino acids in valves with pyrite linings typically exceed those in valves without pyrite within the same age cohort (Fig. 10A-C), and the log-log relationship between postmortem age and amino acid concentrations show that intercepts of valves lined by pyrite exceed intercepts of valves without pyrite by a factor of ~2 (Fig. 10D-F). Qualitative observations show that pyrite at Po and Panzano *V. gibba* preferentially formed both within valves and on internal surfaces in articulated shells, and all articulated shells from Po and Panzano that were opened had pyrite on valve interiors. At the scale of individual specimens, pyrite-lined valves possess some relicts of periostracum or conchiolin layer more frequently than valves without pyrite linings (Fig. 10G-I). At the scale of increments, the relations between preservation of pyrite-lined valves and other types of alteration exhibit three patterns. First, per-increment frequencies of pyrite-lined valves rank correlate *negatively* with the frequencies of disarticulated shells (Fig. 11A), with the frequencies of valves with some relicts of periostracum or conchiolin layer (Fig. 11B-C), and with the frequencies of bioerosion, staining, and encrustation (Fig. 11D-F). Second, the rank correlation between per-increment frequencies of pyrite-lined valves and frequencies of dissolved valves across all sites is low, but partitioning the sites by high and low sedimentation rate (with frequent and rare pyrite, respectively), frequencies of pyrite-lined valves correlate with frequencies of dissolved valves positively at Po and Panzano and negatively at Piran and Brijuni (Fig. 11G). Third, with the exception of pyrite linings, all other types of alterations covary *positively* (Fig. 11H-O). These correlations are determined by the among-

355 site gradient in sedimentation rate (associated with the gradient in grain size and carbonate content): *V. gibba* valves at sites with high sedimentation are well preserved and rarely bored, encrusted, abraded or stained (Fig.4). In contrast, *V. gibba* valves at sites with slow sedimentation show a broader range of preservational signatures, with high abundance of bored, encrusted, worn and stained specimens (Fig. 5). Valves with periostracum or conchiolin layer are abundant at Po and Panzano (with 10-80% specimens per increment), whereas such specimens are extremely rare at Piran and Brijuni, with
 360 almost 100% specimens without periostracum. Principal coordinate analysis of increments from all sites shows a major separation in preservation of *V. gibba* among increments deposited at low and high sedimentation rate (Fig. 12A-B). The first PCO axis correlates negatively with frequencies of pyrite linings and positively with all other alteration variables (with the exception of fine-scale dissolution).

365 4.5 Stratigraphic trends in the frequency of pyrite-lined valves within the mixed layer

The frequency of pyrite-lined valves within the mixed layer is highly irregular at Po prodelta. Valves with pyrite increase in abundance below the mixed layer at the scale of 10 cm increments from 15-24% at 10-20 cm to 35-50% at Po 4. There is no clear downcore trend within this interval at Po 3, and the uppermost increments already contain 40% of pyrite-lined valves. The abundances of pyrite-lined valves within the mixed layer increase from 10-20% at 4-8 cm to 55-70% at 12-20 cm at
 370 Panzano, with the increase coinciding with the base of the ²¹⁰Pb-defined mixed layer at 6 cm. At Piran and Brijuni, the frequencies within the mixed layer also do not show any obvious trend.

4.6 Stratigraphic trends in the frequency of pyrite-lined valves below the mixed layer

At sites with high sedimentation rate, the frequency of pyrite-lined valves is highest (50-80%) in increments with the
 375 smallest bioturbation and the highest organic content (at 20-80 cm at Po and at 8-20 cm at Panzano, Fig. 12D), coinciding with the late 20th century eutrophication and hypoxia. This maximum declines downcore to 20% at Po prodelta (at 80-150 cm) and to 30-40% at Panzano (at 20-150 cm) in units deposited prior to the late 20th century. The frequencies of pyrite-lined valves do not change markedly at sites with slow sedimentation and are typically less than 20% at Piran and Brijuni. The frequencies of pyrite-lined valves at Piran and Brijuni further decline when they are limited to valves not affected by
 380 bioerosion (black circles in Fig. 12D). Focusing on these sites with high sedimentation rate, PCO shows consistent separation between the latest HST and the late 20th century increments (Fig. 12C), reflecting the chronological increase in the frequency of pyrite linings. This within-core increase in the frequency of pyrite linings is coupled with an upcore increase in the frequency of valves without the periostracum (Fig. 13A). The frequencies of articulated valves and valves with fine-scale dissolution also increase upcore (Fig. 13B-C). At sites with slower sedimentation and coarser, carbonate-rich sediments, the
 385 frequency of pyrite-lined valves remains constant upcore (<20%). The frequency of pyrite-lined valves not affected by borers is <10%. The frequency of bored specimens gradually increases from 20-30% in the lower (transgressive systems tract) increments to 70-80% in the upper (late-highstand systems tract) increments at Piran (Fig. 13). In contrast, the frequency of bored specimens gradually declines from 90-100% in the lower (transgressive systems tract) increments to ~40% in the upper highstand increments at Brijuni (Fig. 13).

390

4.8 Relationship between pyrite-linings and ecosystem indices

Per-increment maximum shell size of *V. gibba* correlates positively with its proportional abundance ($r = 0.46$, $p < 0.0001$) and absolute abundance ($r = 0.46$, $p < 0.0001$) across all sites. Proportional abundance of *V. gibba* per increment correlate positively but rather weakly with the per-increment frequency of valves lined with pyrite framboids (r [prop. abundance] = 0.21, $p = 0.016$). Absolute abundance does not correlate with the per-increment frequency of pyrite-lined valves across all sites (r [abs. abundance] = -0.001, $p = 0.99$, Fig. 14). However, in contrast to regional-scale relationships that are affected by between-core differences in time averaging, the positive relationships between proportional abundance and the frequency of pyrite-lined valves are stronger at the scale of individual sites at Po (r [Po 3] = 0.61, $p = 0.0015$, r [Po 4] = 0.6, $p = 0.003$, r [Po pooled] = 0.56, $p < 0.0001$). Similarly, the relationships between absolute abundance and the frequency of pyrite-lined valves are stronger and positive at the scale of individual sites at Po (r [Po 3] = 0.47, $p = 0.02$, r [Po 4] = 0.5, $p = 0.014$, r [Po pooled] = 0.38, $p = 0.008$) and also at Panzano ($r = 0.26$, $p = 0.04$).

V. gibba maximum shell size and biomass per increment correlate moderately positively with the per-increment frequency of pyrite-lined valves across all sites (r [size] = 0.54, $p < 0.0001$; r [biomass] = 0.51, $p < 0.0001$). The relationships between maximum shell size of *V. gibba* and the frequency of pyrite linings are also significantly positive at the scale of individual cores at sites with high sedimentation rate (r [Po 3] = 0.65, $p = 0.0007$, r [Po 4] = 0.49, $p = 0.017$, r [Po pooled] = 0.61, $p < 0.0001$, r [Panzano] = 0.46, $p = 0.0002$, r [Piran] = 0.55, $p = 0.16$, r [Brijuni] = 0.11, $p = 0.71$). Similarly, the relationships between biomass and the frequency of pyrite linings are significantly positive at sites with high sedimentation rate (r [Po 3] = 0.73, $p < 0.0001$, r [Po 4] = 0.6, $p = 0.003$, r [Po pooled] = 0.63, $p < 0.0001$, r [Panzano] = 0.47, $p = 0.00018$, r [Piran] = 0.36, $p = 0.38$, r [Brijuni] = 0.22, $p = 0.36$). Within-core stratigraphic series at Po and Panzano show autocorrelation in the frequency of pyrite-lined valves and in abundance, biomass and maximum shell size at lag 1 (stratigraphic series at Brijuni and Piran do not show autocorrelation in these traits). Although differencing the stratigraphic series to remove autocorrelation reduces the strength of the bivariate relationships, rank correlations between the frequency of pyrite-lined valves on one hand and maximum size and biomass of *V. gibba* on the other hand remain significantly positive at Panzano (r [size] = 0.32, $p = 0.017$; r [biomass] = 0.34, $p = 0.02$) and of borderline significance at Po if increments from Po3 and Po4 are pooled (r [size] = 0.3, $p = 0.047$; r [biomass] = 0.28, $p = 0.033$).

