10 **Abstract.**

Boreal upland forests are generally considered methane (CH₄) sinks due to the predominance of CH₄ oxidising bacteria over the methanogenic archaea. However, boreal upland forests can temporarily act as CH₄ sources during wet seasons or years. From a landscape perspective and in annual terms, this source can be significant as weather conditions may cause flooding, which can last a considerable proportion of the active season and because often, the forest coverage within a typical boreal catchment is much higher than that of wetlands. Processes and conditions which change mineral soils from acting as a weak sink to a strong source are not well understood. We measured soil CH₄ fluxes from 20 different points from regularly irrigated and control plots during two growing seasons. We also estimated potential CH₄ production and oxidation rates in different soil layers and performed a laboratory experiment, where soil microcosms were subjected to different moisture levels and glucose addition simulating the fresh labile carbon (C) source from root exudates. The aim was to find the key controlling factors and conditions for boreal upland soil CH₄ production. Probably due to long dry periods in both summers, we did not find occasions of CH₄ production following the excess irrigation, with one exception in July 2019 with emission of 18200 µg CH₄ m⁻² h⁻¹. Otherwise, the soil was always a CH₄ sink (median CH₄ uptake rate of 260–290 and 150–170 µg CH₄ m⁻² h⁻¹, in control and irrigated plots, respectively). The median soil CH₄ uptake rates at the irrigated plot were 88 % and 50 % lower than at the control plot in 2018 and 2019, respectively. Potential CH₄ production rates were highest in the organic layer (0.2–0.6 nmol CH₄ g⁻¹ d⁻¹), but some production was also observed in the leaching layer, whereas in other soil layers, the rates were negligible. Potential CH₄ oxidation rates varied mainly within 10–40 nmol CH₄ g⁻¹ d⁻¹, except in deep soil and the organic layer in 2019, where potential oxidation rates were almost zero. The laboratory experiment revealed that high soil moisture alone does not turn upland forest soil into a CH₄ source. However, a simple C source, e.g. substrates coming from root exudates with high moisture switched the soil into a CH₄ source. Our unique study provides new insights into the processes and controlling factors

on CH₄ production and oxidation and resulting net efflux, that should be incorporated in process models describing global CH₄ cycling.

1 Introduction

5 Methane (CH₄) is a greenhouse gas with a significant impact on the global climate. CH₄ increases the global temperatures by absorbing infrared radiation into its carbon-hydrogen bonds, resulting in a higher amount of heat energy within the atmosphere (e.g. Chai et al., 2016; Dlugokencky et al., 2011; Whalen, 2005). In soil, CH₄ is predominantly formed in biological anaerobic decomposition processes (Le Mer and Roger, 2001; Wuebbles and Hayhoe, 2002). Archaea called methanogens are responsible for the biological production of CH₄ in anoxic conditions, whereas methanotrophs conduct aerobic CH₄ oxidation (Hanson and Hanson, 1996; Orata et al., 2018; Thauer et al., 2008). The dynamics behind soil CH₄ sources and sinks depend on the
10 ratio between CH₄ production and oxidation and its transport from the soil to the atmosphere, all of which are affected by an extensive network of numerous biotic and abiotic variables. The interannual fluctuations in global and regional CH₄ emissions are influenced by so-far largely unknown variables, the investigation of which is thus essential for understanding the changing dynamics in the current and future CH₄ budgets (Bousquet et al., 2006; Crill and Thornton, 2017; Dlugokencky et al., 2011; Fischer et al., 2008; Kirschke et al., 2013). The boreal zone in the northern hemisphere regularly presents large CH₄ emissions
15 due to the abundance of anoxic wetlands, but part is counterbalanced by high oxidation rates in boreal upland forests. The CH₄ emission estimates from the boreal zone lie between 25 and 100 Tg yr⁻¹, which combined with subarctic tundra environments account for approximately 3–10 % of the global CH₄ emissions (Olefeldt et al., 2013).

Boreal upland forests are broadly considered CH₄ sinks due to strongly oxic soils (Gulledge and Schimel, 2000; Megonigal and Guenther, 2008; Oertel et al., 2016; Whalen et al., 1991; Yavitt et al., 1990, 1995). In upland soils, high-affinity
20 methanotrophs can consume CH₄ at atmospheric concentrations (Knief et al., 2003; Kolb, 2009). Despite the abundance of oxygen in the boreal upland forest soil, there are some indications of smaller-scale CH₄-producing areas, such as wet depressions (Christiansen et al., 2012; Megonigal and Guenther, 2008; Vainio et al., 2021). In addition, some studies have found that upland forest soils may become CH₄ sources of varying significance after long periods of heavy precipitation (Lohila et al., 2016; Savage and Moore, 1997). Methanogenic population can stay constant in forest and other dry aerated soils and
25 becomes active under wet and anoxic conditions (Angel et al., 2012; Peter Mayer and Conrad, 1990). With upland forests occupying a significant portion of the boreal zone, a more thorough examination of the complex dynamics behind the sink-source transitions of the forests is needed, especially in the context of climate change which may alter global and regional precipitation and temperature patterns (e.g. Beier et al., 2012; Lehtonen et al., 2014; Lohila et al., 2016). Lohila et al. (2016) also suggested that wet conditions can potentially affect the CH₄ exchange patterns differently in forests and wetlands by
30 increasing and decreasing the CH₄ emissions in those ecosystems, respectively, amplifying the vital role of upland forests in the regional CH₄ balance in wet years. Furthermore, as precipitation may increase during summer and autumn in northern

latitudes (Jylhä et al., 2009), this flooding-induced source of CH₄ may be activated more frequently in the future. This source is accounted for in the models of global CH₄ emissions, but there are recent observation-based indications that its magnitude may be severely underestimated. The global CH₄ uptake by mineral soils is only 5 % of global CH₄ sink (625 Tg CH₄ yr⁻¹; Saunio et al., 2020) and during wet years the CH₄ sink of mineral soils is significantly suppressed. It has already been suggested that the emissions from wet mineral soils can be the primary driver for the interannual variability in global CH₄ emissions (Spahni et al., 2011).

Soil temperature and moisture manipulations in CH₄ flux studies from upland soils have been very few, but some existing manipulation studies exist that focus on carbon dioxide (CO₂) fluxes (Allison and Treseder, 2008; Billings et al., 2000; Niinistö et al., 2004; Wu et al., 2011). Recommendations have been made to focus on precipitation manipulations carried out either by wetting or drying and establishing those experiments in mostly underrepresented forest ecosystems (Wu et al., 2011). Methanotrophs are known to be more sensitive to soil drying than methanogens (Ebrahimi and Or, 2018; Megonigal and Guenther, 2008). Since the processes and conditions that change mineral soils from CH₄ sink to a source are not sufficiently well understood, direct laboratory measurements of CH₄ formation in different soil layers under controlled temperature and moisture conditions are needed to explain the processes in mineral soil in greater detail.

