Abstract. Shallow tropical marine environments are likely to experience future water temperatures that will challenge the ability of life to survive. Here, the response of a Malaysian microphytobenthic community to temperature and light was examined. The photosynthetic productivity of tropical microphytobenthos (MPB) is largely driven by changes in light intensities and temperature at the surface of sediment flats during emersion. Changes in temperature and irradiance during tidal cycles in the Tanjung Rhu estuary, Langkawi, Malaysia in 2007 significantly affected the photosynthetic capacities of the MPB. Higher photosynthetic parameters, such as maximum relative electron transport rate (rETR_{max}), photosynthetic efficiency (α), maximum quantum yield (F_v/F_m) and effective quantum yield ($\Delta F/F_m$), were recorded at high tide when the temperatures were lower. However, when the community was experimentally exposed to irradiances of 1800 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$, they were only able to photosynthesize at temperatures < 50 °C. Above this temperature, no photosynthetic activity was observed. Not only did high temperatures at high irradiance affect the algal communities, but limited photosynthetic activity was also observed in samples when exposed to limited irradiance. Recovery rates were highest at the lowest temperatures and decreased as the temperature increased. The recovery rates for samples exposed to temperatures of 40 °C were $4.01\text{E-}03 \pm 0.002 \text{ s}^{-1}$ and decreased to $1.01\text{E-}05 \pm 0.001 \text{ s}^{-1}$ at 60 °C, indicating irreversible damage to Photosystem II (PSII). These characteristics suggest that the MPB communities in this estuary were able to adapt to temperature variation. However, enhanced photoinhibition would result if exposed to elevated temperatures, especially during low tide where in situ temperature was already 43°C. Hence, if in situ temperature was to further increase during tidal emersion, 50 °C could be a temperature threshold for photosynthetic performance of tropical estuarine benthic microalgal communities.

30 1 Introduction

Microphytobenthos (MPB) makes a significant contribution to the primary production of shallow coastal and estuarine environments, regularly contributing more than 50% of the total annual production (Underwood 2002, Rajesh et al. 2001). A few key environmental factors influence biomass production. For instance, high turbidity, which is a characteristic of many tropical estuaries, reduces the irradiance reaching the microalgae mats which then limits photosynthesis (Underwood 2002).

35 Intertidal ecosystems in the tropics are affected by large changes in solar irradiance and temperatures, caused by tidal cycles. During prolonged low tides, variation in irradiances, temperatures, and salinity can adversely affect the photosynthetic activity of MPB communities (Underwood 2002, Laviale et al. 2016). To overcome these problems, many taxa have developed adjustment and avoidance strategies. Some can protect themselves physiologically against the damaging effects of exposure (Blanchard et al. 2004, Perkins et al. 2010) by dissipating the excess energy absorbed by light harvesting centres, a process known as non-photochemical quenching (NPQ), while others can move vertically in the sediment, adjusting their position to minimize irradiance (Consalvey et al. 2004a, Perkins et al. 2010, Cartaxana et al. 2013). For instance, in a study by Mouget et al. (2008) it was shown that benthic diatoms with a high migratory capacity could experience high photosynthetic activity without any evidence of photo damage, while non migratory taxa showed a significant depression in photosynthetic activity, which was caused by high irradiance and/or UV-B.

45

It is widely known that temperature plays an important role in the growth rate of all algal cells (Eppley 1972, Davison 1991, Eggert and Wiencke, 2000, Longhi et al., 2003). Prolonged exposure to temperatures significantly above ambient (ideal growth temperature) also leads to a decrease in the concentration of chlorophyll *a* per cell (Defew et al., 2004). Excess light energy can also subsequently cause a decline in photosynthetic activity, which is reflected in the response of Rapid Light

50 Curve (RLC) parameters (Du et al., 2018). With combined stresses, such as high temperature and irradiance and/or UV-B, damage to Photosystem II can be induced, impacting the recovery process; this is apparently more significant in planktonic diatoms by comparison with benthic species (Wu et al., 2017). Photoinhibited cells can mostly regain their capacity for photosynthesis when removed from a high light environment (Wu et al., 2017). The ability of algae to tolerate dynamic intertidal environments such as light and temperature changes during tidal cycles and periods of photoinhibition largely determines estuarine community species composition (Derks and Bruce, 2018). If photoprotective mechanisms are inadequate to mitigate excess light, overexcitation of PSII can occur leading to the production of reactive oxygen species (ROS), thus damaging the photosynthetic apparatus (Müller et al., 2001). The extent of photooxidative damage and the speed of recovery are related to the degradation rate of D1 protein and the subsequent re-synthesis and replacement by new proteins (Derks and Bruce, 2018; Domingues et al., 2012). Similarly, benthic diatoms inhabiting sediment surfaces in estuaries are usually able to recover from extreme temperatures and light photoinhibition caused by tidal changes, since photoinhibition is only rarely recorded in these communities (Defew et al., 2004; Lee and McMinn, 2013; Perkins et al., 2006). Furthermore, many have the ability to migrate vertically, hence positioning themselves within the sediment at a depth

that provides shading from excess irradiance and provides an optimal light environment for their photosynthetic activities (Cartaxana et al., 2011; Mouget et al., 2008; Perkins et al., 2010).