5. Discussion

5.1 Effects of net sedimentation rate on preservation of pyrite linings

Our observation that the pyrite-lined valves are preserved at high abundance in the subsurface stratigraphic record at Po and Isonzo prodeltas whereas they are infrequent at Piran and Brijuni indicates that the condition for their permanent sequestration below the mixed layer is enhanced when net sedimentation rate is high. Some pyrite framboids on valves at sites with slow sedimentation probably represent secondary linings because they directly occur within borings in heavily-bored valves (i.e., the difference between frequencies of pyrite linings in all and non-bored valves is large at Brijuni, Fig. 12D). This preservation contrasts with well-preserved pyrite-lined valves at sites with high sedimentation where exclusion of bored valves does not reduce their frequency (i.e., the difference between frequencies of pyrite linings in all and non-bored valves is small at Po and Panzano, Fig. 12D). The preservation of primary pyrite linings is thus largely limited to sites with high sedimentation rate (> 0.2 cm/y).

First, larger grain size and sediment porosity of coarse-grained sediments enhance advective pore-water fluxes driven by bottom currents, hydraulic sediment reworking, or by bioirrigation (Taylor et al., 2003; Mermillod-Blondin, 2011), promoting higher exposure of organics within shells to O₂ and stronger iron recycling (Aller, 1994) relative to fine-grained sediments where pore water fluxes are dominated by diffusion (Mermillod-Blondin and Rosenberg, 2006; Meysman et al., 2006). Such conditions can inhibit the initial formation of reduced microniches. Second, the lower concentrations of iron in sediments can reduce the probability of initial pyritization at coarse-grained sites rich in carbonate sediments even in reduced microniches, with H₂S diffusing away from the decay sites (Raiswell et al., 1993; Allen, 2002). Third, at sites with slow sedimentation rates (~0.01 cm/y) and coarse and permeable sediments less rich in iron and organic carbon, regardless of bioturbation, valves can be exposed to O₂ in the mixed layer for longer, leading to intense alteration of valves by borers, encrusters, or by pore waters that tend to be undersaturated with respect to aragonite in the upper 10-20 cm at the Po prodelta (Hammond et al. 1999) and in the Gulf of Trieste (Ogrinc and Faganeli, 2003). This effect will minimize both the formation of reduced microniches and their susceptibility to reoxidation, and is supported by higher levels of bioerosion, encrustation, ornamentation loss and staining at Piran and Brijuni than at coarse-grained sites with high sedimentation rates (Fig. 11-12). Pyrite linings that initially formed in microniches will thus not survive recycling driven by bioturbation or by physical mixing of coarse-grained deposits accumulated under a very slow sedimentation rate (~0.01 cm/y). In contrast to very low frequency of pyrite-lined valves at sites with low sedimentation rate, frequency of valves stained by nanopyrritic inclusions is higher at these sites, probably reflecting long (millennial-scale) subsurface exposure of less reactive iron-bearing minerals (relative to highly reactive iron oxide/oxyhydroxides) to sulfidic conditions (Raiswell and Canfield, 1996). Low sedimentation rates associated with coarse-grained sediments thus exacerbate not only residence time of skeletal remains in the shallowest sediment zones but also their net exposure to O₂. Higher recycling of organic carbon, nitrogen and sulfur at sites with slow sedimentation in the northern Adriatic Sea is supported by pore-water biogeochemical profiles that show their higher burial efficiencies at the Po prodelta relative to sites with slower sedimentation in the NW Adriatic Sea (Giordani et al., 1992, 2002; Hammond et al., 1999). Similarly, recycling efficiency of organic carbon and nitrogen is about 85% at Piran and in the central parts of the Gulf of Trieste and less at proximal deltaic locations off the Isonzo prodelta (Faganeli and Ogrinc, 2009).

5.2 Pyrite-lined valves in subsurface zones as a signature of short exposure to O₂ and permanent sequestration

The preferential occurrence of pyrite linings in valves with periostracum and with higher concentrations of amino acids and the negative correlation of pyrite-lined valves with the frequencies of other types of alteration at the scale of increments indicate that pyrite framboids formed soon after, or concurrent with, the decay of tissues of *V. gibba* and associated microbes (framboids arranged in filaments or strings in Fig. 4L or 6F resemble bacterial relicts, Westall, 1999; Wilson and Taylor, 2017). Two steps are necessary for preservation of pyrite-linings in the subsurface stratigraphic record, including their initial formation in reduced microniches and (2) the subsequent lack of their reoxidation.

(1) The early formation of concentrations of pyrite framboids that cluster on valve surfaces requires that the labile organics within shells do not decay or are not scavenged under aerobic conditions, that the degradation of tissues and associated microbial coatings proceeds by sulfate reduction, and that sediment is rich in iron so that sulfides remain confined to the decay location (Fisher and Hudson, 1987; Raiswell et al., 1993; Schiffbauer et al., 2014). Such conditions can occur under the decay of reactive organics in reducing conditions in non-sulfidic, iron-dominated pore-water zones (Berner, 1969; Briggs et al., 1996; Allen, 2002; Stockdale et al., 2010). These early-sequestration conditions can be attained (i) when freshly-dead shells are episodically buried under a deposition of new sediment sourced by river floods or storms and can

decay in reducing conditions beyond the reach of burrowers (Allison, 1988; Brett et al., 2012a, b; Schiffbauer et al., 2014),
 470 (ii) when biomass of decaying organisms is tightly enclosed as in shells or skeletal pores (as in *V. gibba*) or skeletal pores,
 generating reducing microenvironments (Jorgensen, 1977; Thomsen Vorren, 1984), and/or (iii) when the oxygen penetration
 depth is permanently or seasonally shallow in organic-rich and poorly-permeable fine-grained sediments (e.g., when the
 oxic-anoxic interface redoxcline shallows seasonally owing to higher sediment oxygen demand driven by organic
 enrichment from phytoplankton blooms, mucilages or mass mortality). The first scenario with obrution is frequently invoked
 475 in the deep-time stratigraphic record because it explains the short exposure of organic remains to O₂ and their rapid
 sequestration below the mixed layer (Brett et al., 2012a). Distinct layers deposited by major decadal floods preserved in
 cores at Po prodelta (Tesi et al., 2012; Tomašových et al., 2018) may have triggered episodic burial of benthic communities,
 but similar flood-event layers were not detected at Panzano. However, (i) equally-old valves with and without pyrite linings
 occur at similar depths and (ii) age distributions of pyrite-lined valves and valves without pyrite are similar, conforming to
 480 the same disintegration-burial model, indicating that valves with and without pyrite were buried below the mixed layer at the
 same rate. The young age of pyrite-lined valves and their high abundance in the uppermost zones of the mixed layer also
 indicate that they do not represent transient valves that were just recently exhumed from deeper zones. The pyrite framboids
 thus did not preferentially form within valves that were deeper in sediments as predicted by the obrution scenario and rather
 precipitated in near-surface sediment levels naturally inhabited by *V. gibba*.

485 Several lines of evidence rather indicate that the second and the third scenarios are important: the initial phase of
 pyrite precipitation occurred in reduced microniches (within shells) in near-surface muddy sediments with iron-dominated
 pore waters and that the limited O₂ penetration (and temporary shallowing of the redoxcline under seasonally-higher oxygen
 demand of sediments) enhanced the formation of reducing microniches. First, muddy sediments are on average oxygenated
 to less than 1-2 cm in the northern Adriatic Sea (Epping and Helder, 1997; Moodley et al., 1998, 2000), and zones with high
 490 concentrations of dissolved iron tend to be limited to the uppermost 5 cm in the NW Adriatic Sea (Hammond et al., 1999) and
 in the Gulf of Trieste (Faganeli and Ogrinc, 2009). In contrast, sandy sediments exhibit stronger bioirrigation and a thicker
 extent of ferruginous conditions in the upper 20 cm (Faganeli and Ogrinc, 2009). Second, qualitative observations indicate
 that pyrite linings are very rare in valves of *Nucula* that co-occur with pyrite-lined *V. gibba* valves, and pyrite linings occur
 rarely in apertures of gastropods. Therefore, tightly-articulated shells of *V. gibba* with internal conchiolin layers can be
 495 intrinsically susceptible to the formation of reducing conditions. Third, the uppermost sediments become oxygen-depleted
 during late-summer mucilage, hypoxic and mass mortality events in the northern Adriatic Sea (Stachowitsch, 1984), and the
 pyrite formation and the formation of reduced microniches was thus probably further enhanced when the oxic-anoxic
 interface seasonally moved to the sediment-water interface during late summer (Stachowitsch, 1984; Cermelj et al., 2001).

