9 **Abstract.** Dimethyl sulfide (DMS) is a volatile biogenic gas with the potential to influence regional climate as a  
10 source of atmospheric aerosols and cloud condensation nuclei (CCN). The complexity of the oceanic DMS cycle  
11 presents a challenge in accurately predicting sea-surface concentrations and sea-air fluxes of this gas. In this study,  
12 we applied machine learning methods to model the distribution of DMS in the NE Subarctic Pacific (NESAP), a  
13 global DMS hot-spot. Using nearly two decades of ship-based DMS observations, combined with satellite-derived  
14 oceanographic data, we constructed ensembles of 1000 machine-learning models using two techniques, random  
15 forest regression (RFR) and artificial neural networks (ANN). Our models dramatically improve upon existing  
16 statistical DMS models, capturing up to 62% of observed DMS variability in the NESAP and demonstrating notable  
17 regional patterns that are associated with mesoscale oceanographic variability. In particular, our results indicate a  
18 strong coherence between DMS concentrations, sea surface nitrate (SSN) concentrations, photosynthetically active  
19 radiation (PAR) and sea surface height anomalies (SSHA), suggesting that NESAP DMS cycling is primarily  
20 influenced by heterogenous nutrient availability, light-dependent processes and physical mixing. Based on our  
21 model output, we derive summertime, sea-air flux estimates of  $1.16 \pm 1.22$  Tg S in the NESAP. Our work  
22 demonstrates a new approach to capturing spatial and temporal patterns in DMS variability, which is likely  
23 applicable to other oceanic regions.

## 24 **1 Introduction**

25 Dimethyl sulfide (DMS), a volatile biogenic gas, is an important component of the marine sulfur cycle.  
26 This molecule is an important substrate for specific methylotrophic bacteria (Vila-Costa et al., 2006; Lidbury et al.,  
27 2016; Green et al., 2011; Hatton et al., 2012), with a recognized importance to marine microbial metabolism (Vila-  
28 Costa et al., 2006) and food web interactions (Nevitt, 2008). Moreover, DMS constitutes the largest fraction of  
29 bulk non-sea salt (NSS) sulfate emissions to the atmosphere (Bates et al., 1992; Ksionzek et al., 2016), where it is  
30 rapidly oxidized to form aerosols that act as cloud condensation nuclei (CCN; Charlson et al., 1987; Hegg et al.,  
31 1991; Korhonen et al., 2008), potentially influencing regional albedo and climate (Charlson et al., 1987; Ayers and  
32 Caaney, 2007). Given the ecological roles of DMS and its potential influence on global climate, substantial research  
33 has focused on characterizing the dynamics of this compound in seawater. This work has revealed considerable  
34 complexity in the oceanic DMS cycle, which has limited the development of simple predictive algorithms  
35 describing its spatial and temporal variability.

36 Oceanic DMS production and loss are tightly linked with the biological cycling of the related metabolites  
37 dimethyl sulfoniopropionate (DMSP) and dimethyl sulfoxide (DMSO). DMS is believed to be primarily derived

38 from the cleavage of DMSP (Kiene and Linn, 2000), but it can also be cycled through biological DMSO reduction  
39 (Spiese et al., 2009) and oxidation (Lidbury et al., 2016), and abiotically by light-dependent reactions (del Valle et  
40 al., 2007; Royer et al., 2016). DMS cycling is influenced by a suite of environmental and ecological factors,  
41 including release from phytoplankton cells into the dissolved pool via grazing (Dacey and Wakeham, 1986), viral  
42 lysis (Malin et al., 1998), or exudation. Oxidative stress generated by other variables such as temperature (Kirst et  
43 al., 1991), salinity (Dickson and Kirst, 1987), UV radiation (Kinsey et al., 2016), and nutrient limitation (Bucciarelli  
44 et al., 2013; Spiese & Tatarkov, 2014) may also enhance the cycling of DMSP and DMSO, which may regulate  
45 DMS concentrations through cascading oxidative pathways (Sunda et al., 2002). Finally, variability in surface wind  
46 fields can modulate the rates of DMS sea-air exchange, providing a significant source of heterogeneity in surface  
47 water DMS concentrations (Royer et al., 2016). These examples illustrate the complex non-linearity of the oceanic  
48 DMS cycle.

49 Over the past two decades, a number of approaches have been developed to model DMS distributions at  
50 both global (Bock et al., 2021; Galí et al., 2018; Simó and Dachs, 2002; Vallina and Simó, 2007) and regional  
51 (Watanabe et al., 2007) scales. These models have been largely based on linear regression techniques estimating  
52 DMS concentrations using one or two predictors. To date, these studies have focused on a number of variables,  
53 including ratio of chlorophyll a (Chl-a) to mixed layer depth (MLD) (Simó and Dachs, 2002), sea surface  
54 temperature (SST) and nitrate (SSN) (Watanabe et al., 2007), solar radiation dose (SRD) (Vallina and Simó, 2007),  
55 photosynthetically active radiation (PAR) and modelled DMSP concentrations (Galí et al., 2018). Some of these  
56 models have demonstrated reasonably good performance at global scales, but their predictive power is generally  
57 diminished at regional scales (Herr et al., 2019), failing to accurately resolve important smaller-scale features  
58 (Belviso et al., 2003; Nemcek et al., 2008; Royer et al., 2015; Tortell, 2005b).

59 In recent years, machine-learning algorithms have been increasingly used to derive predictions for non-  
60 linear oceanic systems. For example, these methods have been successfully applied to describe the spatial and  
61 temporal patterns of global methane flux (Weber et al., 2019), nitrous oxide dynamics (Yang et al., 2020), and  
62 carbon export (Roshan and DeVries, 2017). To our knowledge, only two studies have thus far applied machine-  
63 learning to describe DMS distributions, with one study focused on the Arctic (Humphries et al., 2012) and the other  
64 exploring a global domain (Wang et al., 2020). Despite producing algorithms with reasonable predictive skill, these  
65 two studies found limited success in resolving the underlying relationships driving DMS variability. This was  
66 partially due to a reliance on indirect sensitivity tests assessing the importance of predictor variables, and also,  
67 potentially, from the large-scale averaging applied to the underlying data fields ( $1 \times 1^\circ$ ;  $111 \text{ km}^2$ ). Analyses at higher

68 spatial resolution may reveal mesoscale (roughly 20-200 km) and sub-mesoscale (roughly 1-20 km) patterns that  
69 would otherwise be obscured, thereby increasing predictive strength.

