Abstract. The frequency and severity of droughts and heat waves are projected to increase under global warming. However, the differential impacts of climate extremes on the terrestrial biosphere and anthropogenic CO₂ sink remain poorly understood. In this study, we analyse the effects of six hypothetical climate scenarios with differing drought-heat signatures, sampled from a long stationary climate model simulation, on vegetation distribution and land carbon dynamics, as modelled by a dynamic global vegetation model (LPX-Bern v1.4). The six forcing scenarios consist of a Control scenario representing a natural climate, a Noextremes scenario featuring few droughts and heatwaves, a Nocompound scenario which allows univariate hot or dry extremes but no co-occurring extremes, a Hot scenario with frequent heatwaves, a Dry scenario with frequent droughts, and a Hotdry scenario featuring frequent concurrent hot and dry extremes. We find that a climate with no extreme events increases tree coverage by up to 10 % compared to the Control and also increases ecosystem productivity as well as the terrestrial carbon pools. A climate with many heatwaves leads to an overall increase in tree coverage primarily in higher latitudes, while the ecosystem productivity remains similar to the Control. In the Dry and even more so in the Hotdry scenario, tree cover and ecosystem productivity are reduced by up to -4 % compared to the Control. Depending on the vegetation type, the effects from the Hotdry scenario are stronger than the effects from the Hot and Dry scenario combined, illustrating the importance of correctly simulating compound extremes for future impact assessment. Overall, our study illustrates how factorial model experiments can be employed to disentangle the effects from single and compound extremes.

1 Introduction

The terrestrial biosphere sequesters about 30% of the anthropogenic CO₂ emissions (Friedlingstein et al., 2020). Different factors such as increasing atmospheric CO₂ concentrations, higher temperatures, or, on a more regional scale, water or nutrient availability, can increase or decrease the terrestrial carbon sink. Different biomes may also react differently. While warmer temperatures are likely to increase productivity in high latitudes and altitudes due to an increase in the growing season length, productivity may be reduced in warmer regions because of higher evaporation and stomatal closure (Friend et al., 2014). Overall, there is evidence that the vulnerability of trees to hotter droughts may increase but this may also be compensated by
higher CO₂ concentrations and associated increased water use efficiency (Allen et al., 2015). However, future projections of the terrestrial carbon sink remain highly uncertain (Friedlingstein et al., 2014).

A potentially large contribution to the uncertainty in carbon cycle response to climate change may stem from the impacts of climate extremes. Climate extremes can cause devastating impacts on the natural environment (IPCC, 2012; Reichstein et al., 2013; Frank et al., 2015; von Buttler et al., 2018; Senf et al., 2020). At the same time, extreme impacts are often not linked to single climate extremes but to a combination of anomalous drivers (Zscheischler et al., 2016; Flach et al., 2017; Pan et al., 2020; Tschumi and Zscheischler, 2020; Van der Wiel et al., 2020; Vogel et al., 2021), also called compound events (Zscheischler et al., 2018, 2020).

Arguably, drought and heat are among the most damaging hazards to terrestrial vegetation (Allen et al., 2010; Reichstein et al., 2013; Zscheischler et al., 2014b; Frank et al., 2015; Sippel et al., 2018; von Buttler et al., 2018; Senf et al., 2020). In particular, an increasing occurrence of warm droughts has already lead to increased vegetation impacts on northern hemispheric ecosystems over the observational period (Gampe et al., 2021). However, differentiating impacts between drought and heat alone and compound drought and heat remains a challenging task. Disentangling these impacts is important, as co-occurring droughts and heatwaves tend to have larger impacts compared to the sum of impacts from droughts and heatwaves separately (Zscheischler et al., 2014b; Ribeiro et al., 2020), for example because a drought exacerbates the impacts of a heatwave through reduced evaporative cooling (Yuan et al., 2016). Furthermore, projections of droughts and heatwaves can differ strongly across different climate models (Herrera-Estrada and Sheffield, 2017; Zscheischler and Seneviratne, 2017).