(2) Most of the sulfide is re-oxidized in environments with bioirrigation and sediment mixing (Canfield et al., 1993;
 500 Thamdrup et al., 1994a). Reduced conditions with pyrite linings within shells or burrows thus will be transient when
 sedimentation rate is low and/or when bioirrigation and sediment exhumation by burrowers oxidize such microniches
 (Bertics and Ziebis, 2010). The positive relation between pyrite and fine-scale dissolution, and transformation of some pyrite
 grains to iron oxides and gypsum indicates that some pyrite-lined valves at Po or Panzano were briefly exposed to
 oxygenated pore waters and were partly dissolved by sulfuric acid (Cai et al., 2006; Pirlet et al., 2010; Hu et al., 2011).
 505 However, this reoxygenation did not erase the pyrite linings, and many valves at Po and Panzano were still buried at
 sufficiently high rate relative to the time scale of pyrite oxidation and shell dissolution (ultimately driven by mixing and
 bioirrigation) so that a significant subset of pyrite-lined valves survived into the subsurface record. The conditions that
 ultimately allow the transit of reduced microniches formed by pyrite-lined shells at sites with high sedimentation rate into the
 subsurface stratigraphic record can occur (i) when the frequency of hypoxic or mucilage events is high, leading to periodic

510 sediment organic enrichment and high oxygen demand of sediments, thus perpetually reducing the extent of O₂ sediment penetration, and/or (ii) when recovery of infaunal communities in the wake of anoxic or hypoxic events in environments affected by eutrophication (as in the northern Adriatic Sea) is slow and in hysteresis (Kemp et al., 2009; Borja et al., 2010; Duarte et al., 2015). Depending on the frequency and duration of sediment organic enrichment, two preservation scenarios can be envisioned (Fig. 15): (i) If the frequency of anoxic or hypoxic events is low and benthic communities rapidly recover, articulated shells will disarticulate and disintegrate when exposed to scavengers, borers and degradation of organics in TAZ. For example, maceration of the conchiolin layer triggers delamination of valves into inner and outer layers (Fig. 3E-H). In such conditions, O₂ penetration and the thickness of the ferruginous suboxic zone will increase (van de Velde and Meysman, 2016), and the thickness of the aerobic zone and the whole mixed layer will increase (Fig. 15A). Pyrite framboids will not nucleate on valves anymore if the labile biomass and microbes coating the decaying tissues were degraded during the earlier phase of decomposition. Therefore, even when sedimentation rate is relatively high and associated with bacterial sulfate reduction in microniches surrounded by iron-dominated pore waters, bioirrigation will catch up with pyrite-lined shells prior to their deep burial and thus inhibit their subsurface sequestration by oxidation. (ii) If the frequency of hypoxic events is high relative to the recovery time of the burrowing community, some subset of pyrite-lined shells can remain preserved if recovery of bioirrigation-inducing burrowers is slow and O₂ penetration depths remains close to the sediment-water interface (Fig. 15B). These conditions with reduced bioturbation and limited iron recycling are typical of oxygen-depleted or strongly-eutrophied environments (Karlson et al., 2007; Lehtoranta et al., 2009). Although the present-day estimates of the mixed-layer depth in the northern Adriatic Sea do not indicate any apparent limitation on bioturbation (see below), we suggest that such conditions also characterized benthic habitats with fine-grained sedimentation in the northern Adriatic Sea in the late 20th century. If the nutrient-fueled eutrophication or other sources of sediment organic enrichment lead to permanent oxygen-depletion and to sulfidic sediments at the sediment-water interface (and the formation of dead-zones), the concentrations of pyrite framboids within shells or within intra-skeletal pores will be limited by iron availability, and most pyrite will be disseminated rather than clustered.

5.3 Temporal changes in bioturbation generate stratigraphic trends in frequency of pyrite-lined valves

535 Within-core trends in the frequency of pyrite-lined valves at prodelta sites and the modality of whole-core age distributions of pyrite-lined valves hint to chronological changes in the preservation of pyrite linings. First, in addition to a general feature of the whole-core age distributions dominated by valves younger than 10 years, generated under active input of new dead shells into the mixed layer, older modes in these distributions are indicative about temporal changes in conditions that favored or inhibited the preservation of pyrite linings. At Po, pyrite-lined valves show a secondary mode at ~30-50 years that is formed by cohorts from the late 20th century, and most valves older than ~100 years do not have pyrite linings (Fig. 9E-F). Similarly, at Panzano, pyrite-lined valves form a mode that is represented by cohorts from the late 20th century (Fig 9G-H). Second, the stratigraphic increase in the frequency of pyrite-lined valves and multivariate segregation in preservation of *V. gibba* valves between the early and the late 20th century increments at Po and Panzano (below the mixed layer) indicate that O₂ exposure of shells in the mixed layer was longer prior to and during the early 20th century than during the late 20th century. Any effects on early diagenetic pathways determined by changes in grain size can be excluded because sediment grain size remains constant downcore at Po and Panzano. Although paleoecological records of foraminifers and dinoflagellates indicate that eutrophication affects the northern Adriatic Sea ecosystems since the 19th century (Barmawidjaja et al. 1995; Sangiorgi and Donders 2004), a main shift in the composition of macrobenthic communities and size of the bivalve *V. gibba* occurs at the same stratigraphic levels where pyrite linings increase in frequency, i.e., at 80-90 cm at Po and at 12-20 cm Panzano stations (Tomašových et al., 2018, 2020). These levels correspond to the mid-20th century at both

prodeltas, and coincide with an increase in nutrient load and in seasonal hypoxia and mucilage frequency in the northern Adriatic Sea (Marchetti et al., 1989; Justic, 1991). Several mutually not exclusive factors probably contributed to the stratigraphic increase in the frequency of pyrite-lined valves, including (1) a temporal increase in hypoxia coupled with an increase in sediment organic enrichment, and (2) a temporal decline in sediment mixing and bioirrigation. Although the initial formation of pyrite framboids in reduced microniches in near-surface sediments can naturally occur in fine-grained and poorly-permeable sediments, it was probably also enhanced by multiple processes that occurred during or in response to hypoxic events and accentuated seasonal shallowing of the oxic-anoxic sediment boundary (Middelburg and Levin, 2009): by a decline in dissolved oxygen concentrations in the overlying water column (reducing sediment penetration by O₂ although permanent anoxia underlain by sulfidic sediment can trigger iron escape from sediment, Pakhomova et al., 2007), by decay of planktonic and benthic phytoplankton or mucilages that increased oxygen demand of sediments as they accumulated on the sediment-water interface (Herndl et al., 1987, 1989), or by decay of high-biomass epifaunal communities during late-summer mass mortality events (Stachowitsch, 1984; Nebelsick et al., 1997). The frequency and magnitude of all these effects probably increased in the late 20th century in the northern Adriatic Sea, thus increasing the likelihood of initiation of reducing microniches within articulated shells of bivalves (rather than being exposed to disarticulation by predators or scavengers).