70 Machine learning algorithms require large datasets for the training and testing process. Traditionally, DMS  
71 measurements were based on time-consuming ship-board analysis of discrete samples, resulting in sparse data  
72 coverage over much of the oceans. More recently, the development of several automated DMS measurement  
73 systems (Royer et al., 2014; Saltzman et al., 2009; Tortell, 2005a) has provided marine DMS observations at a  
74 significantly higher resolution, yielding greater spatial and temporal data coverage. These new datasets potentially  
75 enable new insights into small-scale and regional patterns in oceanic DMS distributions, as well as the  
76 characterization of oceanic DMS ‘hot-spots’. The northeast subarctic Pacific (NESAP) is a region of notably high  
77 DMS concentrations (Lana et al., 2011), with localized DMS accumulation in both highly productive coastal  
78 upwelling regimes, and off-shore, iron-limited waters (Herr et al., 2019; Asher et al., 2017). Several factors have  
79 been proposed to account for the elevated DMS production in the NESAP, including increased primary productivity  
80 driven by nutrient entrainment and upwelling along coastal fronts (Asher et al., 2017), a dominance of high-DMSP  
81 producing prymnesiophytes and dinoflagellates in offshore waters, elevated microbial degradation of DMSP to  
82 DMS (Steiner et al., 2012; Royer et al., 2010), and the stimulation of DMS production in response to oxidative  
83 stress in low iron waters (Sunda et al., 2002; Herr et al., 2020). Although multiple studies have examined empirical  
84 relationships between DMS and various oceanographic factors in the NESAP (Watanabe et al., 2007; Herr et al.,  
85 2019; Asher et al., 2017, 2011), these have all reported low predictive skill based on simple linear correlation  
86 approaches. To date, machine-learning approaches have not been applied to describe DMS distributions specifically  
87 in this region.

88 Here, we present an approach to modelling summertime NESAP DMS concentrations and sea-air fluxes  
89 using ensemble random forest regression (RFR) and artificial neural network (ANN) machine-learning algorithms.  
90 Our statistical models leverage field observations of DMS collected across the NESAP between 1997 to 2017 to  
91 generate a summertime DMS climatology mapped at a higher spatial resolution than previous efforts (Simó and  
92 Dachs, 2002; Vallina and Simó, 2007; Galí et al., 2018; Watanabe et al., 2007; Humphries et al., 2012; Wang et  
93 al., 2020). This new modelling approach represents a significant improvement over previous methods and predicts  
94 regional DMS distributions that are coherent with underlying patterns of oceanographic variability. Most notably,  
95 the modelled DMS concentrations and sea-air fluxes can be explained, to a large extent, by regional and mesoscale  
96 patterns in nutrient supply and physical mixing dynamics. Based on the output of our models, we present  
97 summertime sea-air flux estimates in close agreement with previous studies (Herr et al., 2019; Lana et al., 2011),  
98 further highlighting the importance of the NESAP as a globally-significant sulfur source to the atmosphere.

## 99 2 Methods

### 100 2.1 Data

101 A combination of data sources was used in training our machine-learning models to build a summertime  
102 DMS climatology. For this study, we restricted DMS measurements to the months of June, July and August between  
103 1997 to 2017 in the NESAP (43-60°N, 147-122°W). A total of 26,201 data points were obtained from the NOAA  
104 PMEL repository (<https://saga.pmel.noaa.gov/dms/>; last accessed: February 3, 2021), including measurements  
105 derived from purge and trap gas chromatography and membrane inlet mass spectrometry. The DMS data were  
106 binned to a monthly resolution, regardless of year, and averaged into 0.25 x 0.25° grid cells.

107 Predictor data used to build our machine-learning models included the following variables derived from  
108 the NASA Aqua MODIS satellite at level L3 monthly 0.042° resolution (R2018.0): sea surface temperature (SST),  
109 the ratio of normalized fluorescence line height to chlorophyll a (nFLH:Chl-a), instantaneous and daily observed  
110 photosynthetically active radiation (iPAR and PAR, respectively), particulate inorganic carbon (PIC), the  
111 absorption of gelbstof and detritus at 433 nm ( $a_{\text{cdm}}(443)$ ), and diffuse attenuation coefficients at 490nm ( $K_d$ ).  
112 Satellite-based PIC is considered as a proxy for the abundance of coccolithophores and other calcified  
113 phytoplankton (Franklin et al., 2010), whereas the  $a_{\text{cdm}}(443)$  product is considered a proxy for chromophoric  
114 dissolved organic matter (CDOM; Nelson & Siegel, 2013), which is thought to be an important photosensitizer of  
115 DMS (see Sect. 4.1). For observations prior to 2004, data were from either SeaWiFS (0.083° resolution) or Terra  
116 MODIS (0.042° resolution) when SeaWiFS data were unavailable (*e.g.* nFLH and iPAR). As described below,  $K_d$   
117 and PIC were later excluded from the final models (see Sect. 2.6), as they didn't improve predictive skill.

118 The following predictor variables were also used: 6-day averaged sea surface height anomalies (SSHA)  
119 derived from the TOPEX/Poseidon satellites at 0.17° resolution; Level L4 ESA Sentinel-3 Copernicus monthly-  
120 averaged 0.25° wind speeds; net primary productivity (NPP) from the Vertically-Generalized Production Model  
121 (VGPM; Behrenfeld & Falkowski, 1997) at monthly 0.25° resolution; sea surface nitrate from the 2018 World  
122 Ocean Atlas at monthly 1° resolution (Garcia et al., 2019); and mixed-layer depth (MLD) and sea surface salinity  
123 (SSS) from the MIMOC climatology at 0.5° resolution (Schmidtke et al., 2013). Except for MIMOC data, all  
124 predictors were restricted in time to the corresponding years of DMS sampling (1997 to 2017). Net community  
125 productivity (NCP) was estimated from the algorithm of Li & Cassar, (2016; using NPP and SST). As with DMS  
126 observations, predictor data were interpolated to a 0.25 x 0.25° average monthly resolution using linear radial basis  
127 interpolation functions. Interpolation was constrained to the oceanic region by masking out land pixels using  
128 ETOPO2 bathymetric (0.033° resolution) binned at 0.25 x 0.25° resolution. We note that each of these data sources

129 are likely to have inherent uncertainties associated with either their collection or processing. Data sources can be  
 130 found in Table 1.

131

132 **Table 1. Data sources and spatial and temporal resolution of predictor variables used to develop the RFR and ANN algorithms. Data**  
 133 **processing levels are indicated where relevant. All variables were used as predictors (excluding bathymetry) and post-processed to**  
 134 **monthly-averaged, 0.25° resolution (see sections 2.1-2.2).**

## 137 2.2 Machine-learning models

138 We compared the performance of random forest regression (RFR) and artificial neural network (ANN)  
 139 models at the regional scale. The RFR algorithm is built upon decision tree models, which operate by iteratively  
 140 generating decision rule nodes that dictate which branch the tree will progress through in the next iteration. The  
 141 RFR model builds an ensemble, or “forest”, of these trees, where each tree is trained on a bootstrapped (*i.e.*  
 142 randomly subsampled) set of predictors, and the resulting predictions are averaged among the trees to reduce  
 143 overfitting to noise (Brieman, 2001). In contrast, the ANN model is built as a fully connected network of nodes, or  
 144 “neurons”, in which each neuron consists of an activation function and is connected to other neurons by iteratively-  
 145 determined weights (Gardner and Dorling, 1998). Both algorithms are advantageous because they make no prior  
 146 assumptions on the data distributions and can fit non-linear data (Brieman, 2001; Gardner and Dorling, 1998).