65 Due to the major contribution of MPB to ecosystem processes, they have been widely studied in tropical coral reefs and
intertidal flats and coastal intertidal zones (Mitbavkar and Anil 2002; Mitbavkar and Anil 2004; McMinn et al., 2005;
Underwood, 2002). However, there are relatively few studies of them in tropical estuaries (Patil and Anil 2008). Although
the photosynthesis of tropical benthic MPB communities is likely to be highly sensitive to elevated temperature,
comparatively little attention has been given to the combined effects of both elevated light and temperature. Water
70 temperatures in tropical marine ecosystems are already high and relatively small increases can have severe negative impacts.
Unfortunately, information on the combined effects of temperature and light on the photosynthetic responses from this
region is lacking. To date, the temperature tolerance of tropical microalgae has been studied mostly in plankton, which
cannot usually survive temperatures above ~ 30 °C, which is consistent with the maximal temperature they normally
experience (Indrayani et al., 2020; Thomas et al., 2012). MPB, however, may be exposed to much higher temperatures
75 during low tide that can be several times higher than in the water column. Global temperatures are predicted to increase over
the course of the century, and this will inevitably lead to higher temperatures in shallow benthic ecosystems. Thus, the aim
of this study is to determine the stress response of MPB physiology to the combined effects of elevated irradiance and
temperature and understand their subsequent recovery. We hypothesize that high light could reduce the photoprotection
capacity thus causing severe damage and impair the recovery process. To this end we exposed diatom-dominated
80 communities to a range of temperatures and used PAM fluorometry to measure photosynthetic characteristics during
exposure to different light levels.

2 Materials and methods

2.1 Study area and field sampling

Tanjung Rhu is located on the north coast of Langkawi, Malaysia (Fig. 1). The area has a humid, tropical climate with daily
85 maximum temperatures between 27.0 and 40.0°C. This estuary contains a range of habitats (beaches, mangroves, and
seagrass beds) all within close proximity. The estuary is mesotidal with semi-diurnal tides with a tidal range between 2 m
and 3 m. Much of the ecosystem is exposed during low tide and submerged during high tide. The estuary is surrounded by a
mangrove forest, mainly dominated by *Rhizophora* and *Avicennia* species. The benthic habitat is mostly composed of coarse
sand with patches of mud. The water normally carries a high-suspended load, originating partly from the mangrove forest
90 and from the river sediment itself.

Samples were collected in April 2007 from three sites (Site A, B and C) all in proximity (20 meters) to the intertidal zone of
the Tanjung Rhu Estuary, at ebb and flood tide. Description of sites A, B and C are provided in Table 1. Water height at ebb
tide was approximately 0 to 0.2 m and 0.5 to 1 m at flood tide. On each occasion, seven 15 mm diameter hand-pushed

95 sediment cores were taken; three for photosynthetic parameter analysis, three for chlorophyll *a* analysis and one for species composition. For the temperature incubation experiments, the top 10 mm (approximately) of the sediment was manually scraped off and placed in a dark plastic bag (20 x 20 cm). Samples were stored in the dark and promptly returned (approximately 15 minutes) to the laboratory for the experiments.

100 At each sampling site, environmental measurements (temperature, salinity, and photosynthetically active irradiance (PAR) were measured using a Hydrolab Datasonde 4a (Hach, Loveland CO). Water samples for all parameters and nutrient analyses were collected during high tide (water level: 1.0 m) and low tide (water level: 0.2 m). Nitrate, phosphate, and ammonium were analysed on a Hach Kit DR 2000 Spectrophotometer (Hach, Loveland CO). Ammonia, expressed as ammonia-nitrogen (NH₃-N), was determined using the Nessler method (Hach Company, 1995). Phosphate, expressed as phosphorus-phosphate (PO₄³⁻-P) was determined by the PhosVer (ascorbic acid) method (Hach Company, 1995). Nitrate, expressed as nitrate-nitrogen (NO₃⁻-N) was determined by the cadmium reduction method (Hach Company, 1995).

105 2.2 Chlorophyll *a* biomass

Chlorophyll *a* was measured as a proxy for algal biomass. The chlorophyll biomass was determined following (Jordan et al., 2010). For chlorophyll *a* biomass and fluorescence analysis, a 45 mm diameter clear polycarbonate cores were manually pushed into the sediment and stoppered using a rubber bung and immediately returned to temporarily established working place. Three cores were taken for three for biomass analysis and three fluorescence analysis (see PAM Chlorophyll
110 Fluorescence measurements). The sediment for chlorophyll *a* analysis, for both low and high tide samples, were placed in an ice-filled, light-proof container and immediately transferred to the laboratory. The top 10 mm of sediment was re-suspended in 10 mL methanol, thoroughly mixed, and then stored in the dark for 12 hours at 4 °C. After the sediment had settled, the solvent was decanted off to measure the chlorophyll *a* content using acidification methods (Holm-Hansen and Lorenzen, 1965). A Turner Designs 10AU Fluorometer (Sunnyvale, CA, USA) was used to measure the chlorophyll *a*. The fluorometer
115 was calibrated against a chlorophyll *a* standard (Sigma Chemical Co., St. Louis, MO, USA).

2.4 PAM Chlorophyll Fluorescence measurements

Variable fluorescence was measured using a Pulse Amplitude Modulation (PAM) (Schreiber 2004) fluorometer comprising a computer-operated PAM Control Unit (Walz, Effeltrich, Germany) and a WATER-EDF-Universal emitter-detector unit
120 (Gademann Instruments GmbH, Wurzburg, Germany). The top 10 mm of each core was sectioned on site, 5 for PAM fluorometry analysis. Each sample was mixed with filtered seawater and transferred into a vial wrapped in aluminium foil to protect them from light and to dark-adapt the samples for 15 min. The samples were shaken vigorously and then allowed to settle for approximately 10 s before analysis. The PAM methodology followed (McMinn et al., 2005) and Salleh and McMinn (2011).