Regardless of initial pathways that led to the formation of pyrite linings in reduced microenvironments, hypoxic and mucilage events that are seasonal or inter-annual in frequency in the northern Adriatic Sea tend to be followed by recovery of infaunal species under oxygenated conditions (leading to iron recycling and pyrite oxidation), and oxygen depletion of near-surface sediments is thus not permanent if infaunal communities fully recover. However, seasonal anoxic or hypoxic events have lasting effects on mixing and irrigation rates because benthic communities tend to recover from such events at slow rate (Bentley and Nittrouer, 1999; Solan et al., 2004) and can remain in a hysteresis state (Duarte et al., 2015). This delay, with benthic recoveries occurring over several years (Borja et al., 2010), was also observed in the northern Adriatic Sea (Stachowitsch, 1991). The decline in mixing and bioirrigation in the wake of hypoxic events (that became more frequent during the late 20th century in the northern Adriatic Sea) was probably crucial for transfer of pyrite linings into the subsurface stratigraphic record, as envisioned in the scenario in Fig. 15B. The present-day bioturbation rates are thus probably lower relative to those that characterized the northern Adriatic Sea prior to the late 20th century. This inference is supported by three observations. First, the positive relation between *V. gibba* size and biomass on one hand and abundances of pyrite-lined valves on the other hand support the hypothesis that eutrophication-driven regime shift in the functioning of benthic communities in the late 20th century reduced biomixing and bioirrigation. Second, at Po and Isonzo prodeltas, the late 20th century infauna is dominated by shallow-burrowing deposit- and detritus-feeders that modify surface sediments, including *Owenia fusiformis*, *Varicorbula gibba* or *Ampelisca diadema* (Occhipinti-Ambrogi et al., 2005; Solis-Weiss et al., 2007; N'Siala et al., 2008). These patterns differ from early 20th century ecological surveys (Vatova, 1949; Crema et al., 1991; Schinner, 1993; Schinner et al., 1997) and the early 20th century increments in cores (Gallmetzer et al., 2017; Tomašových et al., 2018) that indicate that pre-eutrophication benthic communities were dominated by biodiffusers such as *Schizaster*, *Amphiura* or *Turritella*. The ophiuroid *Amphiura filiformis* (extensively reworking and irrigating sediments, Solan and Kennedy 2002; Vopel et al., 2003) or the gastropod *Turritella communis* are not abundant at prodelta sites and tend to occur at deeper sites with slower sedimentation rates in the northern Adriatic Sea in the late 20th century surveys (Chiantore et al., 2001). In contrast to *Amphiura*, the ophiuroid *Ophiura albida* that is abundant at Po stations belongs to slow biodiffusers. Third, abundant burrows of shrimps and the 16-20 cm-thick age-homogenized layer the Po stations observed at the time of core sampling in 2013 at Po indicate that biomixing is apparently not limited: the thickness of the mixed layer is typical of mixed-layer thickness observed in other marine shelf environments (Teal et al., 2010). It is also not within the range of mixed-layer thickness typical of persistently-hypoxic environments on the scale of 5 cm on continental

slopes (interspersed with laminated sediments, Meadows et al. 2000; Smith et al. 2000; Levin et al. 2003). However, the estimates of the mixing depths on the basis of ^{210}Pb profiles indicated mixing depths < 10 cm in the late 20th century at Po prodelta (Frignani and Langone, 1991; Frignani et al., 2005; Alvisi et al., 2006, 2009) and the thickness of the mixed layer at the Po prodelta as estimated on the basis of sediment cores probably exceeded 20 cm prior to the late 20th century (Tomašových et al., 2018). In addition to changes in sediment mixing, the nature of benthic communities indicates that irrigation was slower and that iron and sulfide recycling was less efficient in the late 20th century at Po and Isonzo prodeltas than earlier. To conclude, these observations support the hypothesis that the stratigraphic shift towards higher pyrite frequency of pyrite-lined shells coincides with changes in the composition of macrobenthic communities that reduced their mixing and irrigation efficiency during the 20th century.

6. Implications for the fossil record: inferring slow and patchy bioturbation and limited residence time

The pyrite framboids lining intra-skeletal pores (originally filled with organic tissues) in well-preserved shells represent a unique indicator of slow irrigation and their permanent transfer below the oxic-anoxic sediment interface. Such conditions can be produced by delayed recoveries from hypoxic events and/or by community states with low bioirrigation potential that are unable to recover anymore even when the frequency of hypoxic events returns to pre-impact levels (Steckbauer et al., 2011). In permanently-normoxic environments with intense bioturbation where most labile biomass degrades within the aerobic zone and any early pyrite is oxidized, the frequency of shells with shell-lined pyrite transferred into the permanent record will be negligible. This index can be also used to track the net O_2 exposure of skeletal remains and recycling efficiency of iron and sulfides in the deep-time stratigraphic record because pyrite-lined shells represents a distinct taphonomic and diagenetic signature of fossil assemblages preserved in fine-grained sediments (Kobluk and Risk, 1977; Hudson, 1982; Bjerreskov, 1991; Underwood and Bottrell, 1994; Farrell et al., 2009; Brett et al., 2012a), especially in organisms with internal skeletal cavities that do not immediately open after their death (Hudson, 1982; Fisher, 1986; Loope and Watkins, 1989; Jin et al., 2007). On one hand, preservation of well-preserved, frequently articulated skeletal remains of organisms with otherwise fragile elements, coupled with pyrite linings, is a typical taphonomic feature of assemblages preserved in fine-grained sediments in the Paleozoic (Brett et al., 2012a, b) or in the Mesozoic successions (Hudson, 1982; Fernández-López et al., 2000; Paul et al., 2008; Reolid, 2014). On the other hand, actualistic studies assessing skeletal alteration of molluscs, brachiopods or echinoderms rarely record this type of preservation in surface Holocene sediments. It is possible that the concentration of actualistic studies on the taphonomic processes in the mixed layer and on environments with slow sediment accumulation rates underestimate this type of preservation. However, here, we suggest that prodelta sediments in the northern Adriatic Sea affected by the late 20th century eutrophication can represent analogue conditions that lead to preservation of well-preserved and pyrite-lined shells in the deep-time stratigraphic record. In contrast to models invoking rapid episodic burial to explain the initial sequestration of shells so that they do not disarticulate and decay under anaerobic conditions, the pathway observed in prodelta sediments in the northern Adriatic Sea probably occurs without episodic burial. Although background sedimentation rates need to be sufficiently high so that the time for burial of skeletal remains is shorter the time to mix and irrigate the mixed layer, the effect of sedimentation rate is critical for minimizing the potential for reoxidation rather than for initial sequestration of shells in microniches.

7. Conclusions

Preservation of pyrite-lined shells as a function of rapid and permanent sequestration below the taphonomic active zone is an indicator of inefficient mixing and bioirrigation, thus documenting limited iron and sulfur recycling at sites with high

sedimentation rates in the northern Adriatic Sea. The preservation pathway that leads to primary pyrite linings and their long-term preservation is indicative of permanently-limited depths of O₂ penetration and bioirrigation that can be difficult to detect on the basis of trace fossils and ichnofabric only. Pyrite-lined valves thus represent a unique type of alteration that contrasts with other types of alteration whose incidence increases with residence time in the taphonomic active zone. We suggest that the increase in the frequency of valves with pyrite below the mixed layer at 80-90 cm at the Po prodelta and at 12-20 cm at the Isonzo prodelta represents a temporal signal of the decline in the rate of mixing and bioirrigation in muddy sediments of the northern Adriatic Sea driven by a late 20th century increase in the frequency of seasonal or inter-annual hypoxia and organic enrichment that delayed the recovery of infaunal communities. Although the rates of pyrite formation can also vary over long time scales owing to long-term changes in seawater chemistry (Leavitt et al., 2013; Algeo et al., 2015) and depend on the supply of organic matter and iron availability (Goldhaber et al., 1977; Berner and Raiswell, 1983; Berner, 1984; Berner and Westrich, 1985; Kershaw et al., 2018; Wignall et al., 2005, 2010), we hypothesize that the frequency of pyrite-lined shells (belonging to organisms that inhabit oxic sediment zones) can improve inferences about mixing and irrigation and about the net exposure time of skeletal particles to irrigation in the mixed layer.

Acknowledgments

This work was supported by the Austrian Science Fund (FWF) [grant number P24901, 2013, by the Slovak Research and Development Agency (APVV 0555-17) and by the Slovak Scientific Grant Agency (VEGA 2/0169-19). Many thanks to the captain of the sampling vessel, Jernej Sedmak, for his commitment during the sampling campaign in 2014.