147 Both our ANN and RFR models followed a similar design to Weber et al. (2019). Our ANNs were built  
 148 using a feed-forward framework consisting of a single input node, two hidden layers each consisting of 30 neurons  
 149 (using a sigmoidal activation function), and a single output layer (using a linear activation function). A Bayesian  
 150 L2 (Ridge) regularization parameter was tuned to minimize overfitting and the L-BFGS algorithm was used to  
 151 solve for weights (Byrd et al., 1995). Each individual decision tree within the RFR was trained using the standard  
 152 CART algorithm (Brieman, 2001) and constrained to a max depth of 25 decision splits, the simplest configuration  
 153 determined to perform well and minimize overfitting. These models were built using the Scikit-Learn (v0.24.2)  
 154 implementation of the ANN (“MLPRegressor”) and RFR (“RandomForestRegressor”) algorithms in Python 3.8  
 155 (see Code Availability).

156 In both cases, the models were built as an ensemble of either 1000 individual decision trees or individual  
 157 networks to minimize bias in predictions. The input data were randomly divided for use in model training (80%)  
 158 and external testing (20%). Although RFR is not sensitive to large differences in predictor variance, predictor data  
 159 were standardized in both models by normalization to their respective mean and standard deviation. Additionally,  
 160 we applied an inverse hyperbolic sine (IHS) transformation to the DMS data prior to training (Weber et al., 2019).  
 161 Testing results indicated that IHS yielded slightly better performance than the more traditional logarithmic  
 162 transformations for both of our models.

## 163 2.3 Sea-to-air fluxes

164 Sea-air DMS fluxes ( $F_{DMS}$ ,  $\mu\text{mol m}^{-2} \text{d}^{-1}$ ) were calculated from the monthly-averaged observed and  
165 modelled DMS values for June, July and August.  $F_{DMS}$  was calculated using the gas transfer velocity ( $k$ ,  $\text{cm hr}^{-1}$ )  
166 following the modified approach of Webb et al. (2019):

$$167 F_{DMS} = k(DMS)(0.24) \quad (1)$$

168 where the factor of 0.24 converts to the values to daily fluxes. The gas transfer velocity has typically been calculated  
169 using a non-linear parameterization (Nightingale et al., 2000), but recent work has suggested a linear  
170 parameterization is more appropriate for DMS (Bell et al., 2013; Blomquist et al., 2017; Zavarisky et al., 2018).  
171 Since satellite-derived predictors are used to build our models, we calculated the gas transfer velocity using the  
172 linear Goddijn-Murphy et al. (2012)  $k$  parameterization, which is both derived from satellite altimeter data and  
173 normalized to a Schmidt number of 660:

$$174 k_{w,660} = 2.1U_{10} - 2.8 \quad (2)$$

175 Where  $U_{10}$  is the wind speed ( $\text{m s}^{-1}$ ) at 10 m above sea surface.

176 Regional summertime fluxes ( $\bar{F}_{DMS}$ ,  $\text{Tg}$ ) were calculated as the average ( $\pm\text{SD}$ ) quantity of DMS-sulfur  
177 emitted over 92 days (June, July and August) through the area of the mapped study region ( $1.28 \times 10^7 \text{ km}^2$  or 85.0%  
178 of the total bounded area).

## 179 2.4 Comparison against existing algorithms

180 Simple linear regression (LR) and multiple linear regression (MLR) models were built for comparison  
181 against the machine-learning algorithms. We also tested the performance of our RFR and ANN models against the  
182 published algorithms of Simó & Dachs (2002), Watanabe et al. (2007), Vallina & Simó, (2007), and Galí et al.  
183 (2018) (hereafter referred to as SD02, W07, VS07, and G18, respectively). Solar radiation dose, SRD, used in the  
184 VS07 algorithm was calculated using MLD as described by Vallina & Simó (2007):

$$185 SRD = \frac{PAR}{K_d \times MLD} \times (1 - e^{-K_d \times MLD}) \quad (4)$$

186 Each of the four algorithms was assessed using both their original coefficients and coefficients tuned to  
187 our NESAP dataset using nonlinear least-squares optimization at both  $0.25^\circ$  and  $1^\circ$  spatial resolution (Table 2). In  
188 each case, the algorithms were run using the same monthly-averaged predictors used to develop the RFR and ANN  
189 ensembles (see Sec. 2.1). Predictors were spatially matched to either the full DMS dataset (*i.e.* all monthly averaged  
190 DMS observations) or to only the Testing partitioned dataset (see Sec. 2.2) for direct comparison with the RFR and  
191 ANN ensemble performance (Fig. 2, Table 2).

## 192 2.5 Controls on DMS variability

193 Principal component analysis (PCA) was applied to assess the relationships between DMS and the nine  
194 predictors used to build the RFR and ANN ensembles. Additionally, non-parametric Spearman rank correlations  
195 were calculated between each variable and both the modelled and observed DMS concentrations. Correlation  
196 analysis was also extended to assess the role of taxonomy on predicted DMS concentrations, using the outputs of  
197 a chlorophyll-a based taxonomic algorithm by Hirata et al. (2011) with NESAP-tuned coefficients (Zeng et al.,  
198 2018).

## 199 2.6 Sensitivity Tests and Predictor Selection

200 To inform our selection of grid size, we assessed the performance of both the RFR and ANN models using  
201 grid cells ranging from 0.25 to 5° (Fig. 1). From this analysis, we found that model accuracy was highest at 0.25°  
202 resolution (see Sect. 3.1). Smaller grid sizes would presumably further improve model accuracy, but at a  
203 significantly higher computational cost.

204 We also tested the influence of other biological predictor variables on the performance of the RFR and  
205 ANN models, using either NCP, NPP, Chl-a, or PIC. These sensitivity tests indicated no significant difference  
206 between the various biological predictor variables, although accuracy was slightly reduced when PIC was used.  
207 We therefore selected NCP as the biological predictor variable within our model framework. We also removed  $K_d$   
208 as a predictor variable after further sensitivity testing indicated that its exclusion slightly improved results.

209 The inclusion of nFLH:Chl-a represents a proxy for iron limitation (see Sect. 4.1). However, fluorescence  
210 yields corrected for non-photochemical quenching (NPQ) have been suggested to yield a better iron limitation  
211 proxy than nFLH:Chl-a (Behrenfeld et al., 2009). We therefore calculated NPQ-corrected fluorescence yields ( $\varphi_f$ )  
212 by:

$$213 \quad \varphi_f = \frac{nFLH}{Chl-a \times \alpha \times S} \times \frac{iPAR}{iPAR} \quad (5)$$

214 where  $\alpha = 0.0147 \times Chl - a^{-0.316}$  and  $S = 100 \text{ mW cm}^{-2} \mu\text{m}^{-1} \text{ sr}^{-1} \text{ m}$  as described by Behrenfeld et al. (2009). Our  
215 tests indicated nFLH:Chl-a yielded slightly improved performance overall, whereas  $\varphi_f$  decreased both models'  
216 performance. We therefore retained nFLH:Chl-a and excluded  $\varphi_f$  in our final model design.