In this study, changes in forest floor CH₄ fluxes were assessed with an irrigation experiment during the growing period in a boreal upland forest in Kenttäröva in northern Finland over two years. Kenttäröva was chosen as the study site due to significant soil CH₄ emissions detected after a long period of abundant precipitation in 2011 by Lohila et al. (2016). In addition, CH₄ production and oxidation potentials were determined in different soil layers at flux measurement points. Finally, a laboratory microcosm experiment was used to investigate the conditions (temperature, moisture) needed to initialise CH₄ production from the upland soil. The aims of this study were 1) to find if the irrigation has any impact on the soil CH₄ flux and oxidation and production potentials; 2) to find which soil layers are most significant for CH₄ production and oxidation; and 3) to find the optimal conditions and key controlling factors for upland soil CH₄ production and oxidation. We hypothesised that 1) wet conditions prevailing for one or two summers could be seen in the response of microbial populations so that at the irrigated plot, the potential CH₄ oxidation would be smaller and at least short production episodes could be detected in the latter part of the summer either after both summers or at least after the second wet summer; 2) highest CH₄ oxidation potential are found in the surface soils while the maximum production potentials are found in the deeper layers; 3) both wet conditions and fresh organic carbon are needed to create conditions suitable for CH₄ production in podzolic forest soil.

2 Materials and methods

2.1 Study site

The study was carried out at the Kenttäröva forest (67°59.237'N, 24°14.579'E) in the Kittilä municipality in Finland at the transition zone of the northern-boreal and subarctic zones (Fig. 1). The site is located on a hilltop plateau with an approximate elevation of 347 m above sea level and 60 m above the surrounding plains (Aurela et al., 2015). The study site has climatic and vegetational characteristics typical for a northern-boreal environment. The long-term (1981–2010) annual temperature and precipitation within the area are -1.0 °C and 521 mm, respectively, with long-term averages of January and July being -14 °C and 14 °C (Pirinen et al., 2012). The maximum snow depth (average peak: 73 cm) is typically observed in late March; the median end date of snowmelt is May 14th and snow cover start date October 24th, respectively (Lohila et al., 2015). The soil type is podzol with glacial till as soil parent material (Aurela et al., 2015). Typical of the region and soil type, the site represents *Hylocomium-Myrtillus* type (HMT; Cajander, 1926; Ylläsjärvi and Kuuluvainen, 2009), *Picea abies* being the dominant tree species mixed with a variety of some deciduous trees such as *Betula pubescens*, *Populus tremula*, and *Salix caprea*. The forest floor vegetation at Kenttäröva consists primarily of forest shrubs, such as *Vaccinium myrtillus*, *Empetrum nigrum* and *Vaccinium vitis-idaea*, and a continuous and vigorous feather moss cover of *Pleurozium schreberi*, *Hylocomium splendens* and *Dicranum polysetum* with sporadic occurrences of lichens (Aurela et al., 2015). The dominant height of the uneven-aged (1–250 yr) tree stand reached approximately 15 m while the heights of individual spruce trees varied greatly. Some of the birches at Kenttäröva were logged for firewood in the 1960s but since then the forest has grown without human disturbances (Aurela et al., 2015).

2.2 Experimental setup

For examining causal relationships between CH₄ flux and soil moisture and temperature, the field study included two plots: irrigation (S_i) and control (S_c) without irrigation treatment (Fig. 1). The surface areas of S_c and S_i were approximately 280 m² and 120 m², respectively. Both plots included ten measurement points. Measurement points were assigned somewhat randomly in both plots, with the aim to represent as similar vegetational, topographical and sun aspect characteristics as possible. Both the S_c and S_i and measurement points were connected with wooden boardwalks to minimise soil and vegetation disturbance from trampling.

Soil moisture was manipulated by irrigating part of the experimental area with two water sprinklers. The irrigation periods were 28 May 2018–7 September 2018 and 6 June 2019–29 August 2019. The sprinklers were set in the plot so that the irrigated water would evenly reach each measurement point. The irrigated area in practice reached approximately 118 m² with 3–5.5 m width and 10–21 m length, depending on the wind conditions. Tap water was transported to the experimental site with a 1000 l IBC water tank. For ensuring a relatively even distribution of irrigated water in the plot, the spatial distribution of irrigation was checked with rain gauges (unit: mm) and plastic buckets. The amount of water in each bucket was later proportioned to

the rain gauges in mm based on their dimensions. The precipitated water was measured after each irrigation from the end of May 2018 to mid-June 2018, after which the precipitated water was measured only when the weather was notably windy and/or natural rainfall occurred during the irrigation. It was estimated that 1000 l irrigation resulted on average to 11 mm and 2000 l to 21 mm of precipitation. The amount of rainfall added with irrigation was 11 mm on two days per week during 28 May – 1 June 2018, after which the amount was increased to 11 mm on three days per week during 7–18 June 2018 and eventually to 21 mm on five days per week during 20 June 2018 – 7 September 2018. In 2019, the plot was irrigated with 11 mm three times per week throughout the summer.

2.3 CH₄ flux measurements and calculation

Chamber measurements started on 30 May 2017 on eight measurement points, of which four were located on S_i and S_c, respectively. The flux measurements in 2017 were made to check possible differences between the experimental plots before starting the irrigation experiment in 2018. Six additional points were added to both S_i and S_c, and the measurements from these points started on 29 May 2018. The measurements were made mainly between June-September every two weeks in 2017 and weekly in 2018 and 2019. The measurements ended on 19 September 2019.

CH₄ fluxes were measured with 5 min closure time on the forest floor by the closed-chamber system with an opaque rectangular chamber (60 x 60 x 20 cm, length x width x height). The chamber included a fan to mix the air inside the chamber and a vent tube to prevent pressure differences between the chamber headspace and the atmosphere. Also, chamber headspace temperature was recorded with HOBO Pendant Temperature Data Logger (Onset Computer Corporation, Bourne, MA, USA). The bottom of the chamber edges had a foam layer to prevent leakage between the collar and the chamber. All the measurement points had metal collars (58 x 58 x 30 cm, length x width x height) installed about 2 cm deep into the soil. CH₄ and water vapour (H₂O) mixing ratios were measured with G2301 (Picarro Inc., CA, USA) and G1301-m (Picarro Inc., CA, USA) before and after 28 June 2018, respectively. The gas analyser was located inside a cabin about 20 m away from the measurement point. The gas sample from inside the chamber was transported to the analyser by 20 m long tubing (inner diameter 3.1 mm, Bevaline IV) with a 1 l min⁻¹ flow rate where the mixing ratio was sampled every 3–4 seconds. The sampled gas was not returned to the chamber, which causes underpressure inside the chamber and underestimating the flux estimation. Because the chambers had a vent tube, we corrected the leakage with an assumption that the underpressure consisted of ambient air.

CH₄ fluxes were calculated as:

$$F = \left(\frac{dC(t)}{dt} \right)_{t=0} \frac{MPV}{RTA}, \quad (1)$$

where $\left(\frac{dC(t)}{dt} \right)_{t=0}$ is the concentration change over time from an exponential model (e.g. Korhonen et al., 2017) at the beginning of the closure, M is the molecular mass of CH₄ or N₂O (16.04 and 44.01 g mol⁻¹, respectively), P is air pressure, R is the universal gas constant (8.314 J mol⁻¹ K⁻¹), T is the mean chamber headspace temperature during the closure, and V is the air volume of the chamber and the collar, and A is the base area of the chamber or collar. The snow depth and the height of mosses and other vegetation in the chamber headspace volume were taken into account, ignoring the pore space in the soil and snow. The height of the vegetation was measured once a summer. The vegetation height was assumed to remain constant for that year.

When calculating the CH₄ balances, measured CH₄ fluxes were assumed to be daily mean fluxes. The gaps in the data were filled by linear interpolation. To avoid a biased 2019 balance estimate for point I1, the CH₄ emission peak observed on 27 June 2019 was ignored when calculating the balance.