125 To calculate the maximum PSII quantum yield (F_v/F_m) the samples were dark adapted in the field for 15 minutes by wrapping the jars in foil and placing them in a dark container immediately after sampling. Rapid light curves (RLCs) were taken under software control (Wincontrol, Walz) to obtain values for F_v/F_m , NPQ, and E_k (Ralph and Gademann, 2005). Red light emitting diodes (LED) provided the actinic light used in the RLCs at levels of 0, 85, 125, 194, 289, 413, 517, 1046 and 1554 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$. The saturation pulse irradiance was 3000 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ for a period of 0.8 seconds.

130 Samples were exposed to each light level for 10 seconds. Photomultiplier gain settings were between 3 and 8 (Wincontrol, Walz). E_k , the light saturation parameter, was calculated from the intercept between the maximum relative electron transport rate (rETR) and α , the photosynthetic efficiency (Falkowski and Raven 2007). The rETR was calculated by multiplying the irradiance by the quantum yield measured at the end of that interval. PAR versus rETR curves were described using the model of Jassby and Platt (1976) using multiple non-linear regression curve fitting protocols on SPSS software (SPSS Inc.,

135 Chicago, IL, USA).

NPQ is a measurement of the activity of the protective mechanism, which is designed to protect against over reduction of the photosynthetic electron transport chain by dissipation of excess absorbed light energy in the PSII antenna system as heat (Ruban et al., 2004). NPQ is a complex response comprising at least four different, time dependant, responses Fanesi et al. (2016). It is recognised that it is not possible to distinguish process is occurring using this approach. NPQ was determined by

140 the following equation (Schreiber, 2004).

$$\text{NPQ} = (F_m - F_m') / F_m' \quad (1)$$

Non-photosynthetic quenching (NPQ) values presented here were taken from the RLCs data generated by Wincontrol software (Walz GmbH, Effeltrich, Germany). The short light exposure time in this experiment (10 s RLCs duration), would have been insufficient for maximum NPQ development and so are only a relative measure of the ability of the treatments to

145 develop NPQ (Ralph and Gademann, 2005).

2.5 Temperature and irradiance experiments

For the temperature and irradiance incubation experiments samples were collected during low tide and exposed to a combination treatment of irradiances (1800, 890, and 0 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ and high temperatures (30, 35, 40, 45, 50, 55

150 and 60 °C). Samples were always taken from Site C, where the highest temperatures were recorded during *in-situ* data collection (Table 1). The top 0.5 to 10 mm of the sediment was collected by hand using a clear polycarbonate core during low tide and wrapped in a dark plastic bag prior to analysis. Samples were kept upright in the tubes and were immediately returned to lab for the experiments. The sediment samples were suspended in a beaker and excess seawater decanted. Filtered seawater collected from the same site was added to each vial and the vials were placed in three chambers of different

155 irradiance in a temperature-controlled water bath (Lauda 20 L, Brinkmann Lauda Inc. Konigshoven, Germany). Triplicate

sample vials were placed in each irradiance chamber. Fresh algal samples were used for each temperature change. Since irradiance was provided by a halogen lamp (Thorn 300W, Borehamwood, UK), it is understood that the spectrum will have differed from that of natural sunlight. The irradiance in each chamber was measured with a Quantum-Light Meter L1-189 (LI-COR, Nebraska, USA). The irradiance of each chamber was adjusted by the addition of several layers of dark plastic filters. These filters also assisted in reducing the heat produced by the halogen lamps. Care was taken to ensure that the temperature remained constant throughout the incubation. Fresh samples were used for each temperature incubation. The algal samples were exposed to three different irradiance treatments A: 1800 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, B: 890 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, and C: 0 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ with three replicates for each treatment. Samples were placed in the water bath for a period of one hour for each temperature treatment. The temperatures selected were 30 °C, 35 °C, 40 °C, 45 °C, 50 °C, 55 °C and 60 °C. Lower temperatures (30 °C to 35 °C) were used as controls since the community had been growing within that temperature range in the natural habitat. As experiments were conducted in a makeshift laboratory, temperatures <30°C could not be obtained due to equipment limitations. At the end of each incubation, each replicate was immediately transferred into a cuvette for photosynthetic analysis. A Water PAM fluorometer was used to determine the quantum yield at the end of each temperature treatment. RLCs (see above) were run to obtain values for F_v/F_m , $rETR_{max}$, E_k and α . In each treatment, three replicates ($n = 3$) were measured. Before measurement, samples were gently shaken to ensure even mixing and to limit settlement and were then placed inside the measuring cuvette of the Water PAM fluorometer. Measurements were conducted as soon as possible to ensure thermal change minimized during the measurements of the RLCs.

2.6 Rate of recovery

The method of determining and analysing the rate of recovery was adapted from McMinn and Hattori (2006), Salleh and McMinn (2011). The recovery measurements were made after the one-hour light incubation. The recovery rates suggest the ability of cells to reactivate photosynthetic activity after one-hour exposure to high light incubation. The measurement of recovery from photoinhibition was made using the pre-installed routine RLC + Recovery of the Water-PAM. After the last actinic light period of the RLC, the sample was left in the dark, while F_v/F_m was determined after 30, 60, 180, 300 and 600 s. The rate of recovery from photoinhibition was calculated following Oliver et al. (2003):

$$\Phi_t = \Phi_I + (\Phi_M - \Phi_I) (1 - e^{-rt}) \quad (2)$$

Where Φ_t is the given value of F_v/F_m at time t (s), Φ_I is the initial value of F_v/F_m before recovery measurements have commenced, Φ_M is the fully recovered value and r is an exponential rate constant for the recovery of F_v/F_m from photoinhibition (s^{-1}). This formula assumes that the recovery rate of F_v/F_m is dependent on the degree of damage.