217

218

**Fig. 1. Sensitivity of RFR and ANN models to grid size resolution. DMS fluxes (black) and  $R^2$  values (red) derived from sensitivity tests of (a) RFR and (b) ANN models to pixels resolutions of 0.25-5°. The negative  $R^2$  values observed at the lowest resolution (largest grid cells) indicate that the predicted values explain less variance than the overall mean of the dataset.**

## 3 Results

### 3.1 Model evaluation

To benchmark the performance of our RFR and ANN models, we first evaluated the predictive skill of four existing empirical DMS algorithms (SD02, W07, VS07, & G18), in addition to simple and multiple linear regression models. Previous studies have demonstrated that these empirical algorithms show strong predictive skill ( $R^2=0.53-0.84$ ) over large scales and in some oceanic regions (Simó and Dachs, 2002; Galí et al., 2018; Watanabe et al., 2007), but significantly poorer performance in the NESAP (Herr et al., 2019). Consistent with these results, we found that the SD02, W07, VS07, and G18 did not accurately predict NESAP DMS distributions, even with regionally tuned coefficients improving performance (Fig. 2,  $R^2=0-0.01$  at  $0.25 \times 0.25^\circ$ ; Table 2,  $r=-0.15-0.36$ ). We also found that simple and multiple linear regressions performed poorly, yielding virtually no explanatory power for surface water DMS distributions in the NESAP ( $R^2=0-0.05$ ; Fig. 2, 3).

**Table 2. Performance of statistical DMS algorithms on NESAP DMS observations binned to monthly  $1^\circ$  and  $0.25^\circ$  resolution. Pearson correlation coefficients ( $r$ ) and root mean square error (nM) are obtained from the**

SD02, VS07, W07 and G18 algorithms (see 2.4) using either their original published coefficients or coefficients derived from non-linear least squares optimization. Algorithm performance is evaluated using either the full monthly-binned observational dataset or using the Testing partitioned dataset (see Sec. 2.2).

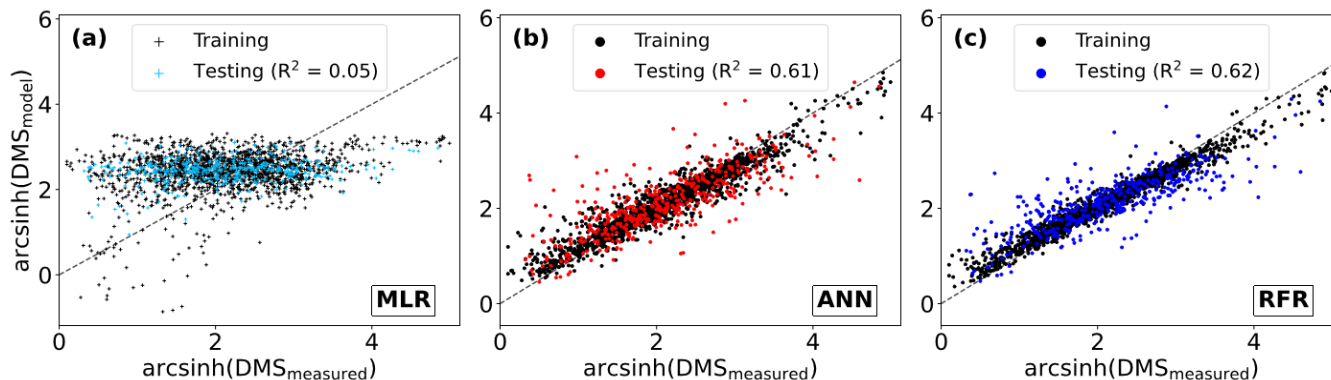

Fig. 2. Taylor Diagram showing comparative performance metrics of each individual Random Forest Regression (RFR) and Artificial Neural Network (ANN) model (1000-model ensembles) against multiple linear regression (MLR) and other statistical DMS models (See sections 2.1 and 2.4). The Pearson correlation coefficients (“Correlation”; outer radius), root mean squared error (“RMSE”; red radial contours), and standard deviations (SDs; grey radial contours from origin) are all computed with respect to the observed DMS samples after inverse hyperbolic sine (IHS) transformation. The reference of a perfect model fit is shown with a gold star. SDs of the model outputs are normalized to the SDs of the DMS observations. RMSE represents a normalized trigonometric derivation from both the correlation coefficients and normalized SDs. Performance of the SDO2, W07, VS07, and G18 algorithms reported here are calculated using regionally tuned coefficients to the NESAP derived from non-linear least-squares optimization (see section 2.4).

Relative to other published modelling approaches, both the RFR and ANN models dramatically improved the representation of NESAP DMS variability, achieving significantly higher predictive accuracy (Fig. 2, 3). The collective ensembles of both the RFR and ANN models yielded strong performance, explaining up to 62% of the observed DMS variability ( $R^2=0.61-0.62$ ; Fig. 3). For individual models within the ensembles, the ANN method

provided slightly better results ( $R^2=0.16-0.50$ ), compared to the individual RFR models ( $R^2=0.16-0.43$ ). However, predicted DMS concentrations and sea-air fluxes derived from the ANN ensembles were more sensitive to the spatial resolution used, although the predictive accuracy of both models degraded significantly with coarser resolutions (Fig. 1).

