The fossil record of marine microplankton provides insights into the evolutionary drivers which led to the origin of modern deep-water plankton, one of the largest component of ocean biomass. We use global abundance and biogeographic data combined with depth habitat reconstructions to determine the environmental mechanisms behind speciation in two groups of pelagic microfossils over the past 15 million years. We compare our microfossil datasets with water column profiles simulated in an Earth System model. We show that deep-living planktonic foraminiferal (zooplankton) and calcareous nannofossil (mixotroph phytoplankton) species were virtually absent globally during the peak of the middle Miocene warmth. Evolution of deep-dwelling planktonic foraminifera started from subpolar-midlatitude species during late Miocene cooling, via allopatry. Deep-dwelling species subsequently spread towards lower latitudes and further diversified via depth sympatry, establishing modern communities stratified hundreds of meters down the water column. Similarly, sub-euphotic zone specialist calcareous nannofossils become a major component of tropical and sub-tropical assemblages during the latest Miocene to early Pliocene. Our model simulations suggest that increased organic matter and oxygen availability for

27 planktonic foraminifera, and increased nutrients and light penetration for nanoplankton, favored
28 the evolution of new deep water niches. These conditions resulted from global cooling and the
29 associated increase in the efficiency of the biological pump over the last 15 million years.

30 **1. Introduction**

31 The biodiversity of planktonic and nektonic organisms is difficult to explain given the uniform
32 character and vastness of pelagic environments, where genetic isolation seems difficult to maintain
33 (Norris, 2000). Planktonic microorganisms with mineralized shells have often been used as a
34 model to study the mode and tempo of species origination in the open ocean, due to the abundance,
35 widespread distribution, and temporal continuity of their fossil record (e.g., Pearson et al., 1997;
36 Norris, 2000; Bown et al., 2004; Ezard et al., 2011; Norris et al., 2013). Because of the great
37 fossilization potential of their calcium carbonate tests across much of the global ocean, their
38 relatively simple and well-established taxonomy, and highly resolved biostratigraphy, planktonic
39 foraminifera and calcareous nanofossils are amongst the most thoroughly studied . Planktonic
40 foraminifera are heterotrophic zooplankton, with different species specialized to feed on different
41 types of food, from other plankton to sinking detritus. In the modern ocean, planktonic
42 foraminifera live stratified across a range of depths spanning from the surface to hundreds of
43 meters down the water column (Rebotim et al., 2017; Meilland et al., 2019). Properties such as
44 food quantity and quality, oxygen, light and pressure all change markedly across the first few
45 hundreds of meters of the ocean. Depending on such down-column variability in environmental
46 conditions, planktonic foraminifera can actively control their living depth of preference, which
47 remains relatively stable during their adult life-stage (Hull et al., 2011; Weiner et al., 2012;
48 Rebotim et al., 2017; Meilland et al., 2019; Duan et al., 2021). A key advantage of using planktonic
49 foraminifera for evolutionary studies is the ability to extract ecological information from their shell

50 chemistry. This provides invaluable information about species-specific functional ecology (e.g.,
51 feeding strategy) and habitat preferences (e.g., surface versus deep waters), which in combination
52 with biogeographic, taxonomic, biometric, and stratigraphic data have often been used to infer
53 speciation and extinction mechanisms (Norris et al., 1993; Norris et al., 1994; Pearson et al., 1997;
54 Hull and Norris, 2009; Pearson and Coxall, 2012; Woodhouse et al., 2021) and reconstruct
55 phylogenetic relationships (Aze et al., 2011).

56 Calcareous nannoplankton also have a highly resolved and continuous fossil record; they are
57 the most abundant microfossils in oceanic pelagic sediments, and similar to planktonic
58 foraminifera, their spatial distribution ranges from tropical to subpolar latitudes (Poulton et al.
59 2017). In the modern ocean they also live stratified in the water column, with species adapted to
60 euphotic waters, and species adapted to live deeper (Poulton et al., 2017). In contrast to planktonic
61 foraminifera, nannoplankton are predominantly autotrophic, performing photosynthesis in water
62 where light penetration is sufficient, although there is evidence for heterotrophy (mixotrophic
63 behavior) in some extant (Godrjian et al., 2020) and fossil (Gibbs et al., 2020) species. In euphotic
64 waters, organic matter production from nannoplankton is at the base of pelagic food chains and of
65 the functioning of the ocean biological carbon pump. Taxonomic, biometric and stratigraphic data
66 have been used to establish phylogenetic relationships between fossil nannoplankton species
67 (Young and Bown, 1997).