5 The micrometeorological sign convention is used throughout the paper: a positive flux indicates a flux from the ecosystem to the atmosphere (net emission), and a negative flux indicates a flux from the atmosphere into the ecosystem (net uptake).

2.4 CH₄ production and oxidation potential measurements

10 Samples for the potential CH₄ production and oxidation were taken on 23 August 2018 and 26 August 2019. Six composite samples were collected from both S_i and S_c next to the chamber collars. Composite soil samples were combined from 3-5 core samples taken by soil auger separating four soil horizons: the organic layer without vegetation (O) and the three mineral soil layers below (zone of eluviation, i.e., leaching layer, E; zone of illuviation, i.e., enrichment layer, I; C-horizon representing the bottom layer, C). Samples were kept at 4 °C during the shipment into the lab and before analyses. The mean depths of the soil layers were 5.7 cm, 10.5 cm, 18.9 cm, and 32.3 cm, while the mean thicknesses were 5.7 cm, 4.8 cm, 8.4 cm, and 13.4 cm for O, E, I and C layers, respectively. The layer depths and thicknesses were determined from 6 spots inside the experimental area.

15 Soil moisture and organic matter contents of the samples were determined with TGA-analyser (LECO TGA-701, Leco Corporation, USA) with the standard method (ISO11465), which measures weight loss as a function of temperature in a controlled environment. Soil pH was determined from methane oxidation bottles after measurement by increasing the ratio of 1:3 of deionised H₂O and measuring them after 24 hours. Average soil pH, soil moisture and organic matter contents for the 2018 and 2019 samples are presented in Table S1. Total nutrients and C and N contents were determined from soil samples
20 taken in 2018 with standard methods (ISO11466, 10694, 13878). Samples for the total nutrients were digested by the closed wet HNO₃-HCl digestion method in a microwave (CEM MDS 2000), and the extract was analysed by iCAP 6500 DUO ICP-emission spectrometer (Thermo Scientific, UK). Total C and N were measured from sieved and air-dried samples on a CN analyser (Leco-TruMac, Leco Corp., St. Joseph, MI). Total nutrient, C and N contents for the year 2018 samples are shown in Table S2.

25 Fresh sieved soil (with 2 mm mesh size) was placed into 120 ml sterile incubation bottles with a standardised volume-based measuring scoop (20 ml). 10 ppm of CH₄ were added as a substrate into the bottles for determining potential CH₄ oxidation rates. Oxidation was measured by gas chromatograph (GC) for 24 hours. Two volumes of deionised H₂O were added into production potential bottles and incubated two times with pure N₂ gas to remove oxygen and create anoxic conditions. Production bottles were measured by GC first twice and then once a week for 42 days to detect productions. Potential rates
30 were calculated from the linear part of the curve showing the decrease or increase of CH₄ concentrations in time. The final potential rates are presented as nmol CH₄ g⁻¹ (dry mass of soil) d⁻¹.

2.5 Microcosm experiment

A microcosm experiment was designed to determine the conditions (temperature and moisture) that are needed to initialise the CH₄ production from the soil. For the experiment, soil profile samples were taken from the pit next to the S₁. Artificial soil profiles were constructed into the plastic jars (volume of 1.6 l), including the vegetation and organic layer and two mineral soils layers (leaching and enrichment layers). Half of the jar volume was left empty for headspace measurements. Jars were placed into two different growth chambers (Binder KBW, Germany) with two different temperatures at 15 °C and 25 °C. Both temperature conditions had three replicate jars, including controls without moisture increase (C) and two different levels of moisture increase, lower (M1) and higher (M2) moisture. The experiment also included separate triplicate jars with glucose added into controls (Cglu) and moisture increase (M1glu, M2glu) treatments. Glucose was added at the beginning of the measurements to simulate the effect of fresh, simple C source for microbes such as existing in root exudates. We added 14 ml of 1 M glucose solution into each jar so that they had two times more C that is approximated to be bound into microbial biomass in forest soils to see the possible effect. Two moisture conditions for the jars were adjusted to be different enough to detect changes between the treatments. Average final moisture conditions were adjusted so that in the jars, the lower moisture content (M1) was about 50 % and the higher content (M2) 80 % and the control jars (C) represented the average moisture content in the soil, which was about 30–35 % (Table 2).

Light conditions in the growth chambers were adjusted to mimic the natural light conditions at the end of August in northern Finland (about 15 hours light and 9 hours dark). Every week, the jars were switched from one growth chamber to another to avoid the differences due to features in the chamber itself. Moisture conditions were kept constant by weighing the jars twice a week and adding the water to minimise the effect of evaporation. CH₄ fluxes were measured from the headspace of the jars once a week with LI-7810 (LI-COR Biosciences, NE, USA). The fluxes for the five-week measurement period were calculated from the exponential model the same way described in Chapter 2.3.

2.6 Soil temperature and moisture measurements

Multiple soil temperature (ST) and moisture (SM) sensors were used to record said variables next to the CH₄ flux measurement points. ST was measured with 10 HOBO Pendant data loggers (Onset Computer Corporation, MA, USA) and SM with 9 EC5 Soil Moisture Smart Sensor (Onset Computer Corporation, MA, USA) with HOBO U30 USB Weather Station Data Logger (Onset Computer Corporation, MA, USA). In addition, 7 Soil Scout online sensors (Soil Scout Ltd, Helsinki, Finland) were used to measure both ST and SM. The time intervals for ST logging were 20 and 30 minutes for Soil Scouts and HOBO sensors, respectively. All the sensors were installed during 23 May – 6 June 2018 5 cm below the soil surface in the mineral soil layer next to the collar and covered carefully with soil. The measurements continued until the experiment ended, except the SM measurements made with EC5 sensors, which broke down at the beginning of June 2019. The locations of the installed sensors are listed in Table S3.

SM was also measured from two different locations about 10 m distance from the S_c and S_i . In both locations, SM was measured at 5 and 20 cm depths with ThetaProbe soil moisture sensor (Type ML2, Delta-T Devices Ltd, Cambridge, UK). In addition, ST was measured next to one of the soil moisture sensors at 5 cm depth (PT100, PT4T, Nokeval Oy, Nokia, Finland).

2.7 Statistical methods

5 Fluxes between the different moisture levels and glucose addition in the microcosm experiment were compared by using the one-way analysis of variance (ANOVA) by using `aov` command in R programming language (R Core Team, 2021, v4.0.5). The same method was used for comparing the CH_4 production and oxidation potentials between the plots and years. In the microcosm experiment, the glucose addition was compared only to the sample without added glucose on the same moisture level and temperature. The effect of three different moisture levels was compared separately for added glucose and without
10 added glucose groups by using Tukey's honestly significant difference (HSD) by 'multcomp' package in R (v1.4-14; Hothorn et al., 2008).

Linear mixed-effect model with Tukey's HSD post hoc test was used for testing the statistical significance of differences in CH_4 fluxes between the S_i and S_c . The linear mixed-effect model was carried out with the R programming language using 'lme4' package (Bates et al., 2015). The chamber points were treated as a random effect. The normality of the model residuals
15 was visually checked using the quantile-quantile plot (Q-Q plot) method.