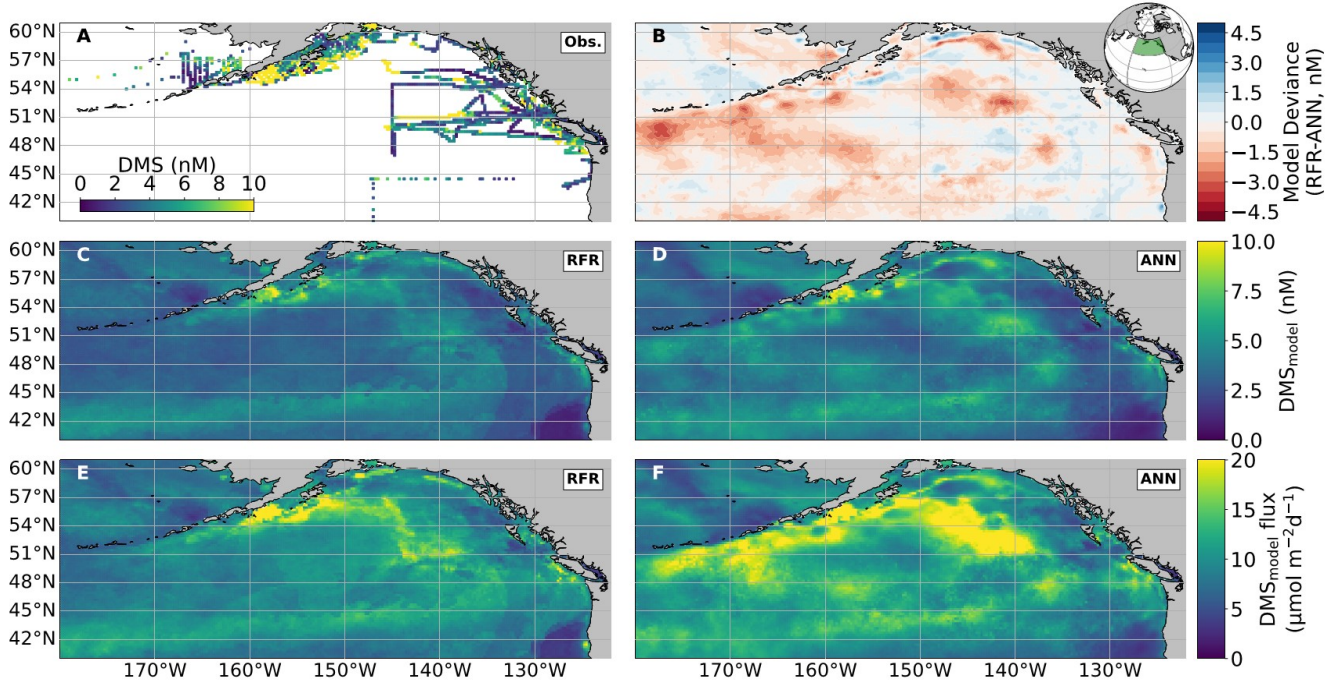

**Fig. 3. Performance of three modelling approaches in predicting observed DMS distributions; (A) multiple linear regression (MLR) (B) ensemble of Artificial Neural Networks (ANN) and (C) ensemble of Random Forest Regression (RFR).** For consistency, all predictions are partitioned by the Training and Testing datasets used to build the ensembles (see section 2.2). Model performance ( $R^2$ ) is computed only for the Testing dataset predictions. The dashed line demonstrates a 1:1 relationship. Modelled DMS concentrations depicted range from 0.4-84.3 (RFR, nM) and 0.3-74.6 (ANN, nM).

### 3.2 DMS distributions and sea-air fluxes

In both the RFR and ANN methods, the predicted spatial distribution of DMS was generally consistent with observations (Fig. 4a,c,d). The average model derived DMS concentrations was  $4.0 \pm 2.1$  nM and  $4.7 \pm 3.0$  nM (mean  $\pm$  SD) for the RFR and ANN ensemble models, respectively, with a similar range from 0.3 to 84.3 nM. In both models, the highest DMS concentrations were largely constrained to coastlines and within the Alaska Gyre adjacent to the Aleutian Islands (Fig. 4b-c, 8C). The greatest discrepancy between DMS concentrations from the two models was observed in these regional ‘hotspots’, where the ANN models emphasize high DMS within the Alaska gyre, while the RFR models emphasize elevated coastal DMS concentrations (Fig. 4b). On average, the models deviated from each other by 0.49 nM, with the greatest offsets observed in an area of particularly sparse DMS observations in the Alaska Gyre (Fig. 4a,b). Future observational data in this region should help improve model agreement.

# June – August

**Fig. 4. Predicted maps of sea surface DMS concentrations and sea-air fluxes. (a) Ship-based observations of mean summertime (June-August) DMS concentrations used to construct the predictive models. (b) Differences between the (c) Random Forest Regression (RFR) and (d) Artificial Neural Network (ANN) ensemble predicted DMS concentrations. (e,f) DMS sea-air fluxes derived from the predicted DMS concentrations. Colormap ranges are restricted to illustrate trends, with <1% of DMS data exceeding the colorbar limits. The inset map in (b) shows the NESAP study region as a shaded green patch in a global orthographic projection.**

Sea-air DMS fluxes (Fig. 4e,f) derived from ANN predictions were 18% higher, on average, than RFR predictions, largely due to higher predicted values in the Alaska Gyre (Fig. 4d-e, Table 3). The distribution of ANN sea-air fluxes was also closer to ship-based observations (Fig. 5). Predicted regional fluxes ranged from 0.8 to 167  $\mu\text{mol m}^{-2} \text{d}^{-1}$  between the two models (Fig. 4e,f, 5), with the highest predicted DMS emissions in August, when derived sea-air fluxes were approximately 1.6 to 2-fold greater than in June and July (Table 3). Our models yielded a summertime integrated sea-air flux of  $1.16 \pm 1.22 \text{ Tg DMS-derived sulfur}$ , which is consistent with the Lana et al. (2011) climatological estimate of  $1.64 \pm 0.51 \text{ Tg}$  (Table 3).

Table 3. Monthly and mean summertime NESAP sea-air DMS fluxes. Total cumulative fluxes of DMS-derived sulfur (Tg, mean  $\pm$  SD) are calculated from the Random Forest Regression (RFR) and Artificial Neural Network (ANN) model predictions (based on an ensemble of 2000 models). Total cumulative NESAP sea-air flux derived from the Lana et al. (2011) climatology is shown for comparative purposes.

	Summertime Sulfur Emissions			
	RFR	ANN	This Study	Lana et al. (2011)
	$\mu\text{mol m}^{-2} \text{ d}^{-1}$	$\mu\text{mol m}^{-2} \text{ d}^{-1}$	Tg S	Tg S
June	$8.0 \pm 5.3$	$8.0 \pm 5.5$	$0.29 \pm 0.19$	$0.59 \pm 0.24$
July	$8.2 \pm 3.5$	$9.7 \pm 4.6$	$0.33 \pm 0.14$	$0.41 \pm 0.16$
August	$12.7 \pm 3.5$	$16.5 \pm 4.6$	$0.54 \pm 0.25$	$0.65 \pm 0.25$
June-August	$9.7 \pm 2.8$	$11.4 \pm 4.0$	$1.16 \pm 0.35$	$1.64 \pm 0.51$

Fig. 5. Histograms of DMS sea-air flux distributions derived from the 1000-model ensemble random forest regression (RFR) and artificial neural network (ANN) predictions as well as cruise observations (Obs.). The sample sizes of both models are equivalent ( $n= 49,632$ ) and are significantly higher than the observational dataset ( $n=2063$ ). Note that the distribution is restricted to show

309 trends, with a maximum flux of 238 nM (Obs.). The upper tail (>50 nM) consists of only 2.9% (Obs.) and <0.1% (both RFR and  
310 ANN) of the values. Note that the ANN better predicts the upper tail of DMS observations greater than 20 nM.

311

### 312 3.4 Drivers of DMS variability

313 In addition to modelling the spatial and temporal distribution of surface water DMS in the NESAP, we  
314 examined the influence of different oceanographic variables as model predictors. As expected based on previous  
315 work (Herr et al., 2019), no single predictor was found to exert a dominant control on modelled DMS distributions  
316 from either the RFR or ANN models (Fig. 6, 7). Rather, the relationship between DMS and other oceanographic  
317 variables exhibited significant region-specific patterns. One of the most compelling regional signatures was the  
318 apparent relationship between DMS and SSHA. In both models, we found significant positive correlations between  
319 DMS and SSHA ( $\rho=0.35$ ,  $0.42$  for RFR and ANN, respectively) across the full spatial domain, with a particularly  
320 notable relationship along the northern Alaskan coastline (Fig. 8, 9). Here, strong winds (Fig. 9j-l), coupled with  
321 the northeastern Alaska current flow, produce two characteristic oceanographic features in the NESAP: strong,  
322 semi-permanent mesoscale eddies collectively referred to as the Haida, Sitka and Yakutat eddies (Fig. 8a), and the  
323 formation of the high nutrient, low chlorophyll (HNLC) Alaska Gyre (Fig. 8c; Okkonen et al., 2001; Whitney et  
324 al., 2005). Both the monthly (Fig. 9a-i) and summertime-averaged (Fig. 8a,b) RFR and ANN-derived DMS  
325 concentrations are low where these downwelling eddies form. In contrast, elevated DMS concentrations were  
326 associated with the negative SSHA coastal upwelling areas (Fig. 8a,b), where phytoplankton productivity is  
327 stimulated by nutrient inputs into the mixed layer.