185 2.7 Statistical analysis

The mean and standard deviations were calculated from three independent replicates of each parameter. To evaluate the effects of temperature and irradiances (fixed factor) on the photosynthetic parameters (F_v/F_m , $rETR_{max}$, E_k , α , NPQ and recovery rate), a two-way analysis of variance (ANOVA) and regression were used with subsequent Tukey *post hoc* comparisons. Before analyses, the data was checked for normality and homogeneity of variances Shapiro-Wilk's and Levene's tests, respectively. Data were transformed whenever necessary to comply with ANOVA assumptions. Differences were accepted as significant at $P < 0.05$ unless otherwise stated. All statistical analyses were performed using SPSS 18.0.

3 Results

The diatom genera *Cocconeis*, *Navicula* and *Rhopalodia* (observed by the author) dominated the MPB communities, which predominantly located on coarse sand with mud/silt patches. The sediment characteristics were similar among the sampling sites. There were significant differences in environmental parameters between high and low tide (Table 2 and Table 4(a)), however, environmental characteristics between sites were similar except for bottom irradiance. Tidal exposure caused significant differences in the irradiance reaching the bottom and elevated the temperature at low tide for all sites. During high tide, bottom irradiances were at their lowest ($173.42 \pm 13.73 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$) at the shaded Site B and were highest in the area that was most exposed, Site C ($1964.33 \pm 99.68 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$), when the algal mats were almost fully exposed. There was a more than six-fold increase in the irradiance from low tide to high tide (Table 2 and Table 4(a)). Water temperature rose from 28 °C during high tide to 43 °C during low tide. The highest nutrient levels were recorded during high tide, when seawater re-entered the estuary (Table 2 and Table 4(a)) There was a least a 50% increase in nitrate and phosphate levels during high tide, although the changes were not significant (Table 2).

3.1 In situ chlorophyll *a* and photosynthetic parameters of benthic diatom

Due to the high turbidity in the Tanjung Rhu estuary, MPB on the sediment surface was generally exposed to significantly lower irradiances at high tide than during low tide. Differences in sediment surface PAR caused a significant decline in chlorophyll *a* biomass and PSII activity, as measured in the RLCs photophysiological parameters. The highest biomass was observed at Site B (Shaded area) where PAR was at the lowest during the sampling time. At low tide the chlorophyll *a* values were between an average of 17.6 to 21.22 mg chl *a* m⁻², but values increased by almost 50% at high tide (20.19 to 37.38 mg chl *a* m⁻²). The photosynthetic parameters for both low and high tide are presented in Table 3. Quantum yield, $rETR_{max}$ and E_k were relatively low during both high and low tide. However, the effects of the tidal cycle could be clearly seen, as most values increased as the tide rose, except for the E_k . The E_k values declined 23% during high tide. The NPQ values were higher at low tide than at high tide. In summary, differences in all parameters were significant between tides by comparison to sites (Table 4(b)).

3.2 Effects of temperatures and irradiances

As the MPB community composition and photophysiological parameters were not significant between sites A, B and C, the diatoms collected from Site C (Exposed) were used for the incubation experiments. These communities were exposed to the highest irradiances and temperatures occurring naturally during the day. In general, the communities maintained at 30 °C, 35 °C, 40 °C, 45 °C and 50 °C were still able to photosynthesize at all light levels. Statistical analysis indicated that the communities were mostly impacted by elevated temperature rather than irradiance. Control samples (30°C and 35°C) incubated at all irradiance levels had higher F_v/F_m by comparison to other temperatures. There were no significant differences between either of these temperatures ($P < 0.05$, Table 5). The very low F_v/F_m values indicate that severe photoinhibitive stress was present when the samples were exposed to high temperatures (55°C and 60°C) (Fig. 2a). The $rETR_{max}$, α and E_k values also decreased rapidly as temperatures increased to 50°C (Fig. 2a-d) and no photosynthetic activity was observed at 55 °C or 60 °C at any irradiance level ($P < 0.05$, Table 5). Significant differences (ANOVA, $P < 0.05$) between temperature treatments were observed in all photosynthetic parameters. Although only limited photosynthetic activity was observed at higher temperatures, higher NPQ values were observed at these temperatures (Fig. 3), however, NPQ values were relatively low in all the treatments, especially at higher irradiances.

3.3 Recovery from temperature treatments

Elevated temperatures affected the recovery rates in the high temperature and irradiance treatments, ($P < 0.05$, Table 5). The highest recovery rate occurred at 40 °C. This corresponds with the maximum in-situ temperature at Site C, where the samples were collected from, was 42.5 °C. The effects of the high temperatures were clearly visible at temperatures of 50 °C, 55 °C and 60 °C, where severe depression of the recovery rate was observed (Fig. 4).

4 Discussion

In the present study, we found that the MPB communities inhabiting the Tanjung Rhu estuary were not inhibited by the high and variable light environment (range: 170 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ - 1900 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$), or temperatures (28.5 °C to 43 °C) during tidal exposure. The surface water temperature increased from 28.5 °C to 43 °C during high to low tide. The emersion at low tide caused the diatoms to migrate into the sediment to avoid excess light as a photoprotective mechanism. During the tidal cycle, the MPB communities were able to acclimatize to these changes by optimizing photosynthesis while minimizing photodamage caused by temperature and light fluctuations through physiological changes (e.g., diversion of excess energy away from photosystem reaction centres) (Consalvey et al. 2005, Coelho et al. 2011, Serôdio et al., 2005).