The impacts of climate extremes on vegetation and the terrestrial carbon cycle can be studied using different approaches including (i) lab or field experiments (De Boeck et al., 2011; Beier et al., 2012; Song et al., 2019); (ii) observational data such as long-term forest observations (Anderegg et al., 2013) and local measurements of carbon exchange (Ciais et al., 2005; von Buttler et al., 2018; Pastorello et al., 2020); (iii) indirect estimates from satellite observations (Ciais et al., 2005; Zhao and Running, 2010; Zscheischler et al., 2013; Stocker et al., 2019); and (iv) dynamical vegetation models (Ciais et al., 2005; Zscheischler et al., 2014a, b, c, d; Rammig et al., 2015; Xu et al., 2019; Bastos et al., 2020; Pan et al., 2020). Vegetation models offer the benefit of being able to analyse new hypotheses in a strictly controlled environment at global scale.

Despite considerable uncertainties in climate models, it is widely acknowledged that drought and heat extremes will increase in frequency and severity in many land regions in the future (Seneviratne et al., 2012). Though it is still uncertain exactly how these increases will affect the terrestrial biosphere, there are concerns they might substantially reduce the current terrestrial carbon sink (Reichstein et al., 2013). While coupled models of the land and atmosphere allow for a more complete representation of the feedback processes (Humphrey et al., 2021) than stand-alone land biosphere models, the analysis of results is more complicated for coupled models, since the coupling is different for different models and uncertainties depend not only on the land but also on the atmosphere module.

In this study, we aim to disentangle the differential effects of different frequencies of droughts, heatwaves, and compound drought-heatwave events on vegetation composition, carbon pools, and carbon dynamics. To this end, we force a dynamic global vegetation model, LPX-Bern v1.4, with six 100 year long climate scenarios featuring varying drought-heat signatures, i.e. different occurrence probabilities of droughts, heatwaves, and concurrent droughts and heatwaves. These scenarios were
sampled from 2000 years of present-day climate data from the EC-Earth climate model, as described in Sect. 2.1. They have a constant CO$_2$ concentration and do not contain long-term trends. The controlled environment of a model setup allows us to attribute changes in vegetation composition and carbon dynamics to differences in drought-heat occurrence.

2 Data and Methods

2.1 Forcing scenarios

Six forcing scenarios featuring different drought-heat signatures were used to run the vegetation model LPX-Bern. These scenarios, each 100 years long, were constructed from a large ensemble climate modelling experiment (Tschumi et al., accepted). 2000 years of simulated present-day climate data were created with the fully-coupled global climate model EC-Earth (v2.3, Hazeleger et al., 2012). The large ensemble was built out of 400 short five-year runs, which were unique in initial conditions and/or stochastic physics seed. EC-Earth combines atmospheric, oceanic, land, and sea-ice model components, and simulates the global climate including feedbacks between land and atmosphere. Within the ensemble the influence of forced climate change is small. We, therefore, assume all variability in the data set is due to natural variability in the climate system.

The selection of the different scenarios from this data set was based on temperature and precipitation values during the time of the year where the vegetation is most active. Arguably, the vegetation is most vulnerable to climate extremes during the growing season. Therefore, for the scenario creation, we focused on the three months around the most productive month in the climatology. We identified the most productive month at each pixel, that is, the month with the highest climatological-mean net primary production (NPP) as simulated by LPX-Bern.

We selected the six different scenarios for each pixel separately based on mean temperature and precipitation over the three months around the month of highest NPP: Control, Noextremes, Nocompound, Hot, Dry and Hotdry. Years contributing to the scenarios were sampled based on quantiles of the three-month temperature and precipitation averages, where the quantiles were computed based on the full 2000-year EC-Earth output. If more than the required number of years fall into the quantiles in question, a random selection was performed. If fewer years than necessary were available, some randomly chosen years were selected multiple times. For each of the Hot, Dry, and Hotdry scenarios, 50 years were sampled from the extreme quantiles and 50 years were randomly sampled from the rest. The reason for this is twofold. Firstly, for many pixels, not many years fall into the extreme quantiles. Sampling only 50 years from there reduces the number of times a year is re-sampled. Secondly, the mean climatology is kept more similar to the other scenarios if only half the years were sampled with extreme conditions and the other half from the rest.

This method of scenario creation, for each pixel separately, destroys any spatial coherence, so that the climate in a pixel is not correlated to the climate in nearby pixels. Furthermore, due to the sampling of individual years, there are always slight discontinuities between 31 December and 1 January in the climate forcing. The same is true for leap years since all leap days (29 February) were removed. We assume that these small discontinuities in the atmospheric forcing do not significantly affect our findings. The scenarios have a daily temporal and a 1° × 1° spatial resolution. The scenarios were sampled from
the percentiles of the EC-Earth data at each location separately as described in Tschumi et al. (accepted) and summarized in Table 1.