329

338 **observations (Obs.), RFR and ANN predictions per variable. (b) Correlations per month for the RFR and ANN DMS**  
339 **predictions. All model correlations are computed on the 1000-model ensembles.**

340 Modelled DMS concentrations also significantly correlated with hydrographic frontal patterns. We found  
341 significant correlations between DMS and SST ( $\rho=0.36$ ,  $0.35$  for RFR and ANN, respectively) which suggested  
342 the central Alaska Gyre and offshore of Vancouver Island are areas of elevated DMS variability (Fig. 8b). Both  
343 models predict high DMS levels in the northern frontal zone of the gyre ( $140^{\circ}\text{W}$ - $145^{\circ}\text{W}$ ) between the  $10.5$  and  
344  $12^{\circ}\text{C}$  isotherms and the southern frontal zone between ( $42^{\circ}\text{N}$ - $45^{\circ}\text{N}$ ) between the  $13.5$  and  $15^{\circ}\text{C}$  isotherms (Fig.  
345 8b,c). By comparison, our models suggest that DMS concentrations are predominantly low in relation to high sea  
346 surface nitrate (SSN) concentrations within the HNLC gyre (Fig. 8, 9). As discussed below, the relationship  
347 between DMS and macronutrient concentrations in the HNLC waters of the central Gulf of Alaska could indicate  
348 an important role for iron limitation as a controlling factor in the DMS cycle. The presence of elevated summer  
349 nutrients in offshore waters is taken as a proxy for iron limitation, which increases over the course of the summer  
350 growing season.

357

**Fig. 8. Physical drivers of summertime (June-August) NESAP DMS distributions. (a) Sea surface height anomalies (SSHA), (b) predicted DMS concentrations derived from the mean of all 2000 RFR and ANN machine learning models, (c) sea surface nitrate (SSN) and (d) photosynthetically active radiation (PAR). Contours in (b,c) show sea surface temperature (SST) isotherms. Coherent features of elevated sea-surface height indicate the presence of mesoscale eddies, whereas nearshore low SSHAs features reveal areas of upwelling. Colormaps ranges are restricted to illustrate trends with <1% of data exceeding the colorbar limits.**

Other variables appear to exhibit a more localized or minimal influence on DMS cycling. For instance, both NCP and DMS are elevated in productive nearshore waters, but NCP generally correlates weakly with both RFR- and ANN-derived DMS concentrations ( $p=0.08$ ,  $0.07$  for RFR and ANN, respectively). It should be noted, however, the empirically-derived NCP estimates may carry more uncertainty than other predictors obtained from direct satellite observations (Li and Cassar, 2016). Similarly to NCP, modelled phytoplankton taxonomic composition (Hirata et al., 2011; Zeng et al., 2018) was not significantly correlated with predicted DMS concentrations ( $p<0.1$ ). Although strong, persistent winds appear to sustain low DMS concentrations off the coast of Oregon and Vancouver Island (Fig. 9), wind speeds only weakly correlate with DMS overall for the region ( $p=-0.15$  and  $-0.12$  for RFR and ANN, respectively). Additionally, high PAR in these areas correspond with low DMS concentrations (Fig. 6d) and there is an overall negative correlation between PAR and DMS for the region (Fig. 6, 7;  $p=-0.21$  and  $-0.27$  for RFR and ANN, respectively). Finally, despite hypothesized links between DMS cycling and iron limitation in the NESAP (Levasseur et al., 2006; Merzouk et al., 2006; Royer et al., 2010), nFLH:Chl-a ratios (taken as a proxy for phytoplankton iron stress; Behrenfeld et al., 2009; Westberry et al., 2013) did not exhibit any coherent spatial patterns, and only weakly correlated to our modelled DMS concentrations ( $p=0.15$  and  $p=0.16$  for RFR and ANN, respectively).

**Fig. 9. Predicted spatial and temporal (June-August) DMS distribution in relation to underlying oceanographic variables. DMS concentrations predicted from (a-c) the Random Forest Regression (RFR) and (d-f) the Artificial Neural Network (ANN) ensemble models are mapped alongside the monthly-averaged (g-i) sea surface height anomalies (SSHA), (j-l) wind speeds (Wind), and (m-o) sea surface nitrate (SSN) for each month. Colormap ranges are restricted to illustrate trends, with at most 1.5% of the data beyond the colorbar limits.**

## 4 Discussion

The relative sparsity of DMS data in many oceanic regions and the complexity of DMS cycling have limited previous attempts to model oceanic distributions of this compound (Simó and Dachs, 2002; Vallina and Simó, 2007; Galí et al., 2018; Watanabe et al., 2007; Herr et al., 2019). Taking advantage of expanding data resources, we employed a new approach to statistically describe DMS distributions in the NESAP. Our results show that both our RFR and ANN models substantially improved predictive strength over traditional empirical approaches (Fig. 2, 3), while identifying several key DMS relationships and regional patterns across the NESAP (Fig. 8, 9). Although our statistical approach does not directly elucidate the underlying mechanisms driving these relationships, and not all variability in predictors may be captured at the single spatial scale used here, we can nonetheless make some

389 reasonable inductive inferences. These inferences are discussed below, along with the implications of the improved  
390 predictive performance observed here.

#### 391 **4.1 Relationships with other oceanographic variables**

392 Among the more prominent spatial relationships we observed was the coherence between predicted DMS  
393 concentrations and SST, and the negative correlation between predicted DMS concentrations and sea surface nitrate  
394 (SSN) within and surrounding the Alaska Gyre (Fig. 6-9). Notably, regional SSN, NCP and Chl-a distributions did  
395 not vary appreciably inside versus outside the gyre, and these variables were poorly correlated with DMS  
396 concentrations ( $r=-0.02$ ,  $\rho=0.08$  with NCP,  $r=0.09$ ,  $\rho=-0.12$  with Chl-a). This suggests that the patterns in surface  
397 DMS across the Alaska Gyre were not simply driven by changes in phytoplankton biomass or productivity. The  
398 DMS-nitrate relationship may be partially explained by the so-called sulfur overflow hypothesis (Stefels, 2000),  
399 which suggests that nutrient-limited phytoplankton increase DMSP production and its subsequent cleavage to  
400 DMS, in order to regulate intracellular sulfur quotas when protein synthesis is limited (Hatton & Wilson, 2007;  
401 Kinsey et al., 2016; Simó & Vila-Costa, 2006; Spiese & Tatarkov, 2014; Stefels, 2000). This mechanism may help  
402 explain the higher predicted DMS concentrations at the northern extent of the Alaska Gyre, where SSN  
403 concentrations begin to decrease (Fig. 6). Nutrient-dependent effects may also be important in explaining seasonal  
404 variability, as the DMS-nitrate relationship becomes positive in August as phytoplankton growth becomes  
405 increasingly nutrient limited (Fig. 7b).