Figure 1 – A. Geographic map with the locations of five sites analyzed in this study: 1 – Po 4 (with two replicate cores M20 and M21), 2 – Po 3 (with two replicate cores M13 and M14), 3 – Bay of Panzano in the northern Gulf of Trieste (with two sediment cores M28 and M29), 4 – Piran (M53 core) and 5 – Brijuni (M44). B-D. Sea floor photographs taken in 2014 at
 1075 Piran (B, with abundant *Ophiotrix*), Po 4 (C, with abundant *Ophiura albida*) and Po 3 (D) documenting abundant burrow and mound structures and uneven topography. The size of the square is 25 cm². The thickness of the mixed layer at Po is ~20 cm on the basis of both ¹⁴C and ²¹⁰Pb and also at Brijuni, and ~ 8 cm at Piran, underlain by a shell bed.

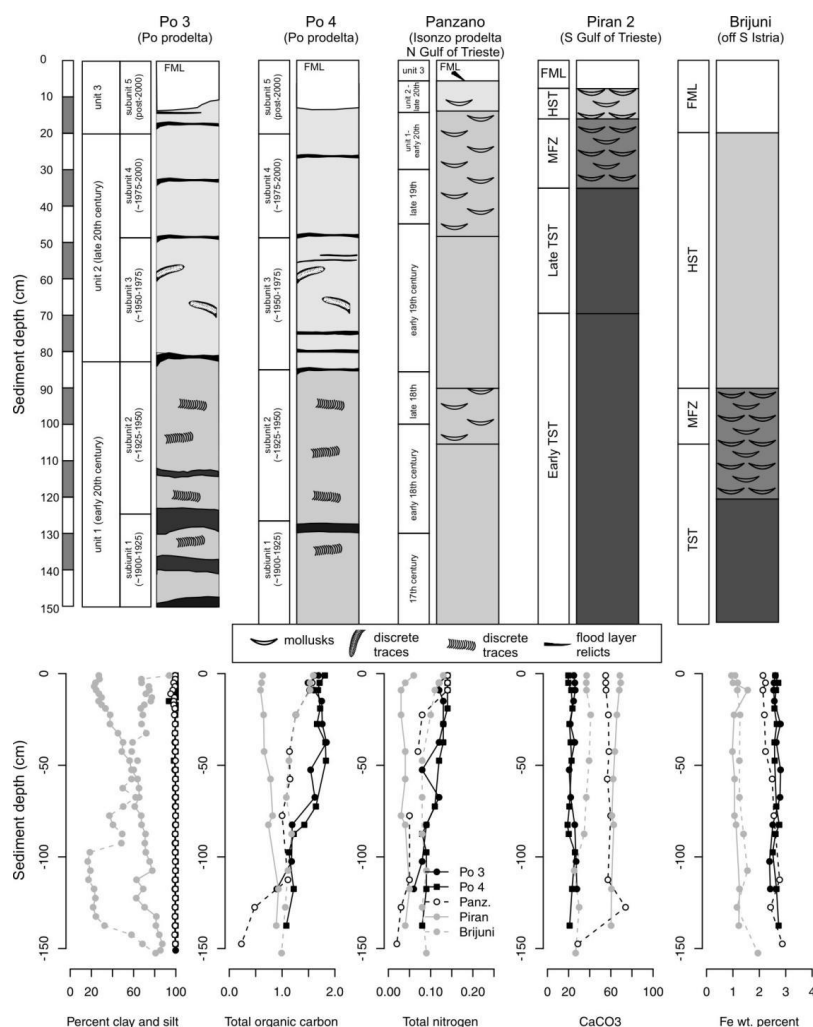

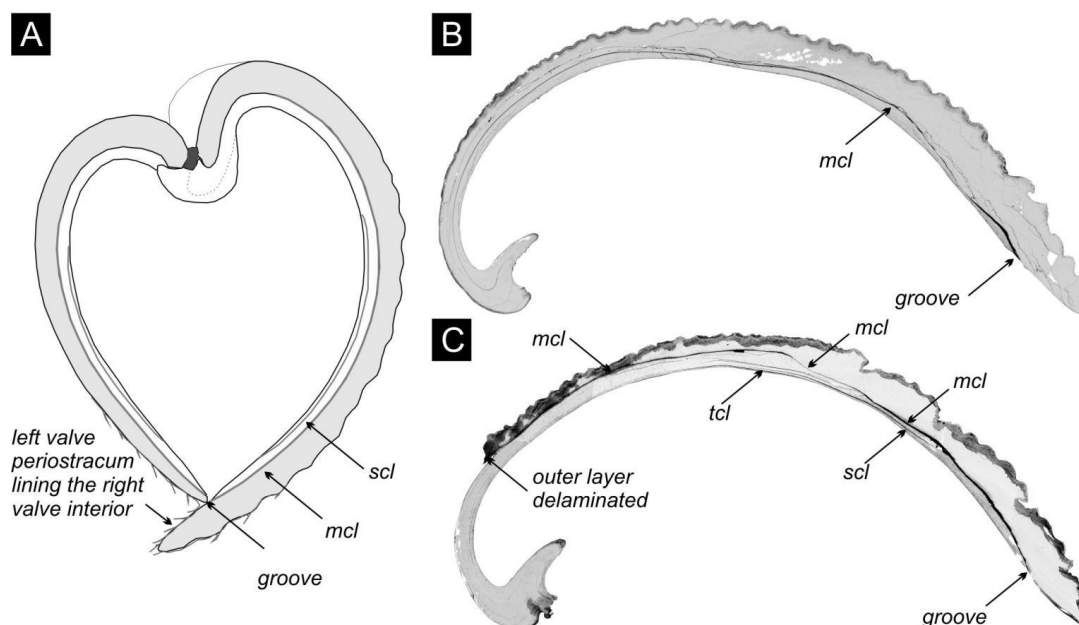

Figure 2 – Top row: Lithologic sections through sediment cores at five locations, with the highest sedimentation rate (1-2 cm/y) at Po stations, intermediate net sedimentation rate (0.2-0.4 cm/y) in the Bay of Panzano, and very slow sedimentation rate at Piran and Brijuni (~0.01 cm/y), with chronostratigraphic subdivisions. TST – transgressive systems tract, MFZ – maximum flooding zone, HST – highstand systems tract, FML – mixed layer. Bottom row: Stratigraphic trends in grain size, total organic carbon and nitrogen (TOC and TN), CaCO₃ (based on total inorganic carbon), and the weight percent of iron also discriminate between sites with higher sedimentation (Po and Panzano) and sites with slower sedimentation (Piran and Brijuni).

1090

Figure 3 – A. The cross-section of the articulated shell of *V. gibba*, modified according to Lewy and Samtleben (1979), shows that the internal conchiolin layer (mcl) separates both valves into an inner later and an outer layer, and the inner layer can contain another secondary conchiolin layer (scl). The left valve fits into a groove with the conchiolin layer on the interior of the right valve. Periostracum on the left valve extends beyond its length and covers the interior of the right valve. B. The section through the right valve with a cavity (in black) initially filled by the single (main) conchiolin layer. Po 3 (core M14) at 40-45 cm. C. The section through the right valve with 10-100 µm-thick cavities (mcl – main conchiolin layer, scl – secondary conchiolin layer, tcl – tertiary conchiolin layer) left by several conchiolin layers (some cavities are still filled by carbonate nodules or by pyrite). Po 3 (core M13) at 65-70 cm.

1100

Figure 4 - *Varicorbula gibba* from Po and Panzano stations (characterized by high sedimentation rates), showing the variability in external and internal preservation, with well-preserved valves with (A-B) or without periostracum (C-D). The interiors of some specimens are lined by pyritic framboids that form isolated and dispersed framboids (A), strings (B), and patchy or continuous coatings on the conchiolin layer (C-F). These specimens tend to be associated with brownish grains and streaks and with surface internal dissolution. Some specimen have blueish color (U-X). A-B. Left valve, M28-65-70 cm-29, C-D. Right valve, M21-90-95 cm-1. E-F. Outer layer of the right valve, M13-65-70 cm-25. G-H. Inner layer of the right valve, M13-20-25 cm-8. I. Internal conchiolin layer exposed in a fragment, M20-120-125 cm. J-K. Left valve with periostracum and finely dispersed pyrite framboids on interior, M21-2-4 cm-2, L. Interior of the right valve with strings of pyrite framboids, M21-90-95 cm, M. Interior of the left valve lined by pyrite framboids, M28-110-115 cm-22, N. Interior of the right valve almost continuously lined by pyrite framboids, M28-110-115 cm-14, O. Interior of the right valve lined by patches of pyrite framboids, M21-30-35 cm-29, P. Interior of the left valve with strings of oxidized pyrite framboids, M28-125-130 cm-21, Q-R. Blue-stained right valve, M28-85-90 cm-1. S-T. Blue-stained right valve, M21-105-110 cm-4. Note: clg – conchiolin groove, pl – pallial line, pyr – framboidal pyrite, icl – internal conchiolin layer.