The linear mixed-effect model was also used for finding the most significant variables affecting CH_4 fluxes (F_{CH_4}). The variables used in the modelling were: 5 cm soil temperature (ST) and moisture (SM), CH_4 oxidation potential ($OP_{CH_4, x}$, where x is one of O, E, I soil layers or the mean of all layers), CH_4 production potential ($PP_{CH_4, x}$, where x is one of O, E, I soil layers or the mean), and carbon and nitrogen content (CC_x or NC_x where x is one of O, E, I soil layers or the mean). The model runs
20 were divided into four parts: using mean values of all soil layers, using only values of a specific soil layer, combining values of multiple different soil layers. Even though SM and temperature were only measured at 5 cm depth, they were included in all the model runs. Measurement points were always treated as a random effect (u). The best model was selected by using stepwise selection. We started with a full model and reduced the number of variables one by one using the Akaike information criterion (AIC) as the criteria, which was conducted using the `drop1` function in R. The initial model in all but the combination
25 model run was:

$$F_{CH_4} = \beta_0 + \beta_1 ST + \beta_2 SM + \beta_3 PP_{CH_4, x} + \beta_4 OP_{CH_4, x} + \beta_5 CC_x + \beta_6 NC_x + \beta_7 (u + e)$$

where e is the model error, β_0 is the model's intercept, and parameters from β_1 to β_7 are the regression coefficients of the explaining variables. We used a 95 % confidence interval ($p < 0.05$) to determine whether the results were statistically significant.

Pearson correlation matrix including potential CH₄ production and oxidation rates and soil data (SM, organic matter, pH, nutrient elements) were created using commands `rcor` and `corplot` in R. Significance level for correlation coefficients between variables was $p = 0.01$. In addition, simple linear regressions at 95 % confidence level with Pearson's correlation coefficient and smoothed marginal histograms were used for primary correlation analyses between CH₄ flux and SM and CH₄ flux and ST using 'ggpubr' (v0.4.0; Kassambara, 2020) and 'cowplot' (v1.1.1; Wilke, 2020) packages in R.

2.8 Meteorological conditions

The mean air temperatures in the May-September period were 8.0, 11.0, and 8.9 °C for 2017-2019. Compared to the long-term (1981–2010; Pirinen et al., 2012) mean temperature of the same period (9.3 °C), 2017 was cooler and 2018 warmer than the average, respectively. In 2019, the monthly temperatures during the measurement period were close to long-term averages (Table S4). 2017 was the coolest year of the measurement period, primarily attributed to much cooler May and slightly cooler August than other years (Table S4). On the other hand, 2018 was the warmest year, primarily due to much warmer May and July. July 2018 was exceptionally warm (18.8 °C) compared to other years (2017: 13.0 °C, 2019: 12.6 °C) and long-term mean (13.9 °C).

The precipitation sums in the May-September period were higher than the long-term average (296 mm) in 2017 (335 mm) and 2019 (357 mm), but about the same in 2018 (293 mm). However, there were notable differences when inspecting monthly precipitation sums. In 2017, May, June and September were drier than in 2018 and 2019 (Table S4). On the other hand, in July 2017, the amount of precipitation (129 mm) was about 100 mm higher than in 2018 (28 mm) and 2019 (33 mm). Therefore, 2017 was markedly wetter compared to the long-term average in July (75 mm). On the other hand, 2018 and 2019 were markedly drier than on average. In 2019 excluding July, the monthly precipitation sums were very similar and higher than the long-term mean. The snow cover melted on 9 June 2017, 21 May 2018, and 26 May 2019. In 2017 and 2019, the first measurement day was made when snow was still on the ground (Fig. 2).

The meteorological data reported in this section was observed by an official weather station (Kittilä Kenttäröva; ID: 101987) maintained by Finnish Meteorological Institute and it was located about 80 m north-east from the experimental site.

Figure 2. Daily mean air temperature (a), daily mean 5 cm soil temperature (b), daily precipitation sum (c) and daily snow depth (d) measured at Kenttäröva weather station in May-September 2017-2019.

3 Results

5 3.1 Impact of irrigation on soil moisture and temperature

The growing seasons of the study years (2018 and 2019) were generally dry, based on the soil moisture data collected in long-term pits near the experimental area (Fig. 3). While in 2019, the whole growing season was dry, in 2018, the driest month was July. On the other hand, August was relatively wet in terms of precipitation (Table S4), but after a severe drought, the high precipitation was not enough to increase the soil moisture to the same range observed in 2017. There were large differences in SM profiles (located outside the experimental area) between the years (Fig. 3). In 2017, 5 cm soil moisture (SM_{5cm}) mainly remained between 25–35 v%. Also, SM_{5cm} in 2019 was relatively stable, varying within 15–20 v%, but it was markedly lower than in the other years, except in July 2018. SM_{5cm} in 2018 had much temporal variation. In May 2018, SM_{5cm} rose to 50 v% but fell quickly to 25 % after the snow had melted. In July 2018, the SM_{5cm} fell quickly below 15 v% and kept decreasing down to 12 % until the beginning of May 2019, after which it started recovering up to 25 % until the measurement period

ended in September 2019. In terms of absolute values, 20 cm soil moisture ($SM_{20\text{cm}}$) did not differ between years compared to $SM_{5\text{cm}}$. In June, August and September, the $SM_{20\text{cm}}$ did not usually differ more than 3 v% between the years. In May, the rapid increases and decreases in $SM_{20\text{cm}}$ associated with snowmelt occurred at different strengths and times. In July, $SM_{20\text{cm}}$ in 2017 was about 5 % higher than in the other years, but the first half of August 2019 was drier than the other years.

5 At the experimental area, $SM_{5\text{cm}}$ was on average 6.5 v% lower at the S_c than at the S_i in June-September 2018. $SM_{5\text{cm}}$ in 2018 varied typically within 14–23 v% and 6–14 v% at the S_i and S_c , respectively. However, one SM sensor measured about 10 % higher values than the other sensors at the S_c (Fig. 4). Also, at the beginning of August, $SM_{5\text{cm}}$ increased at one of the measurement points by 5 %. $SM_{5\text{cm}}$ remained on that higher level until the end of the measurement period in 2018. In 2019, $SM_{5\text{cm}}$ at the S_i remained within 15–18 %, except in August and September.

10 In 2018, irrigation was performed on weekdays and during irrigation $SM_{5\text{cm}}$ rose by 10–15 v% (Fig. 4). However, the $SM_{5\text{cm}}$ decreased fast and usually returned to the pre-irrigation level before the next irrigation 24 hours later (Fig. 4). In 2019, the rise of 5 cm $SM_{5\text{cm}}$ due to irrigation was usually between 2–5 %.

5 cm daily mean soil temperatures ($ST_{5\text{cm}}$) were on average 0.7 °C higher at the S_i compared to the S_c in June-September 2018 (Fig. 5). Also, spatial variation was higher at the S_c (Fig. 5). The biggest difference in daily mean $ST_{5\text{cm}}$ between the plots was observed around mid-July 2018 when the $ST_{5\text{cm}}$ at the S_i was on average 2.0 °C higher than at the S_c . However, in 2019, the difference in daily mean $ST_{5\text{cm}}$ between the plots was small, and the S_i was only about 0.2 °C warmer on average than the S_c . Also, the maximum difference between the plots was about 0.6 °C, which occurred at the end of July and August.

Figure 3. The daily mean 5 (a) and 20 (b) cm soil moisture time series measured from two different locations outside the experimental area from May to October in 2017 (solid grey), 2018 (solid black) and 2019 (dashed black).

Figure 4. Hourly mean soil moisture time series measured at control (grey) and irrigation (black) plots in August 2018. Blue vertical lines show the times when the irrigation plot was irrigated.