The scenarios differ little in their mean climatic conditions but strongly in the occurrence of droughts, heatwaves, and concurrent droughts and heatwaves. More specifically, the difference in global mean temperature and precipitation between the scenarios is about 0.3 °C and 6 %, respectively. The Hot and Hotdry scenarios show an increase in heatwaves (based on cooling degree days) by up to 160 % compared to the Control. Drought occurrence (based on the standardize precipitation index) is strongly increased for the Dry and Hotdry scenario, by up to 200 % compared to the Control. In the Noextremes and Nocompound scenarios, there is an overall decrease in droughts of up to -80 % and heatwaves up to -50 %. The pattern of concurrent droughts and heatwaves is even more pronounced. There are no or very few concurrent droughts and heatwaves in the Noextremes and the Nocompound scenario. Compound extremes are possible for the Hot and Dry scenario, but occur overall less often than in the Control. In the Hotdry scenario, however, concurrent droughts and heatwaves occur up to 50 times more often than in the Control. A more in-depth description and analysis of these scenarios including the definition of droughts and heatwaves are given in Tschumi et al. (accepted).

### 2.2 LPX-Bern

LPX-Bern v1.4 (Lienert and Joos, 2018) is a Dynamic Global Vegetation Model based on the Lund-Potsdam-Jena (LPJ) model (Sitch et al., 2008). The model features coupled water, nitrogen, and carbon cycles and represents different types of vegetation using Plant Functional Types (PFTs). Here, only natural vegetation is considered, which is internally represented by eight tree PFTs and two herbaceous PFTs competing for resources and adhering to bioclimatic limits. In LPX, tree coverage is restricted to 95% of the grid cell. If the total fraction summed over all PFTs exceeds 1, the plants that were the least productive are killed, representing self-thinning. Mortality can also occur if a PFT’s bioclimatic limits are reached due to heat stress, negative NPP, or depressed growth efficiency (Sitch et al., 2003).

In this study, daily temperature, precipitation, and incoming short-wave radiation are provided to the model. Additionally, the model uses information on the soil type (Wieder et al., 2014), CO<sub>2</sub> concentration in the atmosphere at 2011-level (389.78 ppm),
and nitrogen deposition, also at 2011-level (Tian et al., 2018). Each scenario simulation was preceded by a 1500 year long spin-up, which was forced with climate data of the same scenario (‘individual spin-up’). To test how fast vegetation composition and net ecosystem exchange reach a new equilibrium under an altered frequency of droughts and heatwaves, we also performed simulations in which the spin-up was based on climate from the Control (‘shared spin-up’).

LPX-Bern represents natural vegetation with ten PFTs, as described above. For the following analysis, we aggregate them into four broader classes, namely Tropical trees (including tropical broad-leafed evergreen and tropical broad-leafed rainforest trees), Temperate trees (including temperate needle-leafed evergreen, temperate broad-leafed evergreen and temperate broad-leafed summergreen trees), Boreal trees (including boreal needle-leafed evergreen, boreal needle-leafed summergreen and boreal broad-leafed summergreen trees), and Grasses (including temperate and tropical herbaceous). The dominant vegetation class in the control simulation for each pixel, including its fractional cover (the fraction of a grid cell covered with a certain vegetation class), is shown in Fig. 1. Pixels where the total fractional coverage is smaller than 0.1, corresponding to desert regions, are masked white.

![Figure 1. Dominant vegetation class (mean over time) in the Control simulation. The intensity (color bars) shows the fractional coverage of each dominant class.](https://doi.org/10.5194/bg-2021-191)

## Results

We report how different stationary climate conditions (i.e. without long-term trends) with varying intensities of droughts, heatwaves and compound drought-heatwaves affect vegetation coverage (Sect. 3.1) as well as carbon pools and carbon fluxes (Sect. 3.2). These results are based on the simulations using the individual spin-up. In Section 3.3 we report how quickly LPX-Bern reaches a new equilibrium by running simulations for each scenario that use the climate of the Control scenario during spin-up (shared spin-up).
3.1 Changes in vegetation coverage and associated NPP changes