1115

Figure 5 – *Varicorbula gibba* from a Piran and Brijuni stations (sites with slow sedimentation) with worn, bored, encrusted and stained valves. A-B. M53-0-2 cm-7, C-D. M53-0-2 cm-6, E-F. M53-0-2 cm-4, G-H. M53-100-105 cm-1, I-J. M53-0-2 cm-2, K-L. M44-140-145 cm.

1120

1125

Figure 6 – Thin-section photographs showing pyrite framboids on the inner surface of *V. gibba* and preservation of more altered valves. A – A pristine right valve not lined by pyrite framboids, M13-65-79 cm-29. B-C - Internal surface of well-preserved right valve lined by pyrite framboids, M21-90-95 cm. D - Internal surface of well-preserved right valve lined by pyrite framboids, M14-40-45 cm. E – Internal conchiolin layer with a dark-stained mixture of carbonate nodules and pyrite rimmed by Fe oxides, M20-120-125 cm. F – Strongly bored valve filled micrite and stained by nanopartic inclusions, M44-140-145 cm.

Figure 7 - Backscattered electron images showing pyrite framboids on *V. gibba* valve interiors and in the main conchiolin layer in well-preserved valves and pyrite framboids and nanopyrite in microborings or microfractures in highly altered valves. A-D – Pyrite framboids attached to the interior surface, Po 3 (M14)-40-45 cm. E-F – Pyrite framboids attached to the interior surface, Po 4 (M21)-90-95 cm. G-I – Pyrite framboids on the interior and framboids (located between aragonite nodules) rimmed by Fe oxides in the main conchiolin layer, Po 4 (M20)-120-125 cm. J-K – a well-preserved specimen without microborings but with blueish staining contain nanopyritic inclusions (aggregation of micro-sized microcrystals), Piran (M53)-100-105 cm-1. L – a dark-stained specimen with intense microborings, encrustations and cementation of pores and borings filled by framboids (sp - secondary pyrite lining), by nanopyritic inclusions (np), and by high-Mg calcite (darker infills), Brijuni (M44)-140-145 cm-2 – Scale bars: A, E, H – 100 µm, B-D, F, G, I-L - 10 µm.

Figure 8 – Internal surfaces of *V. gibba* with isolated and clustered framboids on well-preserved valves from Po and with intense borings on valves from Brijuni. A-B – Dispersed pyrite microcrystals and isolated framboids clustered around the groove at which the internal conchiolin crops out. C – Dispersed pyrite microcrystals close to the groove. D – Sheets of organics underlain by framboids on the interior of the right valve close to the ventral margin. E – Clusters of dispersed microcrystals and isolated framboids on the well-preserved ventral valve margin. F – Strings of pyrite framboids, irregular flakes of Fe oxides, and small gypsum crystals. G, H – moderate (G) and strong bioerosion (H). A-B - Po4-30-35 cm-28, D-1140 F - Po4-30-35 cm-28, G - Brijuni-M44-70-75 cm-3, H - Brijuni-M44-70-75 cm-1. 1145

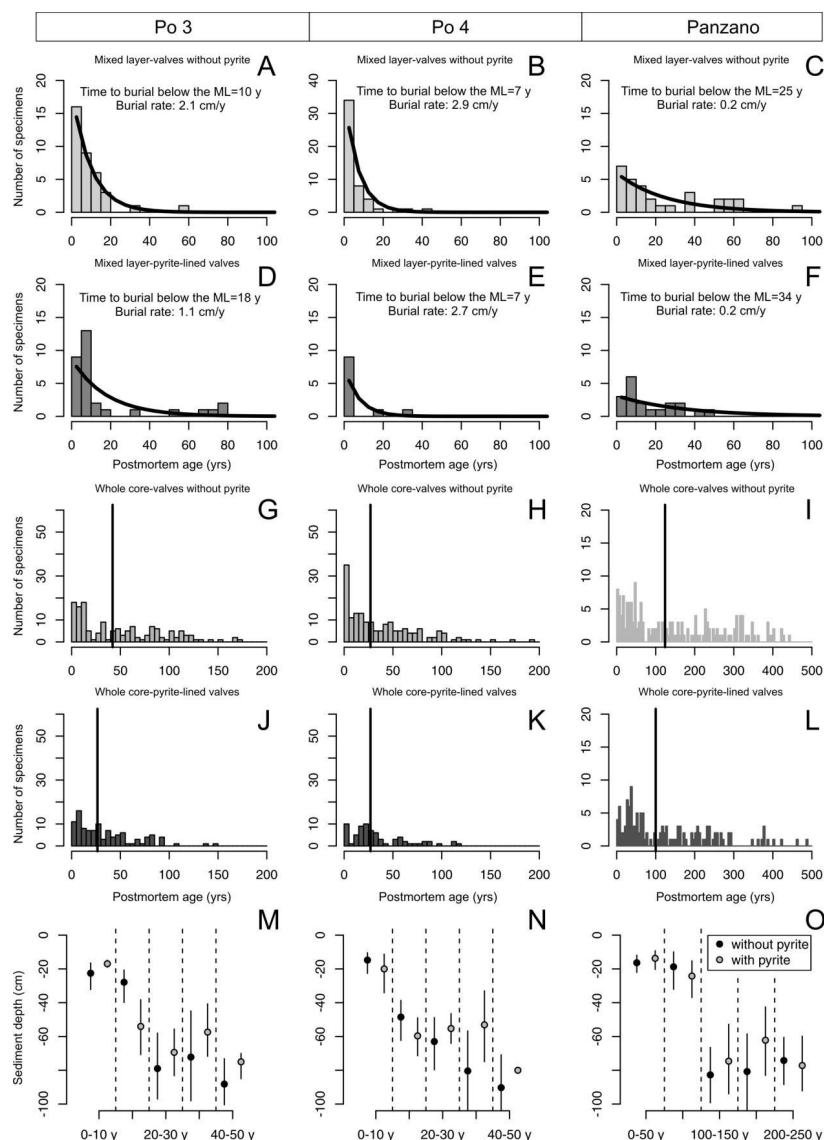

Figure 9 – A-L. Mixed-layer (A-F) and whole core distributions (G-L) of postmortem ages from Po 3, Po 4, and Panzano with valves with and without pyrite show that first, even the youngest valves less than 5-10 years old have pyritic linings.

Second, the mixed-layer distributions of valves with and without pyrite show similar right-skewed shapes well-fitted by a simple disintegration-burial model (black lines) that indicate that both types of valves are burial below the mixed layer at a similar rate (time to loss corresponds to the mean age of the distribution). The time to valve loss is congruent with ^{210}Pb -based estimates of sediment accumulation, indicating that loss rates primarily correspond to burial rates. At the scale of whole cores, pyrite-lined valves exhibit a mode at ~25 years Po 4 and a mode at ~50 years at Panzano. M-O. Mean sediment depths of valves with (gray) and without pyrite (black) of the same age are similar. Both age and depth distributions indicate that the scenario that pyrite formation is not associated with deeper burial and occurs in reduced microniches in near-surface sediment zones.