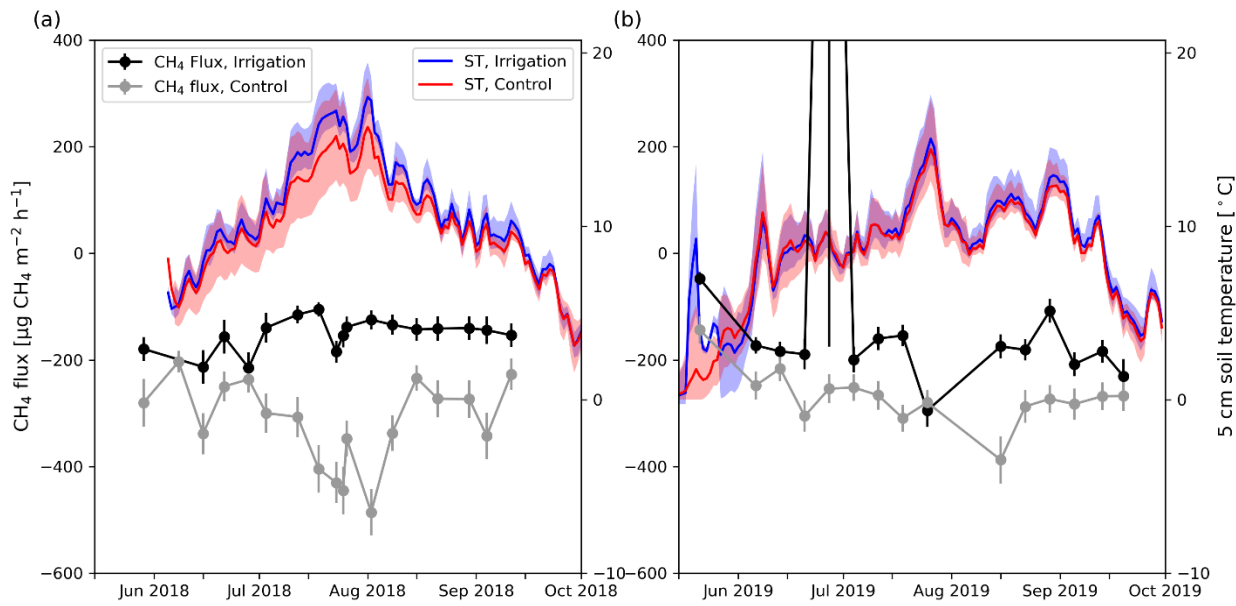

Figure 5. Daily mean CH₄ flux measured at the irrigated (black) and control (grey) plots in 2018 (a) and 2019 (b). The error bars show the standard error of the mean. Blue (irrigated) and red (control) lines represent daily mean 5 cm soil temperature (ST) and shading shows the minimum and maximum daily values measured by different sensors (irrigation: n=7, control: n=9).

5 3.2 The effect of irrigation on CH₄ uptake

Before the irrigation experiment started, all the measured CH₄ fluxes were negative, indicating CH₄ uptake, and did not differ significantly between S_c and S_i. In 2017, the fluxes were measured from four points at each plot and median fluxes (S_c: -220 µg CH₄ m⁻² h⁻¹, S_i: -230 µg CH₄ m⁻² h⁻¹) and mean June-September CH₄ balances were similar between the plots (Fig. 6). However, there was notable spatial variation between the points as the June-September CH₄ balances varied between -950 and -470 mg CH₄ m⁻²).

In 2018 and 2019, when irrigation started, the fluxes measured at the S_i and S_c differed significantly from each other in terms of points where measurements started already in 2017 (I2, I3, I4, I9, C1, C4, C6, C8; 2018: $p < 0.001$, 2019: $p = 0.01$). The mean summertime CH₄ uptake rates of these points in 2018 were 37 % larger and 15 % smaller than in 2017 at S_c and S_i, respectively (Fig. 6; Table S5). In 2019, the mean June-September balances (S_c: -940±120 mg CH₄ m⁻², S_i: -660±70 mg CH₄ m⁻²; Fig. 6; Table S5) remained at about the same level as in 2018 and the fluxes did not differ significantly from fluxes measured in 2018.

The median measured CH₄ uptake rate (Fig. 6; Table S5) across all the measurement points at the S_i (150 µg CH₄ m⁻² h⁻¹) was 48 % lower than at the S_c (290 µg CH₄ m⁻² h⁻¹) in 2018 and 35 % lower in 2019 (S_i: 170 µg CH₄ m⁻² h⁻¹, S_c: 260 µg CH₄ m⁻² h⁻¹).

1). The fluxes differed significantly between the plots in both years ($p < 0.001$). All but one of the measured fluxes were negative, indicating CH_4 uptake. One large CH_4 emission pulse ($18200 \mu\text{g CH}_4 \text{ m}^{-2} \text{ h}^{-1}$) was observed in point I1 on June 27th 2019. Similar differences were also observed in mean four-month (June – September) CH_4 balances (Table S5). There was lots of variation in fluxes between the measurement points. CH_4 balances varied from $-1280 \text{ mg CH}_4 \text{ m}^{-2}$ to $-480 \text{ mg CH}_4 \text{ m}^{-2}$ at the S_c and from $-740 \text{ mg CH}_4 \text{ m}^{-2}$ to $-180 \text{ mg CH}_4 \text{ m}^{-2}$ at the S_i in 2018. Some of the measurement points at the S_i had higher CH_4 uptake rates than some points located at the S_c , but on average CH_4 uptake rates were noticeably larger at the S_c ($-850 \pm 80 \text{ mg CH}_4 \text{ m}^{-2}$) than at the S_i ($-450 \pm 60 \text{ mg CH}_4 \text{ m}^{-2}$). In 2019, CH_4 uptake rates increased in most of the points at the S_i , averaging at $-570 \pm 60 \text{ mg CH}_4 \text{ m}^{-2}$, but the balances remained mostly the same at the S_c (mean: $-830 \pm 70 \text{ mg CH}_4 \text{ m}^{-2}$).

10

Figure 6. CH_4 fluxes measured by long-term (C1, C4, C6, C8, I2, I3, I4, I9) (a) and all (b) chamber points in May-September in different years. Positive flux values indicate net emission and negative values indicate net uptake. For comparison, the flux of the points located on the irrigated plot in 2018 and 2019 have been calculated already for 2017, even though the irrigation setup was established only in 2018. The boxes show the quartiles of the dataset and the horizontal line inside the boxes is the median flux. Whiskers show the range of the data, except for the points that are determined to be outliers, which are shown with black diamonds.

15

3.3 CH₄ production and oxidation potentials

Oxidation potential rates were quite similar in all soil layers, except for C-layer where the rates were lower. Between the years, however, the rates differed as those in 2019 were generally higher and more variable than in 2018 (Fig. 7ab). The most notable increase was detected in the organic layer, where the oxidation potential rates were mainly non-existent in 2018, but about 15 nmol CH₄ g⁻¹ d⁻¹ in 2019 at both S_i and S_c. However, the change was significant only at the S_i ($p = 0.03$). Oxidation rates were significantly ($p = 0.03$) higher in 2019 (median: 22 nmol CH₄ g⁻¹ d⁻¹) than in 2018 (median: 15 nmol CH₄ g⁻¹ d⁻¹) also in I layer at the S_c, but there was no significant difference in the same layer at the S_i. There were no statistically significant differences between the years in any other soil layers at either plot. Comparing the soil layers between the plots revealed that the oxidation rates were significantly higher ($p = 0.01$) in the C layer at the S_c than in S_i in 2018. The rates were significantly higher ($p < 0.01$) at the S_c in I layer in 2019, but there were no other significant differences between the plots in other soil layers.