245 Maximum quantum yield (F_v/F_m) values are often used as a sensitive indicator of photosynthetic stress (Du et al., 2018; McMinn et al., 2005). In a review by Campbell and Tyystjärvi (2012) it was suggested that for photoinhibition measurements dark-adapted F_v/F_m values can be used if measuring the rate of oxygen evolution is not possible. Thus, in this study, dark-adapted F_v/F_m values were used as a proxy of diatom health/stress (Consalvey et al., 2005; Du et al., 2018) upon exposure to light and temperature stress. An increase in temperature and irradiance during low tide caused a decline in F_v/F_m at all sites in the Tanjung Rhu estuary; these were low compared with optimum values of ~ 0.650 for healthy microalgae (McMinn and Hegseth, 2004). Similarly, low values were found by McMinn et al. (2005) on the tropical shore of Muka Head and Songsong Island, Malaysia, where the average maximum quantum yields, which were only 0.325, were probably caused by either high irradiances or nutrient stress. Falkowski and LaRoche (1991) suggested that nutrient limitation would decrease the optimal quantum efficiency of phytoplankton. However, mangrove ecosystems are highly dynamic, and support relatively high microalgae biomass and nutrient availability should not be a limiting factor (Hilaluddin et al., 2020; Rahaman et al., 2013). Nutrient concentrations (phosphate and nitrate) measured in this study were within the average range for other tropical mangrove estuaries (Rajesh et al. 2001) and are unlikely to be limiting. Thus, it is likely that the high temperatures, of up to 42.5 °C during low tide in this study, were contributing to the low F_v/F_m values.

260 Loik and Harte (1996) suggested that PSII reaction centres are susceptible to high temperatures and that the thermal stability of PSII can be influenced by the interaction between irradiance and high temperature since they will usually occur simultaneously in the field. An increase in F_v/F_m values may be attributed to a prolonged low light period during emersion at high tide. Prolonged exposure to high irradiances during low tide also affects F_v/F_m values and reduces the algae's ability to fully recover during high tide. Du et al. (2018) also noted that NPQ and F_v/F_m in benthic diatom were not impacted by low light $<250 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$ by comparison to high light $>500 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$. Furthermore, photoinhibition has rarely been recorded in intertidal diatoms (Perkins et al. 2006). This is almost certainly due to their ability to migrate into the sediment and away from damaging light (Consalvey et al. 2004a, Mouget et al. 2008). Their ability to subsequently recover during high tide suggests that down-regulation of photosynthesis and up-regulation of photoprotection occurs, which prevents serious damage to the photosystems during the high irradiances at low tide. Long and Humphries (1994) suggested that photoinhibition that occurs during low tide, where F_v/F_m declines, but recovers at high tide. However, this response was not identified by Serôdio et al. (2008), who suggested that this short-term photoinhibition happened due to the incomplete recovery of photosynthetic activity at low light and under nutrient depletion.

275 The reduction in *in situ* F_v/F_m values at Tanjung Rhu were probably due to NPQ (non-photochemical quenching) mechanism rather than photoinhibition that characterises the estuarine intertidal environment (Serôdio et al., 2008). During low tide, the MPB community reacted rapidly to the sudden increase in irradiance and temperature, protecting their photosystem reaction centres by dissipating excess energy in the antenna complex of PSI and PSII (Goss and Lepetit, 2015). NPQ values during low tides were higher than during high tides, suggesting that under high irradiance, the community compensated for the

possible over-excitation of the photosynthetic machinery through the dissipation of excess absorbed light through xanthophyll-pigment-dependent energy dissipation. These communities were also able to modify their photophysiology by maximizing their light-harvesting efficiency and hence had higher values of α at high tide than at low tide. E_k values were highest during low tide at Site C (Exposed), ($265.76 \pm 45.86 \mu\text{mol photons m}^{-2} \text{s}^{-1}$), which indicates that they were able to adapt to the changing light climate. Hence, at low tide the community modified its light harvesting capacity to utilize the high irradiances to which they were exposed. Similarly, Perkins et al. (2006) found that benthic diatoms grown in high light had higher $rETR_{\text{max}}$ and E_k values, and lower α values. However, it should be noted that the length of light exposure during RLCs affects these values, as short-term light exposure, e.g., 10 s in this study, is insufficient for complete equilibration to each light level by comparison to P verse E curves, based on oxygen measurements (Torres et al., 2014).

4.1 Effects of irradiance and temperature incubations

Chlorophyll *a* fluorescence is an ideal tool for measuring the response of photosynthesis to changes in temperature, since PSII is the most thermo-labile component of photosynthesis, and the majority of chlorophyll *a* fluorescence originates from PSII under normal physiological conditions (Falkowski and Raven, 2007). Photosynthesis is extremely sensitive to stress caused by intense temperatures and irradiance, and it is often inhibited before other cellular functions are harmed. When the diatom dominated MPB samples were exposed to higher temperatures and irradiance, symptoms of irreversible thermal damage were clearly visible at 55 °C and 60 °C. Limited photosynthetic activity at these temperatures suggests that the cells would be suffering damaging effects from periodic increases in seawater temperatures greater than 50°C, especially during low tide when the irradiance levels are also high. This suggests that high temperatures cause structural closure of the PSII reaction centres and chloroplast dysfunction. Furthermore, at high temperatures and irradiances, light dependent RUBISCO activation is inhibited, and this is closely correlated with a reversible reduction of CO₂ fixation. This is consistent with the decrease in the effective quantum yield, which displays a strong, quantitative relationship with the quantum yield of CO₂ assimilation (Oxborough and Baker, 1997).