The different drought-heat scenarios lead to a change in fractional vegetation coverage (Fig. 2a). Trees generally benefit from a climate with no droughts and heatwaves. The increase in tree cover is stronger for higher latitudes. While the relative difference in Tropical tree cover is 1.2 %, it is 9.4 % for Boreal trees (green bars in Fig. 2a). Grass coverage in turn decreases to make room for the trees. To a lesser extent, the same pattern also holds for a climate with no compound extremes, which however does feature univariate extremes (blue bars in Fig. 2a). The increase of tree coverage towards higher latitudes is also evident for the Hot scenario, while for this scenario grass cover does not change compared to the Control (red bars in Fig. 2a). The Dry and, even more strongly, the Hotdry scenarios lead to an overall decrease of tree coverage (orange and purple bars in Fig. 2a, respectively). The decrease is particularly strong for Temperate tree coverage in the Hotdry scenario (-5.6 %), while there is little change in Boreal tree cover. For the Hotdry scenario, the overall decrease in tree cover is compensated by an increase in grass cover, in contrast to the Dry scenario, in which grass cover also decreases. While it is generally true that grasses seem to compensate for declining tree coverage, the compensation is not necessarily complete. As an effect, the total sum of fractional plant cover may change as well. However, at the global scale, there is hardly any change in fractional coverage between the scenarios (not shown). Overall, the differences in vegetation cover between the scenarios are smallest for Tropical trees and tend to be similarly ordered, but larger in magnitude, for the other vegetation classes.

The above-described relative differences in coverage directly translate into changes in annual NPP (Fig. 2b). In particular, if tree or grass coverage increases, so does NPP and if coverage decreases, we find an associated decrease in NPP. Overall the variability in the relative differences in NPP is larger than the variability in the relative differences in vegetation cover (compare lengths of bars in Fig. 2a to Fig. 2b).

Figure 2. Relative difference of the scenarios to the Control for (a) coverage and (b) annual NPP. The bars show the minimum to maximum range over the 100-year long simulations.
We compare the spatial patterns of the differences of tree (all tree types aggregated) and grass cover between the two scenarios with the strongest effect and the Control, i.e. Noextremes-Control and Hotdry-Control, in Fig. 3. In the Noextremes scenario, tree cover increases on all land pixels compared to the Control, especially in western North America and Mid-Eurasia (Fig. 3a). In contrast, grass cover decreases everywhere except in very dry regions such as the Sahara, the Arabian Peninsula, and Australia, where a constant climate without extremes leads to a slight increase in grass cover (Fig. 3b). For Hotdry, tree cover decreases in most regions except the very high latitudes, compared to the Control (Fig. 3c), while grass coverage increases except for very dry regions (Fig. 3d).

Figure 3. Difference in fractional coverage of (a) Noextremes trees, (b) Noextremes grasses, (c) Hotdry trees and (d) Hotdry grasses compared to the Control.

3.2 Changes in carbon dynamics

The effects of the scenarios on vegetation coverage (Sect. 3.1) are reflected by the globally aggregated carbon fluxes and pools (Fig. 4). Noextremes, Nocompound, and Hot generally show higher or similar flux magnitudes compared to the Control, whereas fluxes are strongly decreased for Dry and Hotdry, by up to more than -4 % for global GPP in Hotdry (Fig. 4a). Similar patterns are evident for global vegetation carbon (Fig. 4b). Overall, relative differences are much smaller for global soil carbon.

We further explore the spatial patterns in the differences of NPP separately for trees (all tree types aggregated) and grasses between the two scenarios with the strongest effect, i.e. by looking at Noextremes-Control and Hotdry-Control (Fig. 5). NPP of trees increases nearly everywhere in Noextremes compared to the Control, by up to 200 gC m$^{-2}$ yr$^{-1}$ in some regions in the mid-west of the US (Fig. 5a). NPP of grasses shows slight increases in the lower latitudes but strong decreases in the
Figure 4. Relative difference of the scenarios to the Control for (a) the global annual GPP, NPP, and heterotrophic respiration \(r_{\text{het}}\) as well as (b) vegetation carbon and soil carbon. The bars in (a) show the minimum to maximum range of the 100 year-long simulations. Because the interannual range for carbon pools in (b) is very small we only show the mean over the 100 years.

higher latitudes, which are of similar magnitude as the increases in tree NPP (Fig. 5b). The pattern is more diverse for Hotdry, where NPP of trees generally decreases in the low-to-mid latitudes by up to -150 gC m\(^{-2}\) yr\(^{-1}\) but increases in the very high latitudes (Fig. 5c). NPP of grasses tends to increase in most regions except some very dry regions in the Sahara and Middle East, Australia, Namibia, and the Southwest of the US (Fig. 5d).