The highest CH₄ production potential rates occurred in O layer and some production potential was observed in E layer, while in the lowest soil layers, the production rates were negligible (Fig. 7cd). At the S_i, the production potential rates were significantly lower in 2019 than in 2018 in O ($p = 0.04$) and I ($p = 0.001$) layers. At the S_c, the production rates differed significantly ($p < 0.02$) only in the C layer, but the rates were negligible in both years. Comparing the production rates between the plots revealed that the rates were significantly ($p < 0.04$) higher in O layer at the S_c in 2019. A significant difference ($p < 0.01$) between the plots was also found in the C layer in 2018.

Potential CH₄ production rates in 2018 had strong positive Pearson correlation coefficients (ρ) with organic matter content ($\rho = 0.94$), moisture contents ($\rho = 0.90$), total N and C amounts ($\rho = 0.95$ and 0.94 , respectively) determined from the soil samples (Fig. S1a). Potential CH₄ production rates in 2019 had a similar stronger positive correlation with organic matter ($\rho = 0.96$) and moisture contents ($\rho = 0.93$; Fig. S1b).

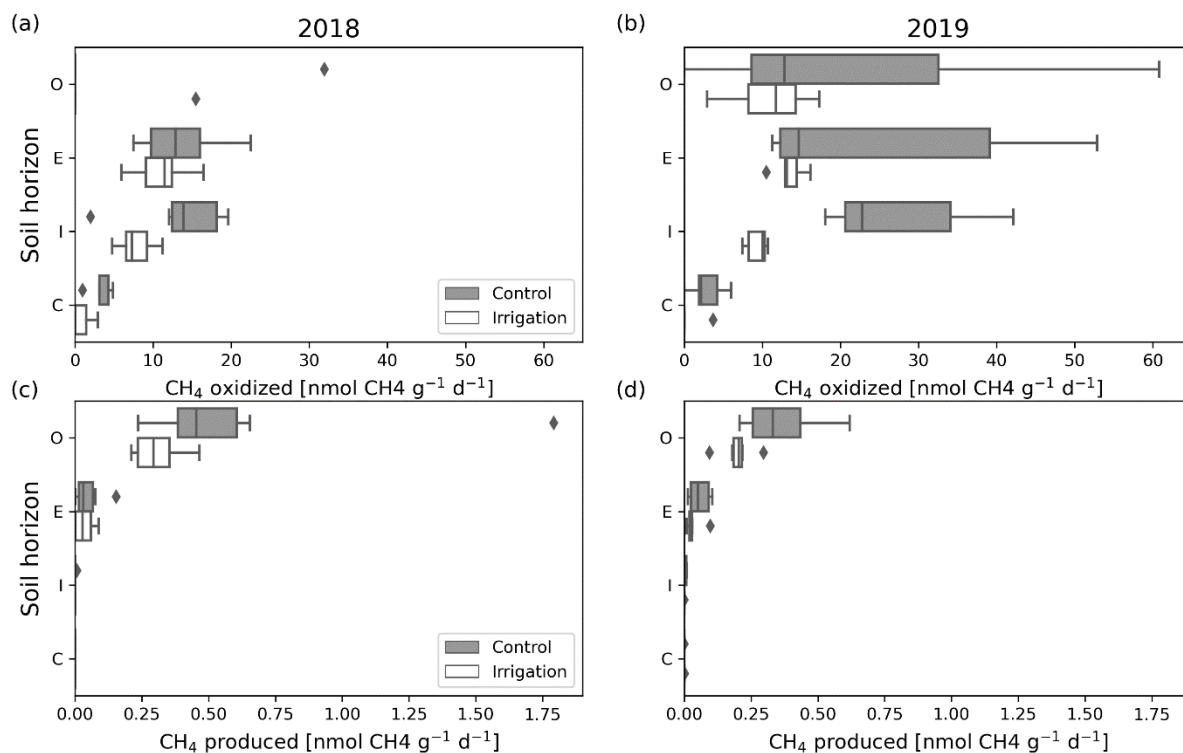

Figure 7. CH₄ oxidation (a, b) and production (c, d) potentials in different podzolic soil layers (organic layer, O, mean depth: 5.7 cm; leaching layer, E, mean depth: 10.5 cm; enrichment layer, I, mean depth: 18.9 cm; bottom layer, C, mean depth: 32.3 cm) in 2018 (a, c) and 2019 (b, d) (n=9). The boxes show the quartiles of the dataset and the vertical line inside the boxes is the median flux. Whiskers show the range of the data, except for the data that are determined to be outliers, which are shown with black diamonds.

3.4 Factors controlling field CH₄ fluxes

Correlations between field CH₄ flux and SM were nearly negligible ($\rho < 0.2$) in both S_i and S_c in both years (Fig. 8), with the exception of S_i in 2019 with an ρ value of -0.5 ($p < 0.001$). In both 2018 and 2019, correlation trends were weakly negative between CH₄ flux and SM, except for S_c in 2018 with a weak positive correlation ($\rho = 0.17$, $p = 0.07$). In contrast, CH₄ flux and ST had generally stronger correlations in both S_i and S_c, the latter having the highest ρ values in both years (2018: $\rho = -0.57$; 2019: $\rho = -0.49$), only 2018, however, being statistically significant ($p < 0.001$). S_i showed differing correlation trends between years, 2018 having relatively weak positive ($\rho = 0.4$, $p = 0.01$) and 2019 almost negligible negative correlations ($\rho = -0.19$, $p = 0.16$).

Several mixed-effect model runs were made to investigate the environmental drivers behind CH₄ fluxes. SM_{5cm} and ST_{5cm} were among the significant variables explaining CH₄ fluxes in all the model runs. The rest of the significant drivers varied depending on the soil layer. In the organic layer, the most significant model, in addition to SM_{5cm} and ST_{5cm}, included oxidation potential and nitrogen content. The model explained 51 % of the variation in CH₄ fluxes (Table 1). The significant drivers were otherwise similar to O layer in E layer, except nitrogen content was replaced by carbon. However, the model had weaker explanative power ($r_{fix}^2 = 0.44$) than the O layer model ($r_{fix}^2 = 0.51$). It should be noted that carbon and nitrogen contents had strong cross-correlation, and using either of them in the model would have given almost the same result. The I layer model had the weakest model explaining CH₄ fluxes ($r_{fix}^2 = 0.42$), and the significant drivers included only SM_{5cm} and ST_{5cm} and the carbon content in the I layer. Using the drivers' mean values over all soil layers also resulted in a relatively weak model ($r_{fix}^2 = 0.44$), and it included only oxidation potential and SM_{5cm} and ST_{5cm}. Finally, a model combining drivers from multiple depths was made, and it explained the CH₄ flux the best ($r_{fix}^2 = 0.65$). In that model, CH₄ flux was most influenced by SM_{5cm} and ST_{5cm}, oxidation potential in the organic layer, production potentials in the organic and E layer, and carbon content in the E layer (Table 1).