406 The apparent relationship between DMS and nitrate could also result indirectly from the underlying effects of  
407 iron limitation. Excess summertime nitrate concentrations are taken as evidence for iron limitation in the NESAP  
408 (Boyd and Harrison, 1999; Boyd et al., 2004; Martin and Fitzwater, 1988; Whitney et al., 2005). Under iron-limiting  
409 conditions, DMS is thought to function, together with DMSP and DMSO, as part of an antioxidant response to  
410 oxidative stress (Sunda et al., 2002). This hypothesis suggests that iron limitation should stimulate net production  
411 of DMS and DMSP (Bucciarelli et al., 2013; Sunda et al., 2002), which is inconsistent with the overall negative  
412 dependence predicted between DMS and SSN (Fig. 8b,c).

413 Satellite-based, chlorophyll-normalized fluorescence has been suggested as an additional proxy for iron  
414 limitation. Low iron conditions can lead to both a reduction in photosystem I relative to photosystem II (Strzepek  
415 and Harrison, 2004), and an apparent increase in energetically-decoupled light harvesting complexes (Allen et al.,  
416 2008; Behrenfeld & Milligan, 2013), resulting in elevated fluorescence-to-chlorophyll a ratios (nFLH:Chl-a)  
417 (Westberry et al., 2013). To our knowledge, this proxy has not been widely investigated with respect to DMS  
418 cycling. In our analysis, we found that nFLH:Chl-a ratios, and the NPQ-corrected fluorescence yields ( $\phi_f$ ), exhibited

only weak positive correlations with the RFR and ANN predicted DMS concentrations (Fig. 6, 7). Moreover, neither of these metrics exhibited coherent spatial patterns with predicted DMS concentrations, suggesting a limited role for iron in driving spatial patterns of DMS cycling within the NESAP. However, it is important to note the potential temporal mismatch between our monthly DMS predictions and these more instantaneous metrics of iron limitation, which reflect short-term physiological changes (days to weeks; Behrenfeld et al., 2009; Westberry et al., 2019) that depend on sporadic iron loading (*e.g.* aerosol deposition; Mahowald et al., 2009). Indeed, both natural and artificial iron-fertilization events have thus far been detected from satellite-derived nFLH:Chl-a at daily resolution (Westberry et al., 2013), in contrast to the monthly-averaged data used here. Therefore, modelling frameworks utilizing shorter temporal scales may find a clearer connection between DMS cycling and iron limitation using the chlorophyll-a fluorescence proxy.

Beyond nutrient limitation effects, ambient light fields are believed to exert significant direct and indirect effects on DMS cycling (del Valle et al., 2007). At the community level, high irradiance may inhibit bacterial consumption of DMS (Slezak et al., 2001; Toole et al., 2006; Lizotte et al., 2012), while covarying changes in mixing and high irradiance can induce transient selectivity for high-light acclimated species and influence the proportion of high DMS/P producers within assemblages (Galí et al., 2013; Vance et al., 2013). Ultraviolet radiation has been noted to induce high DMS production and turnover through a proposed cascading oxidation pathway, which acts to remove harmful reactive oxygen species (Sunda et al., 2002; Archer et al., 2010). In contrast, more recent evidence has indicated the potential for elevated DMS production in the NESAP from the reduction of DMSO due to light-induced oxidative stress over diurnal cycles (Herr et al., 2020). Although our modelled DMS concentrations exhibited an overall negative correlation with PAR (Fig. 6, 7a), monthly correlations indicate a stronger positive correlation between DMS and PAR in June, where the summer solstice drives high irradiance. In contrast, July and August exhibit much weaker negative correlations as the summer bloom declines (Fig. 7b). These results provide indirect evidence that light-induced oxidative stress, possibly coupled with inhibition of microbial DMS consumption, may influence regional NESAP DMS distributions, particularly early in the summer.

The overall negative association of DMS and incident light (Fig. 6, 7a) may also indicate a role for photolysis in DMS loss through (del Valle et al., 2007). Since DMS does not have strong light absorption properties, the presence of photosensitisers is necessary for the abiotic photooxidation of DMS (Brimblecombe and Shooter, 1986). To account for this process, our models incorporated nitrate (SSN) and  $a_{\text{cdm}}$  (443) (as a proxy for CDOM; Nelson & Siegel, 2013), both of which are thought to be dominant photosensitisers of DMS in marine systems (Taalba et al., 2013; Bouillon and Miller, 2004, 2005; Galí et al., 2016). In the NESAP, nitrate appears to exert a stronger influence than CDOM on the apparent quantum yields (AQY) of DMS (Bouillon and Miller, 2004). In

450 support of this, our results suggest a stronger negative dependence of predicted DMS concentrations on nitrate  
451 compared to CDOM within the NESAP, particularly in June when irradiance is high (Fig. 6, 7). We acknowledge,  
452 however, that the DMS-nitrate relationship likely also reflects physiological impacts of nutrient limitation, as  
453 discussed above. Nonetheless, our results are consistent with elevated rates of DMS photo-oxidation in the nitrate-  
454 replete, low iron waters of the Alaska Gyre, where photolysis may drive strong DMS oxidation and explain the low  
455 predicted DMS concentrations (Fig. 8, 9). Further *in situ* work will be required to resolve the relative contributions  
456 of these biotic and abiotic processes to DMS cycling within these areas.

457     Among all the statistical relationships we observed, perhaps the most striking was the association of DMS  
458 variability with SSHA, particularly along the Alaskan coast and in relation to mesoscale eddies (Okkonen et al.,  
459 2001; Whitney et al., 2005; Fig. 8, 9). To our knowledge, only one other study has linked SSHA to DMS within  
460 the NESAP. Herr et al., (2019) demonstrated contrasting positive and negative correlations between DMS and  
461 SSHA in offshore and coastal waters, respectively, in general agreement with our results. Presently, the underlying  
462 mechanisms explaining the relationship between SSHA and DMS cycling remain unclear, yet it is likely that  
463 physical mixing processes are important. For example, enhanced biological production is known to be stimulated  
464 by eddy re-supply of iron and macronutrients via vertical advection and diffusion (Whitney et al., 2005; Bailey et  
465 al., 2008). These nutrient supply processes would also be expected to influence DMS cycling, as outlined above.  
466 Elevated abundances of high DMS-producers within anticyclonic eddies with positive sea surface height anomalies  
467 have been noted in the Sargasso Sea (Bailey et al., 2008), while eddy-induced vertical transport likely supplements  
468 nearshore, current-driven upwelling that can also resupply iron into the coastal waters of the NESAP (Cullen et al.,  
469 2009; Freeland et al., 1984). In addition, eddy propagation can allow cross-shelf transport, distributing  
470 micronutrients to offshore waters (Fiechter and Moore, 2012), potentially contributing to the apparent elevated  
471 DMS concentrations in the outer Alaska gyre between the 10.5 and 12°C isotherms (Fig. 8). These mixing and  
472 transport mechanisms could partially explain the influence of elevated productivity in driving increased nearshore  
473 and northern NESAP DMS concentrations (Fig. 4, 7-9), representing a novel source of DMS variability in this  
474 region.