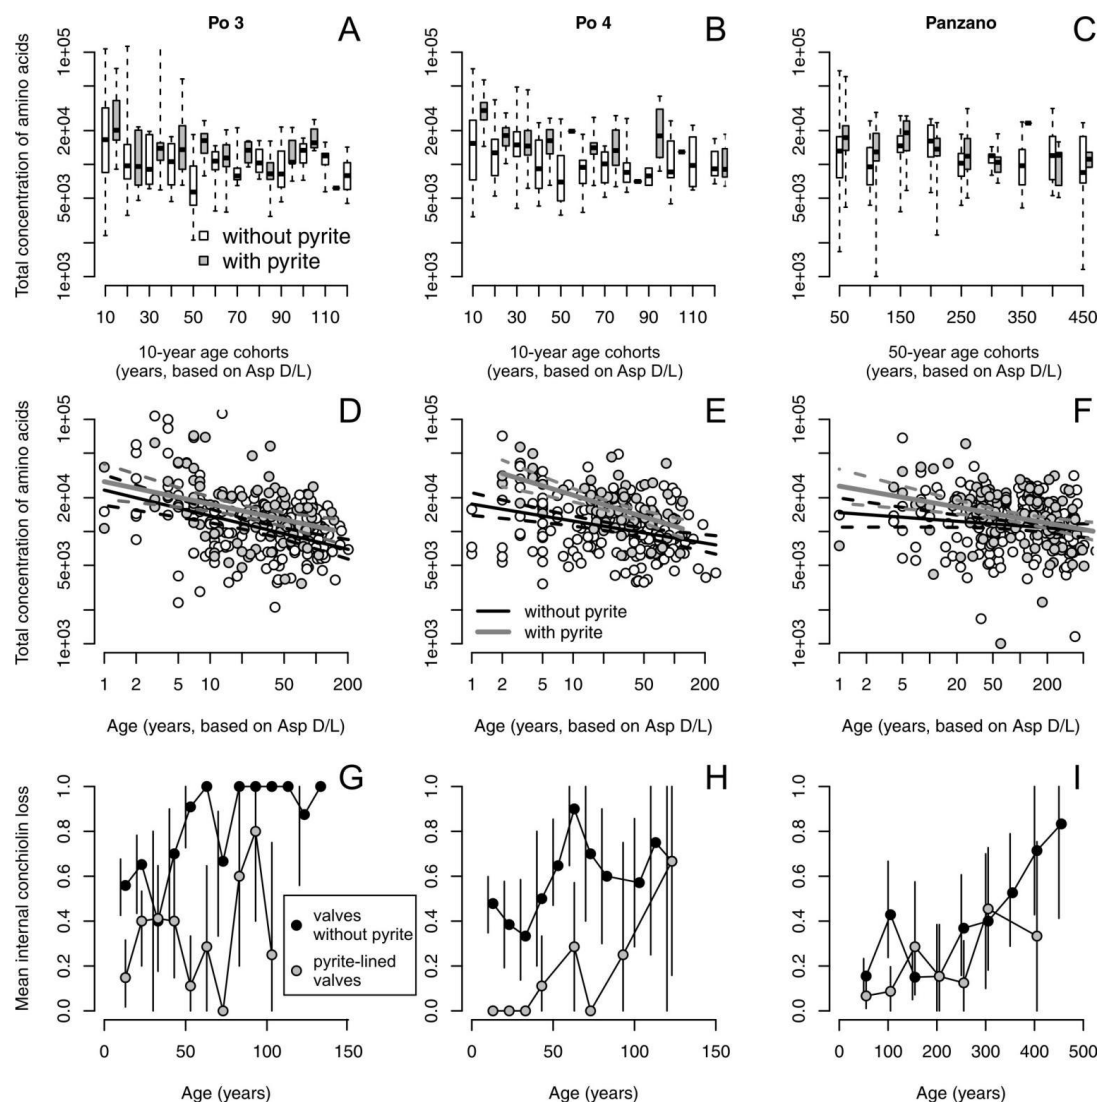

Figure 10 – A-C. Equally-old valves of *Varicorbula gibba* lined by pyrite tend to have higher concentrations of amino acids (visualized by boxplot pairs of valves with pyrite in gray boxes and without pyrite in white boxes) in the upper row, with age cohorts aggregated to 10 years at Po and 50 years at Panzano. D-F. Valves lined by pyrite possess higher intercepts of the linear dependence of log-transformed amino acid concentrations on log-transformed postmortem age than valves without pyrite. G-I. Valves lined by pyrite show higher mean frequency in preservation of periostracum or conchiolin layer than valves not lined by pyrite, with age cohorts aggregated to 10 years at Po and 50 years at Panzano.

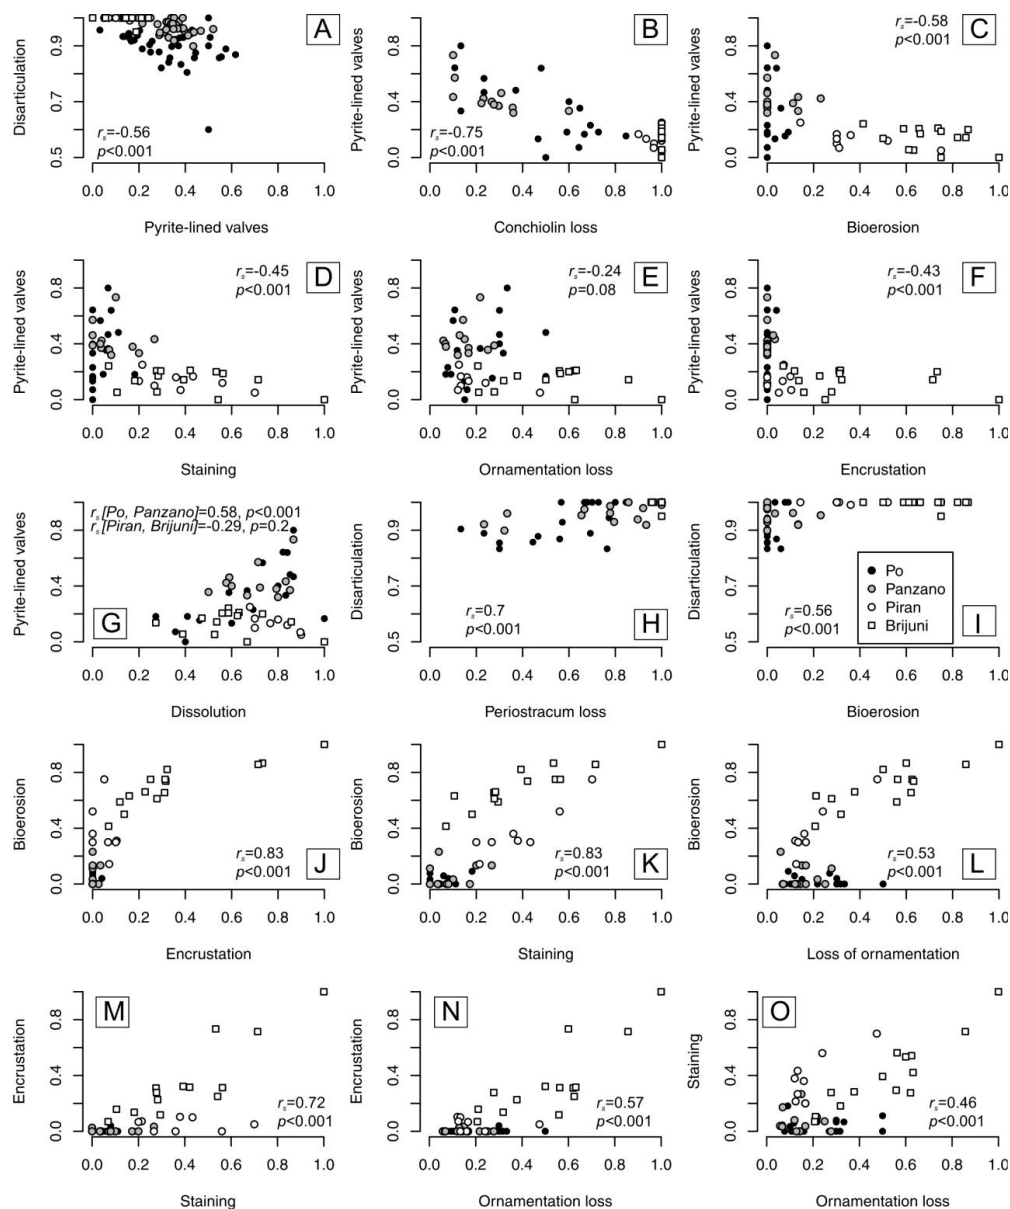

Figure 11. A-F. Negative relationships between per-increment frequencies of pyrite-lined valves and frequencies of other types of alteration (r_s values refer to Spearman rank correlations). G. The relation between frequencies of pyrite-lined valves and fine-scale dissolution depends on the site location and the pathway that ultimately leads to dissolution (pyrite oxidation at Po and Panzano or bioerosion at other site). Valves with pyrite commonly show internal fine-scale dissolution but are still associated with some surviving portions of periostracum or conchiolin layer. However, high frequencies of dissolved specimens are associated with low pyrite preservation as specimens from Piran and Brijuni are bored and dissolved but rarely associated with pyrite grains. H-L. Pairwise positive relationships between frequencies of disarticulation, conchiolin loss, bioerosion, encrustation, staining, and loss of ornamentation. M-O. Pairwise positive relationships between frequencies of encrustation, staining, and ornamentation loss.