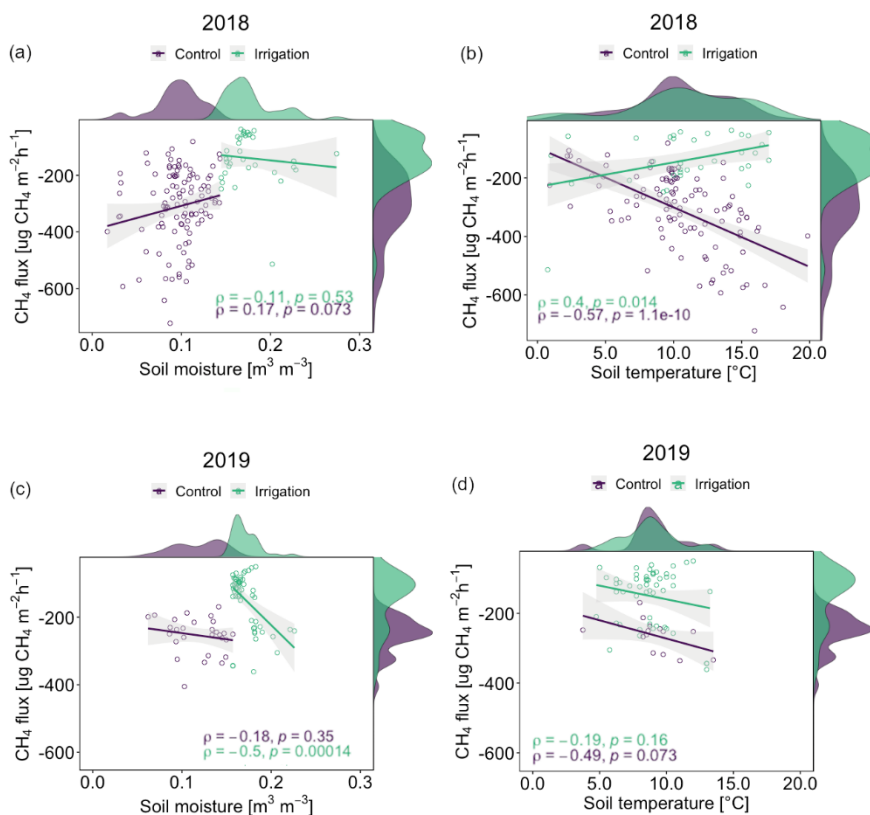

Figure 8. Correlations (Pearson's coefficient, ρ) between soil moisture and CH₄ flux (a, c) and soil temperature and CH₄ flux (b, d) with smoothed frequency histograms in 2018 and 2019. The emission case of 27 June 2019 was removed from the data in the correlation analyses for more clear presentation.

5 Table 1. Linear mixed-effect models fitted against CH₄ fluxes (F_{CH_4}) and experimental factors. The fixed effects in the model were: SM – 5 cm soil moisture; ST – 5 cm soil temperature; $OP_{CH_4, x}$ - CH₄ oxidation potential at soil layer x (O, E, I soil layers or the mean of all layers), $PP_{CH_4, x}$ - CH₄ production potential at soil layer x, CC_x - carbon content at soil layer x, and NC_x - nitrogen content at soil layer x. The table shows the r^2 of the fixed effects (r_{fix}^2) and the whole model (fixed effects + random effects, r_{mod}^2), p-value of the model (p), AIC of the model and the degrees of freedom (df). The models in bold are the best-fitted models.

3.5 Microcosm experiment

15 Adding glucose to the sample and keeping the moisture level similar did not cause significant changes in the potential CH₄ uptake rate, but on average, CH₄ uptake rate was lower or the CH₄ emission was higher with added glucose on the same moisture level (Fig. 9). There was an exception to this case at high 25 °C temperature and moderate moisture (M1), where the added glucose samples had a higher CH₄ uptake rate, but as said above, these were not statistically significant differences.

Generally, increasing soil moisture with no added glucose decreased the mean potential CH₄ uptake rate, but even with the high SM (M2) group, the soil did not turn into a CH₄ source (Fig. 9). Also, the differences between the different moisture

groups were generally not statistically significant. Significant differences were only observed between the M2 and the control group in the first two weeks of measurements. The weekly mean CH₄ uptake rates also decreased further in time in all groups, except in the M2 group, where the changes in time were negligible.

5 In samples with added glucose, increasing SM significantly ($p < 0.05$) decreased potential CH₄ uptake rate in both M1 and M2 groups compared to the control group. On the other hand, M1 and M2 groups did not differ significantly, except in week two at 25 °C temperature. In that case, relatively high CH₄ emission was measured in the M2 group with added glucose, but emission dropped rapidly already in the third week, although it remained a small CH₄ source (Fig. 8). At 15 °C temperature, there was no such CH₄ emission peak in the M2 group.

10

Figure 9. Weekly mean CH₄ flux measured at 15 °C (a) and 25 °C (b) without (solid lines) and with (dashed lines) added glucose on different moisture levels (black: control, green: low added moisture, blue: high added moisture). The error bars show the standard error of the mean (n=3). Positive flux values indicate net emission and negative values indicate net uptake.

4 Discussion

In this study, our initial aim was to mimic a wet growing season in a boreal upland forest with podzol soil in Northern Finland by irrigating the area regularly and studying the conditions needed to switch the forest floor to a CH₄ source. Earlier, we discovered that the soil of the same site turned into a CH₄ source in August after long-lasting rains during the growing season of 2011 (Lohila et al. 2016). Therefore, we assumed that we could reach the conditions needed to initiate the CH₄ production in the podzolic soil by at least tripling the long-term mean precipitation. However, the two study summers of 2018 and 2019 turned out to be the driest summers of the decade, with a long warm and dry period in June-July 2018 and generally dry summer in 2019. Unfortunately, due to the remote location of the experimental site and a distance of several kilometres to the closest water tap, we were not able to counter the effect of the droughts. As a result, our control plot could be considered a drought experiment, while the irrigated plot followed the moisture and CH₄ flux patterns of a “normal” summer. Therefore, it is recommended that similar studies in the future, the experiment is set in a location where the irrigation system is able to distribute higher amounts of water and with higher frequency than what was practically possible in this study. In the Lohila et al. (2016) study, we also speculated that the reason for the CH₄ emission occurring in August and not in spring after the snowmelt could be that fresh carbon substrates consumed by soil microbes are needed to make the soil anoxic, i.e. the wet soil alone is not enough to make the CH₄ production to initiate. To confirm this hypothesis, we conducted a laboratory mesocosm experiment in which the temperature and moisture responses were studied, and glucose was added to some of the samples to mimic the root exudation providing fresh carbon substrates to the soil microbes.

We found that the field CH₄ uptake at the control plot was higher during the study years than a more typical summer of 2017. This comparison was possible since some of our study plots were established already a year before the experiment. On the other hand, the irrigated plot showed similar uptake rates during the previous summer, which was close to normal in terms of temperature and precipitation. The same pattern was observed for the soil moisture: the soil was as moist in the irrigated plot in 2018 and 2019 as it was without irrigation in 2017. One single occasion when clear CH₄ emission was detected took place in the irrigated plot at the end of June 2019, but the emission was only observed in one of the irrigated plots. The mean emission rate during that day from the irrigated plots was 1670 µg CH₄ m⁻² h⁻¹ (data not shown, the point removed from Fig. 5b). Although encouraging, the observation unfortunately did not provide means to systematically study the conditions needed to switch the soil into a CH₄ source, since the soil moisture or any other variable at the same measurement point did not differ from the other points.