475     The taxonomic composition of plankton assemblages is also a likely source of variability influencing DMS  
476 cycling. Significant changes to DMS production and consumption rates within the NESAP are expected in response  
477 to variable microbial and phytoplankton taxonomy (Vila-Costa et al., 2006; Lidbury et al., 2016; Sheehan and  
478 Petrou, 2020). Such taxonomic variability may, in turn, reflect transient community composition shifts in response  
479 to mixing (Bailey et al., 2008), nitrate (Bouillon and Miller, 2004), and iron availability (Levasseur et al., 2006;  
480 Merzouk et al., 2006). The monthly averaging used in our data processing removes autocorrelation associated with

individual sampling expeditions (Wang et al., 2020), but it may preclude capturing these transient taxonomic responses. For instance, coccolithophores are believed to influence DMS cycling in the NESAP (Herr et al., 2019; Asher et al., 2011), yet monthly-averaged calcite distributions did not yield increased predictive strength for DMS concentrations in our analysis (see Sect. 2.6). However, as satellite PIC preferentially reflects the optical signature of detached coccoliths, monthly-averaged satellite PIC observations may represent the senescence of coccolithophore blooms, rather than active growth phases. Additionally, applying a chlorophyll-a based taxonomic algorithm (Hirata et al., 2011; Zeng et al., 2018) yielded no further explanation of the DMS variability predicted. The influence of taxonomic composition thus remains cryptic within our modelling framework.

## 4.2 Implications of Improved Predictive Power

As noted above, both the RFR and ANN approaches demonstrate significantly improved accuracy over existing models, explaining up to 62% of observed DMS variability (Fig. 2, 3). This predictive skill is somewhat lower than that achieved for methane fluxes (Weber et al., 2019) and dissolved inorganic carbon dynamics (Roshan and DeVries, 2017), where  $R^2$  values ranging from 0.7 to 0.95 were obtained. Nonetheless, the dramatic accuracy improvement of our algorithms over traditional methods (Fig. 2, 3) encourages the further use of these techniques in modelling DMS distributions.

Improved predictive accuracy provides opportunities to gain insight into the mechanisms driving DMS cycling. Our approach has yielded accurate DMS predictions at a 4 to 40-fold higher resolution than previous algorithms (Simó and Dachs, 2002; Vallina and Simó, 2007; Galí et al., 2018; Watanabe et al., 2007), enabling the description of mesoscale patterns and processes (Fig. 8). Extending these methods to sub-mesoscale resolution will enable investigations into the dependence of DMS on finer-scale hydrographic processes, particularly stratification and frontal dynamics, which have been increasingly linked to DMS cycling but remain unresolved mechanistically (Royer et al., 2015; Asher et al., 2011). Moreover, coupling machine learning algorithms with biophysical and tracer export models holds promise to resolve the contributions of eddy dynamics and upwelling intensity on DMS variability, likely through nutrient availability and physiological mechanisms (Asher et al., 2011; Bailey et al., 2008; Cullen et al., 2009). Recent work has also developed a new database of DMS apparent quantum yields (Galí et al., 2016). As the availability of these measurements increases, simultaneous mapping of both DMS quantum yields and concentrations will become feasible, enabling future studies to better parse out the contribution of photolysis, physical mixing, and biological drivers of DMS cycling.

Although used in a diagnostic capacity here, our statistical models also hold potential for prognostic applications. Frameworks utilizing shorter time scales will likely be able to detect underlying mechanisms

511 driving observed diel cycling (Galí et al., 2013; Royer et al., 2016), even if the underlying mechanisms are still  
512 unresolved. We note, however, that caution will need be exercised as machine learning models have a tendency  
513 to overfit noise (Weber et al., 2019; Roshan and DeVries, 2017; Wang et al., 2020), thus requiring appropriately  
514 large training datasets and the use of known “future” observations to validate predictive accuracy in this context.  
515 The significant variability in DMS cycling across oceanic regimes will likely also render predictions more  
516 successful at regional, rather than global, scales (Galí et al., 2018; Royer et al., 2015). Nonetheless, prognostic  
517 applications of these algorithms should be investigated to aid in the future development of improved mechanistic  
518 models.

## 519 **5 Conclusions**

520 We have presented a statistical approach for modelling DMS distributions, which provides significantly  
521 higher predictive skill than traditional methods (Simó and Dachs, 2002; Vallina and Simó, 2007; Galí et al., 2018;  
522 Watanabe et al., 2007; Lana et al., 2011), and yields estimates of the summertime NESAP DMS sea-air fluxes to  
523  $1.16 \pm 1.22$  Tg S in agreement with previous findings (Herr et al., 2019; Lana et al., 2011). Our results further  
524 underscore the importance of the NESAP to global DMS production and motivate further observations in  
525 traditionally under-sampled areas such as the Alaska Gyre and Aleutian Islands. Although we are unable to directly  
526 examine the mechanistic drivers of DMS variability, our findings suggest nutrient limitation, light-driven  
527 processes, and eddy-induced mixing are potentially key drivers of DMS cycling in the NESAP. Future studies will  
528 benefit from using such statistical algorithms, in conjunction with field-based process studies and mechanistic  
529 models, to better understand the underlying dynamics and driving factors in the oceanic DMS cycle.

530 *Code availability.* The analysis in this study makes extensive use of the Numpy, Matplotlib, & Scikit-Learn libraries  
531 in Python. The custom codes used can be downloaded at  
532 [https://github.com/bjmenabb/DMS\\_Climatology/tree/main/NESAP](https://github.com/bjmenabb/DMS_Climatology/tree/main/NESAP) or are available upon request from the  
533 corresponding author.

534 *Data Availability.* DMS observations and predictor datasets are described in the Methods with relevant links to  
535 repositories. Data from the Lana et al. (2011) climatology used for comparison in Table 3 are available via the  
536 SOLAs project (retrieved from [www.bodc.ac.uk/solas\\_integration/implementation\\_products/group1/dms/](http://www.bodc.ac.uk/solas_integration/implementation_products/group1/dms/)), where  
537 the DMS sea-air fluxes were calculated as described in Sect. 2.3. The gridded climatologies produced from each

538 algorithm in this study can be obtained at  
539 [https://github.com/bjmcnabb/DMS\\_Climatology/tree/main/NESAP/Climatologies](https://github.com/bjmcnabb/DMS_Climatology/tree/main/NESAP/Climatologies).

540 *Author Contribution.* BM and PT designed the study. Model code was written and implemented by BM. BM  
541 prepared the manuscript with significant contributions from PT.

542 *Competing Interests.* The authors declare that they have no conflict of interest.

543 *Acknowledgements.* We would like to thank Dr. Valentina Radic for her advice in model design and four  
544 anonymous reviewers for their helpful comments that improved this manuscript. This work was supported by grants  
545 to BM and PT from the Natural Sciences and Engineering Research Council of Canada (NSERC).