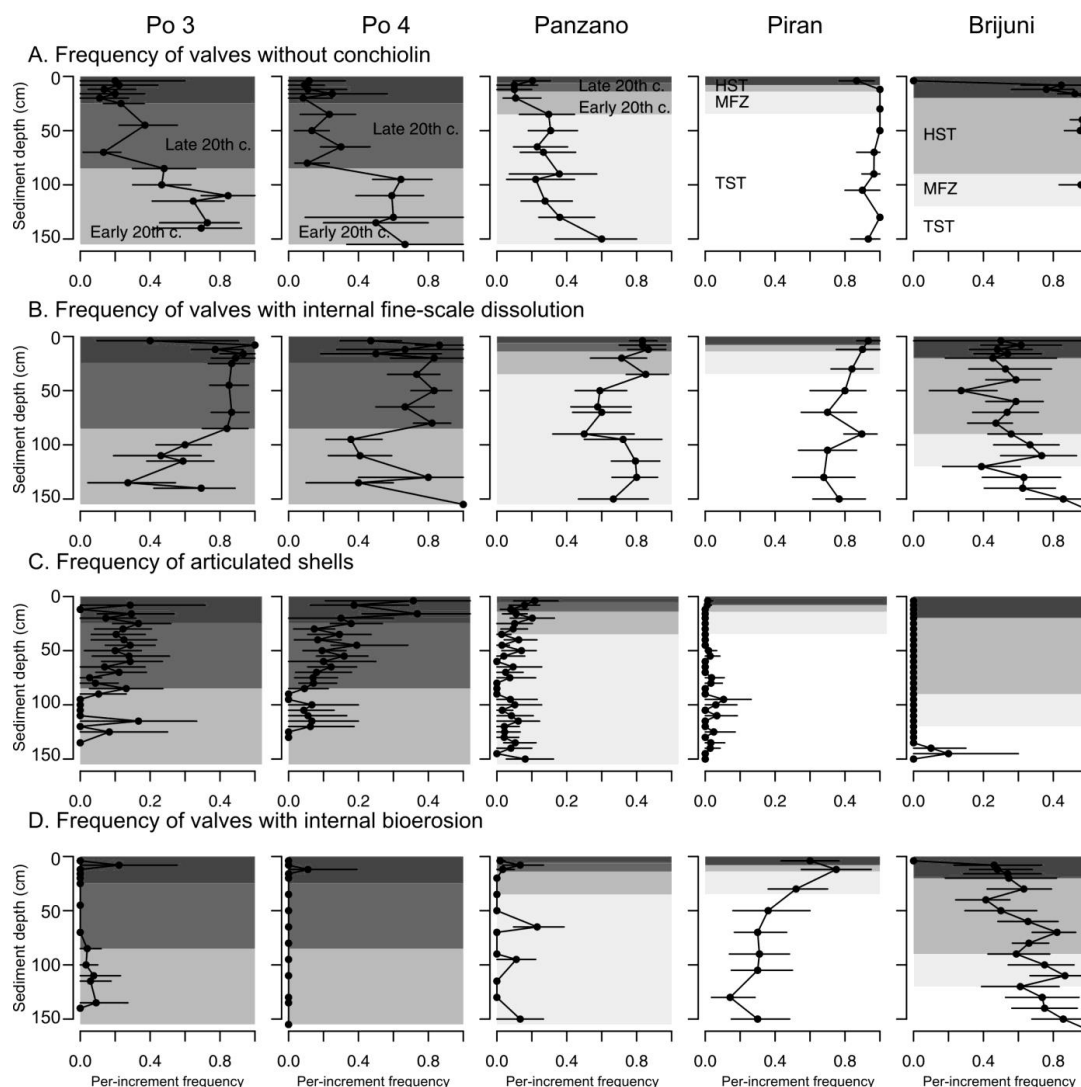

Figure 12 – A. Principal coordinate analysis (PCO) based on *V. gibba* alteration (using seven variables) in increments from all sites (excluding increments from the mixed layer). B. Correlations between PCO axis 1 and eight alteration variables show that pyrite varies inversely with other alteration variables. C. Principal coordinate analysis of increments Po and Panzano, showing the separation between the latest HST (white circles) and the late 20th century increments (black circles), mainly determined by the frequencies of pyrite-lined specimens (contours). D. Stratigraphic changes in the frequencies of all pyrite-lined valves (gray circles) of *V. gibba* peak at 40-50% in the upper part of cores at Po 3 and Po 4 and at 50% at ~10-20 cm at Panzano. The frequencies of pyrite-lined valves are typically less than 20% at Piran and Brijuni where sedimentation rates are slow. The frequencies of pyrite-lined valves at Piran and Brijuni further decline when the frequencies of pyrite-lined valves are limited to valves not affected by bioerosion (black circles), magnifying the contrast between well-preserved pyrite-lined valves at sites with high sedimentation (primary linings) and variably-preserved pyrite-lined valves at sites with slow sedimentation (with some pyrite corresponding to secondary linings).

1190 **Figure 13** – Stratigraphic changes in the per-increment frequency of valves of *Varicorbula gibba* affected by the loss of conchiolin (A, external periostracum and internal conchiolin), by internal surficial fine-scale dissolution (B), characterized by the presence of articulation (C), and by internal bioerosion (D). TST – transgressive systems tract, MFZ – maximum flooding zone, HST – highstand systems tract.

1195

Figure 14 – The positive relationship between *V. gibba* biomass per increment and the frequency of valves lined by pyrite grains, interpreted to reflect the response of ecological and taphonomic processes as responding together to higher hypoxia frequency and a narrower extent of aerobic respiration in sediment, possibly linked by higher input of organics at times of mass mortalities and reduced mixing during the recovery. Within-core relationships show stronger relationships than regional-scale relationships that are affected by between-core differences in time averaging and thus absolute and proportional abundances are noisy.

1200

Figure 15 – Two pathways characterized by differences in the frequency of sediment organic enrichment and hypoxic events and/or by differences in recovery rate of infaunal communities with high mixing and irrigation potential. Both pathways promote the initial formation of reduced microniches when shallow-infaunal shells decay in sediments with iron-dominated pore water. A. In the aftermath of hypoxia, reduced microniches are formed initially, but these are recycled under recovery of infaunal communities that oxidize sediment and contribute to skeletal disintegration of initially articulated shells. B. If the frequency of hypoxic events associated with higher oxygen consumption is high, the oxic-anoxic interface repeatedly shallow within the sediment. The recovery of burrowing infauna is slow and bioirrigation remains patchy, and some subset of reduced microniches is thus not oxidized. Therefore, shells with pyrite linings can escape the mixed layer in the subsurface stratigraphic record even when the sediment fabric is bioturbated. In the historical layer, valves permanently remain in reducing conditions.

Table A1 – The results of fitting age-frequency distributions (with valves with and without pyrite) from the mixed layer at three stations to a simple disintegration model (with temporally-constant loss rate from the mixed layer) and to a
 1220 sequestration model with three parameters. AICc - Akaike Information criterion corrected for sample size.

	Simple disintegration model (1 parameter)				Sequestration model (3 parameters)				
	Sample size (n)	lambda (loss from mixed layer)	Neg. log-likelihood	AICc	lambda1 (early loss from mixed layer)	lambda2 (late loss from mixed layer)	tau (sequestration)	Neg. log-likelihood	AICc