Light and temperature exposure is expected to influence the sensitivity of response to changing light climate (Davison, 1991) during tidal cycles and hence affect values of photosynthetic efficiency (α). However, α can also be impacted by temperature changes, which can have a strong influence on the photosynthetic capacity (Claquin et al., 2008). The α values observed here showed a significant decline when exposed to high irradiances (up to $1800 \mu\text{mol photons m}^{-2} \text{s}^{-1}$) and temperatures (up to 60 °C). The reduction in α as temperature increased is consistent with the results reviewed by Davison (1991), where α also declined as temperature increased. The effects of temperatures on α values were only significant when the cells were exposed to both adverse irradiances and temperatures. Defew et al. (2004) showed that in temperate microalgae, there were no clear trends in α values, with either temperature or light, when samples were exposed to temperatures ranging from 10 °C to 26 °C and irradiance up to $350 \mu\text{mol photons m}^{-2} \text{s}^{-1}$. This variation in α response to

310 temperature between studies is probably a result of thermal acclimation being species dependent (Claquin et al. 2008) and
also that major impacts only occur at the extremes. Fanesi et al. (2016) also discussed how temperature affected absorbed
light in different freshwater phytoplankton groups but did not examine the effects at temperature extremes. Furthermore,
some of the variation could also have been caused by the fluorescence method itself and the duration of RLCs exposure. For
example, Lefebvre et al. (2011) noted that α was systematically lower due to the slower relaxation of NPQ in 10 s RLCs.

315

The E_k index provides an indication of the irradiance at which energy is diverted from photochemistry to heat dissipation. It
represents the degree of acclimation to the ambient light climate (Schreiber, 2004). E_k is used as an indicator of the
photoacclimation status of photosynthetic organisms. Higher values of E_k suggest acclimation to higher irradiances (McMinn
et al. 2005). Benthic diatoms exposed to high irradiance herein ($1800 \mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$) were not able to adjust their
320 metabolism to maximize their response to these irradiances. Similarly, in their natural habitat, during low tide the *in-situ* data
showed that the samples were light saturated at an *in-situ* irradiance of $1900 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$. However, the E_k values
recorded at all experimental irradiances and temperatures ($40 \text{ }^\circ\text{C}$ to $50 \text{ }^\circ\text{C}$) were similar to the *in-situ* E_k values. When higher
temperatures (above $50 \text{ }^\circ\text{C}$) were imposed, significant declines in E_k were observed. Falkowski and Raven (2013) suggested
that as temperatures and irradiances increase, E_k also increases. This suggests that these temperatures (above 50°C) were
325 approaching a critical temperature threshold and affecting the cells' capability to photosynthesize. These effects were also
observed in the rETRmax values.

The rETRmax parameter has been used in many recent benthic diatom studies (e.g Cartaxana et al. 2011, Du et al. 2018) as it
is closely related to the maximum photosynthetic capacity, which is obtained when the rate of photosynthesis is limited by
330 the activity of the electron transport chain or Calvin cycle enzymes (Ralph and Gademann 2005). The rETRmax values
recovered here were typical of diatom responses to high irradiances, where, as irradiance increases, photosynthetic rates
become increasingly nonlinear and rise to a saturation level (Blanchard et al. 2004). Perkins et al. (2006) suggested that
rETRmax determined after 10s of actinic light during RLCs are lower when cells have been previously acclimated to higher
irradiance. However, to minimize the potential for the RLCs irradiance to cause photoacclimation the RLCs duration should
335 be as short as possible (Ralph and Gademann, 2005). Unlike *in-situ* studies, where natural biochemical and physical gradient
are preserved, experiments such as those described here, where cells are suspended, will give a slightly different result.
Higher E_k and rETRmax are typical of high irradiance-acclimated samples, where the cells have modified their light
harvesting pigment to utilize the irradiance to which they were exposed. Benthic microalgae acclimated to low irradiance are
able to modify their physiology and maximize their light harvesting efficiency, thus providing higher values of α . These
340 characteristics were observed in both the low and high irradiance only at ambient temperatures (up to $45 \text{ }^\circ\text{C}$). The
photosynthetic rate declined when samples were exposed to elevated temperatures. Severe effects were seen in higher

irradiance experiments. Here, as the temperatures increased above 55 °C, these algae appeared to be affected by thermal stress and were not able to acclimate to the high temperatures.

345 Although being exposed to variations in irradiance and temperature during tidal cycles, MPB has a range of mechanisms to
facilitate and optimize light interception and utilization. Here, cells exposed to high irradiances and temperatures of 40°C did
not show any sign of photoinhibition as they were naturally growing at temperatures up to 43 °C during low tide exposure.
The cells were able to dissipate the excess light via NPQ or possibly migration. Although migration was not investigated in
this study, behavioural photoprotection by vertical migration is a common response to avoid high light by pennate diatoms
350 (Cartaxana et al., 2011; Du et al., 2018; Mitbavkar and Anil, 2002). In contrast, samples exposed to the same irradiance
level, but higher temperatures (55 °C and 60 °C) were not able to protect themselves from photodamage and photoinhibition.
Exposure to high irradiances coupled with high temperatures caused an excess of absorbed light energy that was unable to be
used in the photosynthetic process, resulting in the increases in NPQ values observed in this study. Although no
photosynthetic activity was present at the highest temperatures (55 °C and 60 °C), heat dissipation was still active.
355 Xanthophyll cycling is especially significant when short term changes in the light climate occurs (seconds to minutes), such
as those happening in the Tanjung Rhu intertidal sediments. Samples incubated in the dark and at high temperatures (55 °C
and 60 °C) were seen to have higher NPQ levels. In addition, these samples showed sudden increments in NPQ from 50 °C
to 55 °C. However, as no photosynthetic activity was observed at 55 °C, it is possible that the NPQ signal was generated
from dead diatom cells. Nonetheless, the ability of dark-adapted diatoms to develop NPQ has been considered an adaptive
360 advantage, providing a method to prevent degradation of light harvesting pigments (Serôdio et al. 2006b, Lavaud and
Lepetit, 2013). Hence further investigation is required to better understand the impact of extreme temperatures on the
mechanism of NPQ, formation of reactive oxygen species, photodamage, and ultimately inactivation of PSII.