The laboratory experiments for studying the possible differences in the CH₄ production and oxidation potentials indicated no significant differences between the control and irrigated soils. Initially, we hypothesised that the wet conditions prevailing for one or two summers could be seen in the response of microbial populations so that at the irrigated plot the oxidation would be smaller and the production higher either after both summers or at least after the second wet summer. Unfortunately, the dry summers turned the whole setup around so that we ended up examining the effect of dry growing seasons on the response of

microbial populations. Hence, our results suggest that the period of one or two dry summers did not impact soil production or oxidation potentials, although we found differences in the actual CH₄ uptake between the irrigated and control plots. Therefore, it seems likely that the differences in observed field fluxes were due to the impact of soil moisture on the gas diffusion rate: the drier the soil, the higher the air-filled porosity and the quicker the diffusion of oxygen and CH₄ into the soils, and the higher the CH₄ uptake rates (Dörr et al., 1993; Van Den Pol-van Dasselaar et al., 1998; Striegl, 1993).

We also hypothesised that the oxidation potentials would be highest in the topsoil, which is closest to the main source of the substrate for oxidation, namely atmospheric CH₄ (Bradford et al., 2001), while the production potentials would be higher deeper in the soil, where the oxygen is more likely to be depleted periodically after wet conditions when diffusion rates are suppressed. The oxidation potentials indeed peaked in the topsoil, but interestingly, so did the production potentials, showing clearly the highest rates in the organic/humus layers (Fig. 7).

Our findings are parallel with the previous ones from forest soils since the highest CH₄ oxidation has been detected both in the uppermost mineral soil below the organic layer (Saari et al., 1998) and, on the other hand in the organic layer (Wang and Ineson, 2003). Thus, the distribution of CH₄ consuming organisms in the upland soil horizon seems to vary somewhat depending on the year and prevailing physical and chemical conditions. High potential CH₄ productions in the surface layers in 2018 and 2019 (Fig. 7) are most likely linked to higher soil organic matter and moisture content of soils, which is also supported by a strong positive correlation with the soil organic matter and moisture content. Potential CH₄ oxidation did not show a strong correlation with these. Similar results obtained from upland soils and especially from forest soils are hard to find. However, high organic C content has simulated CH₄ production under hypoxia in agricultural soil (Brzezińska et al., 2012), and water content was observed as a major influencing factor regarding CH₄ production potential in subalpine upland soil (Praeg et al., 2014). Thus, over two times higher moisture content and about ten times higher organic matter content in the organic layer compared to mineral layers below most likely explain partly the higher CH₄ production potentials observed in this study.

The mesocosm experiment provided interesting insights into the CH₄ dynamics of the podzolic soil. First of all, this experiment confirmed the result of field fluxes by showing that the CH₄ uptake decreased along with higher soil moisture. Also, CH₄ uptake was totally ceased in the high soil moisture treatment (M2) due to suppression of diffusion rates in waterlogged conditions. The higher temperature increased the net uptake, most likely by increasing the oxidation, but this was true only for the mesocosms with “field conditions” (no water added). In other words, CH₄ uptake was higher in warmer soils but smaller in wetter soils (as expected), so it seemed that increasing either the temperature or the soil moisture, or both, affect the CH₄ oxidation straightforwardly but is not able to induce CH₄ production in the soil. However, only if the soils were made wet enough and glucose was added, significant CH₄ production was initiated, which was further increased by higher temperatures. Thus, the results obtained here supported our hypothesis that both excess moisture and easily decomposable carbon are needed to initiate CH₄ production in podzolic soil. Indeed, the root exudate analogues containing simple sugars accelerated CH₄

production in tropical peat soil (Girkin et al., 2018). However, in a study conducted in Japanese upland soil, added glucose was rapidly decomposed within seven days of the incubation, and part of the glucose-derived C flow ended up to methanogens even under unflooded conditions (Watanabe et al., 2011). Even though it is largely known that methanogens can survive and tolerate dry and oxic conditions for some periods, they become active only when the conditions turn favourable for CH₄ production (i.e., wet and anoxic). Since methanogenic archaea cannot use glucose directly as C source, methanogens probably utilised acetate or CO₂ produced by the glucose-decomposing bacteria. Thus, the obtained results from the microcosm experiment may reflect the situation that in wet conditions, glucose has increased the activity of microbial communities that supply methanogenic substrates (hydrogen-producing bacteria or acetyl-producing bacteria), promoting the activity of methanogens production as was detected in a forested wetland (Koh et al., 2009). Simultaneously decreased activity of CH₄ oxidisers may have been followed by the competition of other aerobic microorganisms, which have metabolised glucose rapidly, creating more anaerobic conditions favouring CH₄ production. However, the comparison of the obtained results with earlier findings is rather obscure since similar experiments conducted in boreal forest soil do not exist. Thus our results are one of the first attempts to understand the complex conditions which initiate CH₄ production. In addition, our study is unique since we are presenting both CH₄ fluxes and laboratory CH₄ potentials from the soil taken from the same field points.

15 **5 Conclusions**

Based on our field and laboratory experiments, the main conclusion is that CH₄ production from boreal upland forest soil cannot occur solely by prolonged wet conditions, but there also has to be enough fresh carbon in the soil. Therefore, we expect the possible CH₄ production episodes to occur in late summer and autumn rather than in spring, even though the soil can be very wet after snowmelt. These findings can be applied in CH₄ process models to improve estimations of regional and global upland forest CH₄ balances.

We did not observe any changes in CH₄ production and oxidation potentials due to irrigation over two summers, meaning microbial communities were not very sensitive to environmental variables. This suggests that the measured field fluxes are rather controlled by the physical soil conditions by limiting gas diffusion rates and not by the changes due to microbial function. One conclusion from our results is that CH₄ production and oxidation are controlled by different driving variables and processes: the oxidation is boosted when the conditions for higher gaseous diffusion are optimal (dry soil), while the production is boosted only if anoxic conditions are created (wet soil reducing diffusion + microbial activity consuming oxygen) and there are fresh organic substrates available for CH₄ production. In our field experiment, CH₄ production episodes were not detected (with one exception), and the changes in net field CH₄ flux were solely caused by the changes in CH₄ oxidation. The net CH₄ flux (here total oxidation) was primarily controlled by soil temperature and soil moisture. Increasing soil temperature enhanced oxidation and gas diffusion, and increasing soil moisture limited oxidation by making conditions for methanotrophs unfavourable and diminished diffusion. We also found that upland forest soils have the potential to produce CH₄, but contrary

to wetlands, the potential is highest near the soil surface and decreases rapidly as a function of soil depth. This could happen because the conditions for methanogenic archaea are more favourable in the topsoil layer due to the higher amount of organic matter.

5 Our study confirms that soil moisture is a critical variable in explaining the soil CH₄ uptake rate and suggests that the diffusion rate of both CH₄ and oxygen into the soil is the primary constraint of oxidation. For the onset of CH₄ production in podzolic soil, not only high soil moisture but also the addition of sugar, mimicking root exudates from trees, was needed. Glucose impacts CH₄ production mainly by boosting the consumption of oxygen in the soil and providing substrates for CH₄ production. We also found that the highest potential production and oxidation rates were found in the same topsoil layers, suggesting that the surface soil plays the main role in the soil-atmosphere exchange of CH₄ in boreal upland forest

10 **Data availability**

The flux, meteorological and soil data are available at Zenodo (<https://doi.org/10.5281/zenodo.5153347>, Korhonen et al., 2021)

Author contribution

15 AL, TP and KP designed the study. MK, AL, TP and TM constructed the experimental site. KP took the soil samples and calculated methane production and oxidation potentials and did the laboratory work for the microcosm experiment. TM made the flux measurements and took part in the data analysis. MK calculated the fluxes for the field and microcosm experiments and did the statistical analysis. MK prepared the manuscript with contributions from all co-authors.

Competing interests