Finally we investigate whether the interannual variability in NPP for four vegetation classes changes between the Control and the different scenarios. Overall, interannual variability in NPP is smallest in Tropical and Temperate trees and largest in Boreal trees (Fig. 6). Most scenarios tend to decrease variability in particular for trees, with Noextremes leading to significant decreases in all vegetation classes. In contrast, Hotdry tends to increase variability, though the difference to the Control is only significant for Boreal trees and Grasses. For Grasses, also the Hot and the Dry scenario lead to a significant increase in NPP variability.

3.3 Path to model equilibrium

We explore how fast vegetation composition and net ecosystem production adjust towards a new equilibrium after a step-like change in extreme statistics. To this end, we analyse the 100-yr scenario simulations that started from the shared model spin-up forced by the Control climate. At the start of each scenario simulation, frequencies of droughts and heatwaves suddenly change from those in the Control climate to those in the scenario.

Using the simulations based on the shared spin-up, we explore whether LPX-Bern reaches a new equilibrium (measured in terms of stable vegetation composition and neutral net ecosystem production) within the 100-year simulations after frequencies of droughts and heatwaves suddenly change from Control to the different scenarios. Overall, the Noextremes and the
Figure 5. Difference in NPP for (a) Noextremes trees, (b) Noextremes grasses, (c) Hotdry trees and (d) Hotdry grasses compared to the Control.

Figure 6. Variability of NPP (calculated as interannual standard deviation across years for the four vegetation classes with the mean taken over all grid cells). The stars show the scenarios that are significantly different from the Control at a 5 % significance level (based on a t-test).

Hotdry scenarios cause the largest disturbance in vegetation cover (Fig. 7). For most vegetation classes and most scenarios, the scenario simulations starting from the shared spin-up are within the range of variability of the scenario simulation starting from an individual spin-up at the end of the simulation. Exceptions are Tropical trees in the Noextremes and the Hot scenarios, Temperate trees in the Hot and the Hotdry scenarios and Grasses in the Hotdry scenario. The strongest response in vegetation cover occurs in the first 20 years. Grasses show a particularly fast response in the Hotdry scenario, where there is an initial decrease in coverage followed by a rapid increase. The reason for this seems to be that (predominantly temperate) grasses that are adapted to the climate in the control quickly die due to the frequent hot and dry conditions but then a regrowth of
(predominantly tropical) grasses that can tolerate such conditions occurs. Overall, the above results suggests that, for the more extreme scenarios, 100 years may not be enough to fully reach equilibrium after a sudden change in drought-heat occurrence.

Figure 7. Time series of the fractional coverage (foliar projective cover) from the simulations that use the shared spin-up (black line). Scenarios are shown in colored dashed lines for (a) Tropical trees, (b) Temperate trees, (c) Boreal trees, and (d) Grasses. The first 20 years (-20 to 0) represent the last 20 years of the shared spin-up. The variability (minimum to maximum) in vegetation cover in the individual spin-up simulation (spin-up uses data from the respective scenarios) is indicated by the bars on the right-hand side. Note the different ranges of the y-axes.

The findings based on vegetation cover are confirmed when investigating the temporal evolution of global annual net ecosystem production (NEP) in the simulations with shared spin-up (Fig. 8). Again, the disturbance is largest for the Noextremes (about 1 PgC yr$^{-1}$ more uptake at the beginning of the simulation) and the Hotdry scenario (about 3 PgC yr$^{-1}$ less uptake at the beginning). In all scenarios, global annual NEP converges towards 0 at the end of the 100-year simulations and varies within the range of interannual variability of the individual spin-up simulations. Nevertheless, NEP is slightly larger than 0 in the Noextremes scenario and slightly smaller than 0 in the Hotdry scenario even at the end of the simulation, indicating that not all carbon pools are in full equilibrium after 100 years.