The ability of protists to recover from stress is a major characteristic determining their ability to survive under hostile
365 conditions (Wu et al., 2017, Ralph and Gademann, 2005). In this study, at higher temperatures, there are indications that
degradation of D1 proteins may have occurred and that it disrupted the recovery of PSII, thus preventing cells from adapting
to the ambient conditions. At 40 °C, dark acclimated samples were able to recover faster than at higher temperatures,
suggesting that high irradiances (1800 and 890 $\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$) increases PSII damage and contributes to the slower
recoveries. In addition, these sample had been exposed to similar temperatures to those *in-situ* samples during low tide, thus,
370 suggesting that combined high light and temperature could have a more significant than of temperature alone. These
experiments showed that samples that were exposed to lower temperatures, had a better recovery rate than those exposed to
higher temperatures (>55 °C). The lack of recovery at temperatures higher than 55 °C suggests that the photosynthetic
enzymes had been inactivated or damaged, and acclimation to these temperatures was not possible. Inhibition of
photosynthesis is reversible when temperatures are only a little higher than optimal (moderate heat stress), whereas damage
375 to the photosynthetic apparatus is permanent under severe heat stress (Berry and Bjorkman 1980). At low tide in tropical

estuaries water temperatures already regularly exceed 50 °C, temperatures usually considered outside the range of survival of marine phototrophs. With predicted global warming these conditions are likely to become both more frequent and more extreme (Stocker et al. 2014). The 50 °C environmental water temperature seems to be a tipping point, above which photosynthesis is irreparably impaired. In these circumstances, it is likely that tropical estuarine MPB community composition will change, and benthic primary production will decrease. This will likely have a cascading effect throughout these ecosystems.

Conclusions

This study provides an insight into the capacity of tropical diatom dominated MPB communities to tolerate these environmental stresses, and the degree to which those stresses could damage the photosynthetic apparatus. Thus, parameters derived from RLCs were useful to indicate the photosynthetic capacities over a series of temperature and light, even though they are derived from measurements over a range of irradiances. Likewise, since most previous studies of the combined impacts of high temperature on benthic communities have focussed on light tropical and temperate communities, responses of tropical communities are unknown and is likely to vary significantly. Short-term changes (hours) in temperatures up to 45 °C, such as experienced by the community in Tanjung Rhu estuary, will not severely affect their photosynthetic apparatus, but higher temperatures (55 °C and 60 °C) will cause severe damage and irreparable photoinhibition. The responses of MPB to light are also dependent on the temperature regime under which they are exposed. The MPB in Tanjung Rhu experience these effects during tidal emersion and during the night period. In summary, optimal temperatures for benthic microalgae photosynthetic performance is up to 45 °C, beyond this temperature the PSII function will be severely damaged and could lead to chronic photoinhibition.

Table 1: Site description of *in-situ* environmental and fluorescence parameters data collection.

Site	Description
Site A: Submerged	This site is located at the middle to the Tanjung Rhu estuary. The sediment collected from this area are constantly being submerged during low tide with an average water level of ~ 0.2 meters.
Site B: Shaded	This site is located at the estuary bank (inner section) and is shaded by mangroves trees. During low tide the sediment is exposed and partially dried without any seawater.
Site C: Exposed	This site is located at the estuary bank (outer section) without any trees or any shaded structure. At low tide the sediment is exposed and partially dried without any seawater.

560 Table 2: Average values (n=3) of the pore-water physical variables measured during high and low tide at Site A, B and C. Data are means \pm SD, $n = 3$.

Parameters	Site A: Submerged		Site B: Shaded		Site C: Exposed	
	Low tide	High tide	Low tide	High tide	Low tide	High tide
Sampling time (UTC +8)	1500 - 1700	1000 - 1200	1500 - 1700	1000 - 1200	1500 - 1700	1000 - 1200
Light level ($\mu\text{mol photons} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$)	932.38 \pm 57.11	244.60 \pm 6.37	662.77 \pm 101.84	173.42 \pm 13.73	1978.27 \pm 99.68	273.60 \pm 24.37
Temperature ($^{\circ}\text{C}$)	40.1 \pm 0.11	29.2 \pm 0.12	35.0 \pm 0.06	28.5 \pm 0.06	42.5 \pm 0.05	29.3 \pm 0.05
Salinity	33.0 \pm 0.0	33.0 \pm 0.0	33.0 \pm 0.0	33.0 \pm 0.0	34.0 \pm 0.0	33.0 \pm 0.0
Nitrate (mg/L)	0.325 \pm 0.020	0.431 \pm 0.047	0.319 \pm 0.045	0.326 \pm 0.034	0.299 \pm 0.046	0.346 \pm 0.059

Recovery Rate	Temperature	6	37.111	<0.001
	Irradiance	2	1.836	0.172
	Temperature x Irradiance	12	8.107	<0.001

Significant difference ($P < 0.05$) indicated in bold.

Fig. 1: Location of the sampling station in Tanjung Rhu estuary, Langkawi, Malaysia. a) Map of Peninsular Malaysia. The square indicates Pulau Langkawi, b) Map of Pulau Langkawi and c) Map of Tanjung Rhu. The red star indicates the sampling area.