4 Discussion

Using stationary climate scenarios with varying drought-heat signatures and a dynamic vegetation model we show that different occurrence frequencies of droughts, heatwaves, and compound drought-heat events lead to differences in vegetation coverage and related differences in global NPP (Fig. 2). The fraction of land area covered with vegetation is similar in all scenarios. However, there are shifts in coverage and NPP between vegetation classes. A key finding is that the climate, as represented by
the Noextremes scenario, which features no extreme droughts or heatwaves and relatively little interannual variability, favors tree coverage (Fig. 2). This is evident in the tropical biomes to some extent but even more evident at higher latitudes. For trees to grow well, typically more stable environmental conditions are needed as compared to grasses (Sitch et al., 2003). For example, the biomass of grasses, with their fast biomass turnover and short life cycle, recovers much faster after an increase in mortality, e.g., due to a drought-heat event, than tree biomass. Hence, overall, a more stable climate with few extremes is very beneficial for trees. In models such as LPX-Bern, trees are favored over grasses. In particular, they get priority for foliar coverage if conditions are suitable for tree growth. This explains why, in a more stable (i.e., less variable) climate, tree cover increases and grass cover decreases, and vice versa.

While a climate with more heatwaves has little influence on tree coverage in the tropics, it tends to increase coverage in higher latitudes (Fig. 2). Trees in higher latitudes are typically temperature limited (Way and Oren, 2010). So a climate with more heatwaves alleviates some of these temperature constraints. While overall more heatwaves increase tree coverage globally, there are strong regional variations, meaning that not everywhere higher temperatures lead to more growth (Ruiz-Pérez and Vico, 2020). In higher latitudes, more frequent heatwaves mean overall warmer temperatures during the growing season without necessarily exceeding the temperature limit of boreal trees, while in other regions such a limit might be reached more quickly, leading to a decrease in tree cover. Grass coverage does not significantly change for the Hot scenario compared to the Control.

If water is restricted, as it is for the Dry scenario, tree coverage is slightly reduced overall. However, unlike the other scenario, grasses in a dry climate do not compensate for changes in tree coverage. Rather, grass coverage is decreased as well. This likely happens because grasses tend to grow in already dry regions, where tree coverage is unlikely. If these regions get drier, it might even get too dry for grasses to grow. When comparing the Hot and Dry scenarios, we see that the effects on global NPP as well
as the vegetation carbon pool are more negative for the Dry than Hot scenario (Fig. 4). A drought event, therefore, does not have to be as extreme as a heat event to have a comparable impact, which is also supported by findings of Ribeiro et al. (2020).

The scenario with frequent compound hot and dry extremes clearly causes the strongest response and leads to a reduction in tree coverage across all climate zones. Hence, here even the warmer conditions in the northern latitudes that generally promote tree growth are superseded by the negative impacts of droughts (Belyazid and Giuliana, 2019; Ruiz-Pérez and Vico, 2020), though the effect is less pronounced for Boreal trees than for Temperate trees. Grass coverage, on the other hand, increases because it can fill the areas that were previously covered by trees. In dry regions, however, grass coverage is reduced for the Hotdry scenario as well, likely because here likely dryness thresholds under which vegetation cannot grow anymore are frequently exceeded. Global NPP as well as vegetation coverage is overall reduced for this scenario compared to the Control (Fig. 4).

Generally, trees grow nearly everywhere if the climate is favourable and features few extremes, leading to a reduction in grass cover. Only in dry regions do we observe an increase in grass coverage. There, conditions might still be unfavourable for trees to grow, but grasses benefit from the stable climate. In contrast, in a climate with frequent droughts and heatwaves, tree coverage is generally reduced, leaving room for grasses to grow, except in already dry regions, which become too dry even for grasses.

Globally, the effects of extremes are larger in the extratropics than they are in the tropics. The effects on Tropical trees are small for all scenarios compared to the Control, including the Hot and Dry extremes scenarios. One reason for this might be that strong evaporative cooling is maintained in tropical forests, even in a drier climate (Bonan, 2008) since the tropics (in particular tropical forest) are not so much water-limited but rather energy limited. The variability between the scenarios is small for Tropical trees and larger for Temperate and Boreal trees. The latter biomes are more water- and/or temperature-limited than the tropics and therefore react more strongly to variations in these variables. Grasses also show quite a large variability between scenarios owing to the fact that grasses react quicker to climate variations, meaning they die and regrow faster than trees (Ahlström et al., 2015).

While vegetation carbon displays a pattern that correlates with the changes in coverage, the same is not true for soil carbon. Rather, the changes in soil carbon (Fig. 9) resemble the changes in grasses (Fig. 3).

![Figure 9. Difference in soil carbon for (a) Noextremes vegetation (b) and Hotdry vegetation to the Control.](https://doi.org/10.5194/bg-2021-191)
Choosing an appropriate spin-up when modelling vegetation and the carbon cycle is important to make sure the model is in equilibrium. In our case, 1500 years seems appropriate. The type of spin-up also matters, since a different spin-up might lead to a different end point and therefore also to different results. We used the ‘individual spin-up’ runs for the analysis, since these are the runs where the model had time to reach equilibrium.

Scenarios, where the occurrence of heatwaves, droughts, and drought-heat events is changed in a step-like manner, reveal the characteristic time scales and magnitudes of the adjustment of a system, here the land biosphere, to the change. Our simulations reveal that plant coverage and NPP adjust on decadal time scales (Fig. 7) to altered extreme event statistics, while, in addition, multi-decadal-to-century response time scales are evident for global NEP (Fig. 8). The response time scales and magnitudes of change are likely model specific to some extent. It would be illustrative to probe the response to step changes using other models. Though the setup of the step change in the occurrence of droughts and heatwaves is somewhat unrealistic, long-term trends in the dependence between temperature and precipitation have been detected in climate model projections (Zscheischler and Seneviratne, 2017). Such changes in the dependence structure can be quite relevant, for instance they may exacerbate climate change impacts on crops (Lesk et al., accepted).

All results, such as the exact changes in vegetation distribution and carbon uptake, are somewhat sensitive to the choice of the dynamic global vegetation model and the employed climate model. Furthermore, land-atmosphere feedbacks may play an important role (Humphrey et al., 2021), which are not considered in such an offline model setup as we have conducted in this study. A model intercomparison project using our scenarios as forcings for different vegetation models has already been set up and will reveal insights on model differences and their effects on the results.

5 Conclusions

It is widely acknowledged that extreme climate events can have large impacts on ecosystems and society. This study investigates the effects of different drought-heat occurrences in six hypothetical climate scenarios on vegetation distribution and terrestrial carbon dynamics, as simulated by the LPX-Bern dynamic global vegetation model. Generally, effects of changes in extreme event frequency are more pronounced in the extratropics than in the tropics. We found that global carbon cycle variability is most stable in a climate without any extreme events, which favours more tree cover and a higher global terrestrial carbon stock. The effects on vegetation cover and carbon stocks and fluxes of a climate with many heatwaves are generally smaller than the effects of a climate with many droughts. The largest effect, however, has a climate with frequent concurrent droughts and heatwaves. Here, forest cover and global vegetation carbon is strongly reduced. Grasses, in contrast, are more abundant. These effects surpass the simple linear combination of the effects of single droughts and single heatwaves.

Overall, our results highlight the importance of considering compound events when analysing impacts of climate extremes. Impacts may potentially be underestimated when only looking at single event extremes instead of compounding extremes. Furthermore, the results suggest that uncertainties in projections of vegetation distribution and carbon dynamics in Earth system models may stem from different drought-heat signatures in the atmospheric module (Zscheischler and Seneviratne, 2017), in addition to structural model differences in the vegetation component. It is important to investigate and understand
these issues in order to improve models as well as our knowledge about extreme events and their processes, which may lead to significant impacts on society and ecosystems.

Data availability. The forcing scenarios are described in (Tschumi et al., accepted) and can be accessed via zenodo (10.5281/zenodo.4385445). The LPX-Bern simulations are very large and are available from Elisabeth Tschumi (elisabeth.tschumi@climate.unibe.ch).

Author contributions. J.Z. conceived the study. E.T. performed all analysis, performed model simulations with LPX-Bern, created all figures and wrote the first draft. K.v.d.W. performed the model simulations with EC-Earth. S.L. and F.J. helped with the setup of LPX-Bern and interpretation of the results. All authors contributed substantially to the writing and revisions of the manuscript.

Competing interests. The authors declare that they have no competing interests.

Acknowledgements. E.T. and J.Z. acknowledge the Swiss National Science Foundation (Ambizione grant 179876). J.Z. further acknowledges the Helmholtz Initiative and Networking Fund (Young Investigator Group COMPOUNDX, Grant Agreement VH-NG-1537). K.v.d.W. acknowledges funding for the HiWAVES3 project from the National Natural Science Foundation of China (41661144006), funding was supplied through JPI Climate and the Belmont Forum (NWO ALWCL.2 016.2 and NSFC 41661144006). F.J. and S.L. acknowledge funding from the Swiss National Science Foundation (Grant no. 200511) and from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 821003 (project 4C, Climate-Carbon Interactions in the Current Century).