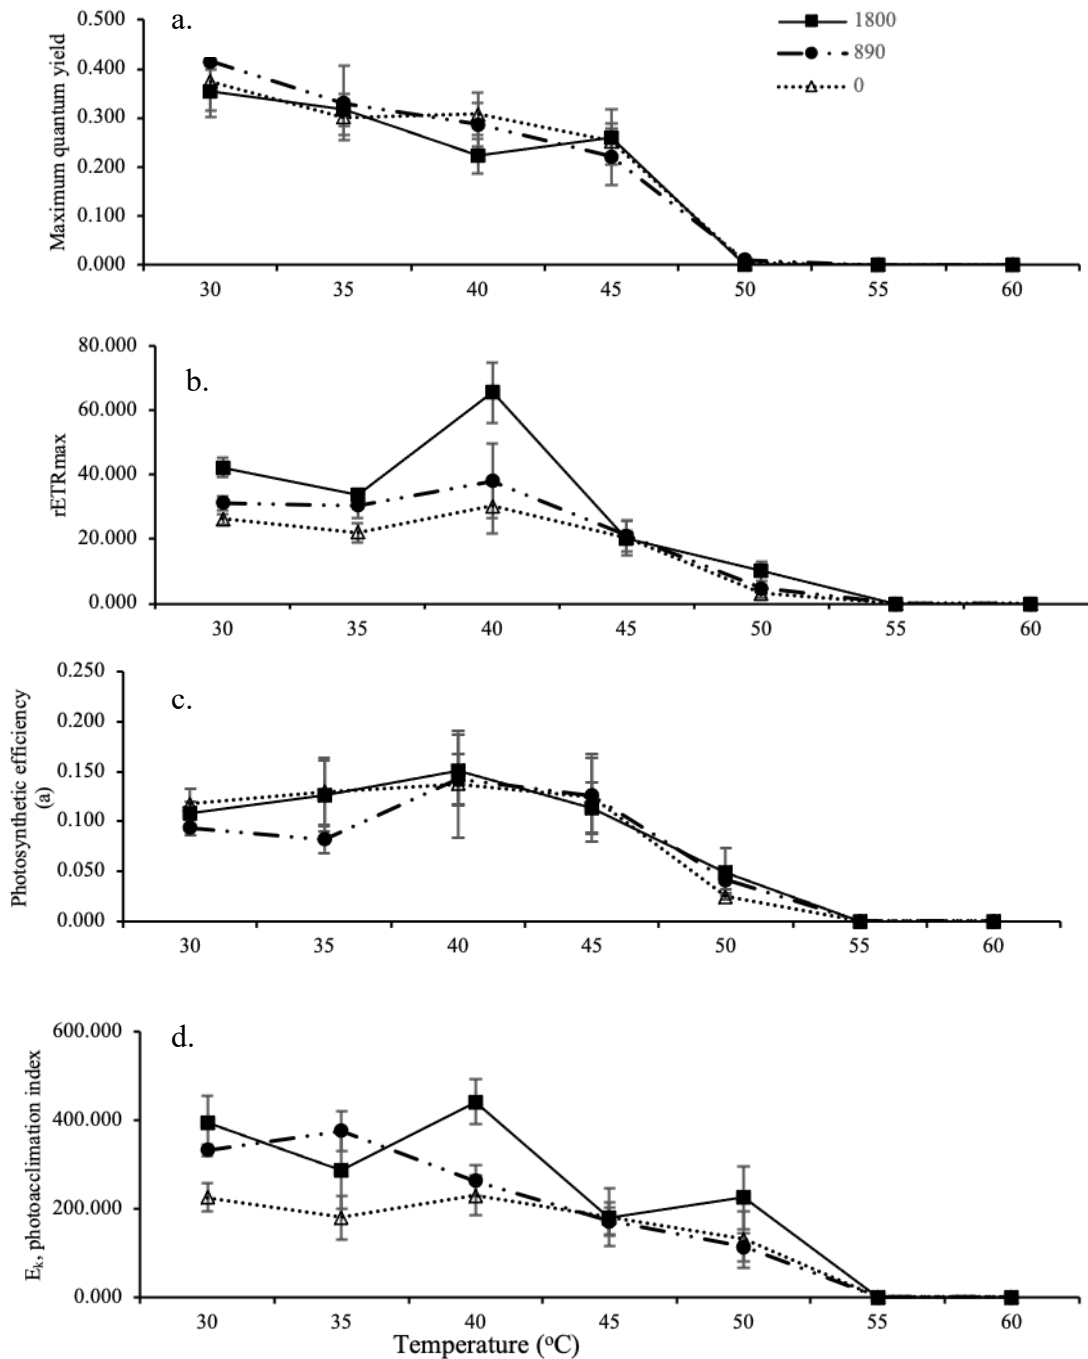

Fig. 2: Derived photosynthetic parameters of RLC. Parameters were plotted against experimental temperatures (30, 35, 40, 45, 50, 55 and 60 °C) at irradiances of 1800 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ (close square), 890 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ (close circle) and 0 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ (open triangles). a) Maximum quantum yield, b) Photosynthetic efficiency (α), c) rETRmax and d) Photoacclimation index, (E_k). Values are means \pm SD ($n = 3$).

600

Fig. 3: The NPQ of samples at each irradiance level (1800 photons m⁻² s⁻¹ (close square), 890 photons m⁻² s⁻¹ (close circle) and 0 photons m⁻² s⁻¹ (close triangles)) and temperatures (30, 35, 40, 45, 50, 55 and 60 °C). NPQ was obtained at the end of the RLCs with actinic irradiance of 1554 μmol photons m⁻² s⁻¹. Values are means ± SD (*n* = 3).

605

Fig. 4: Recovery rate s⁻¹ of F_v/F_m after the RLC for low irradiance experiments. Recovery rates were plotted against experimental temperatures at irradiances of (1800 μmol photons m⁻² s⁻¹ (close square), 890 μmol photons m⁻² s⁻¹ (close circle) and 0 photons m⁻² s⁻¹ (open triangles)) and temperatures (30, 35, 40, 45, 50, 55 and 60 °C). In this recovery analysis, samples of 30 °C and 35 °C were analyzed without replicates; thus, no error bar was obtained.