68 Little emphasis has been given to the long-term drivers of evolutionary patterns observed in
69 fossil plankton from species to phylum level, although more recently, a broad connection with
70 changing climate and ocean properties has been suggested (e.g., Ezard et al., 2011; Norris et al.,
71 2013; Frass et al., 2015; Henderiks et al., 2020; Lowery et al., 2020). Boscolo-Galazzo, Crichton
72 et al. (2021) showed that over the last 15 million years the remineralization of particulate organic

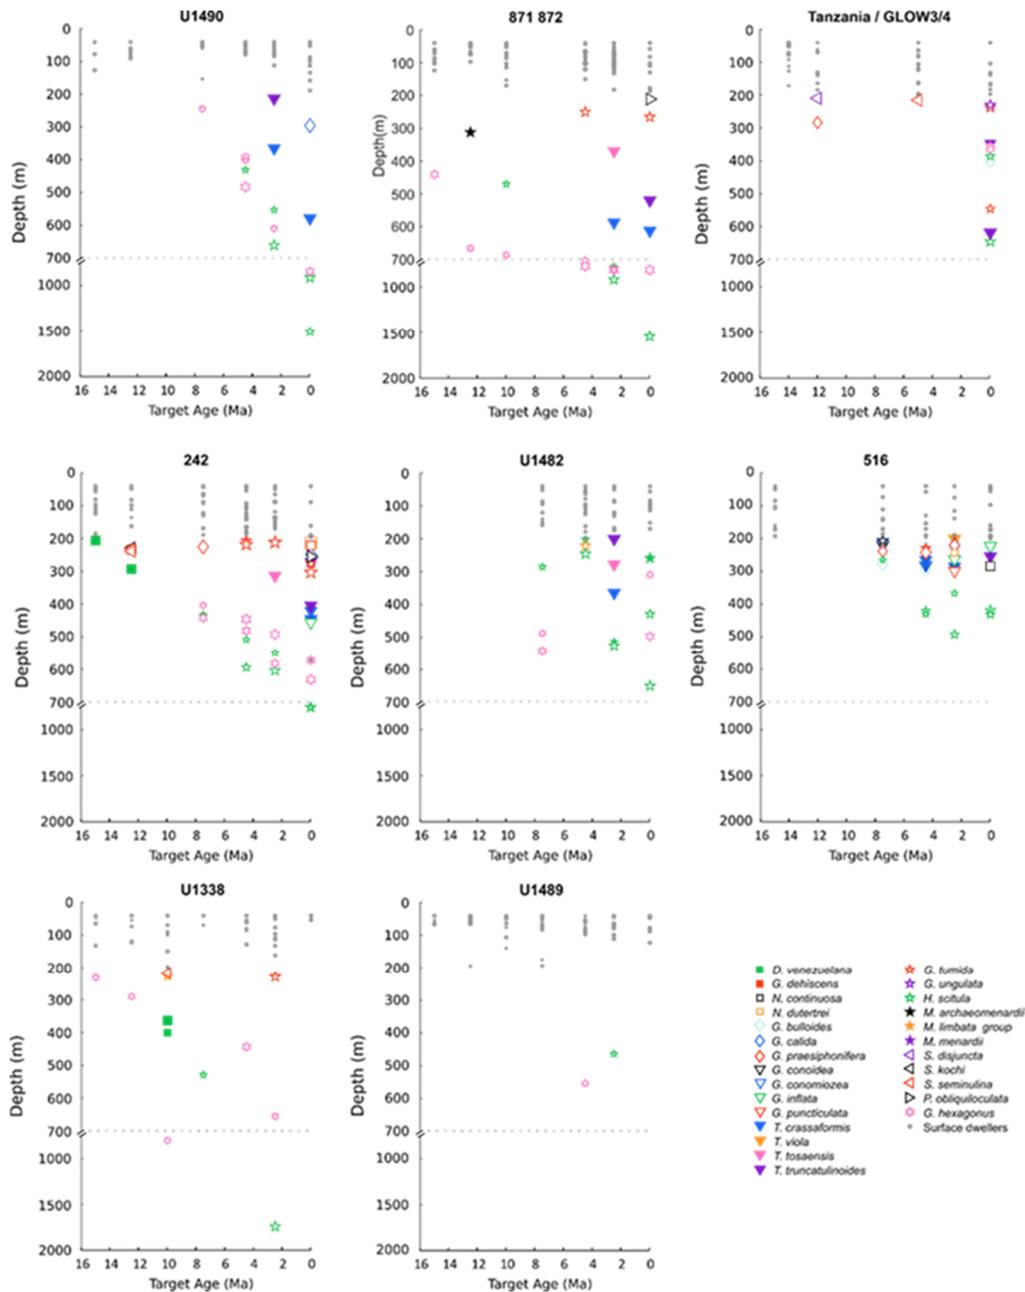

73 carbon (POC) in surface waters declined markedly driven by climate and ocean cooling (Kennett
74 and Von der Borch, 1985; Kennett and Exon, 2004; Cramer et al., 2011; Zhang et al., 2014; Herbert
75 et al., 2016; Sosdian et al., 2018; Super et al., 2020), increasing the efficiency of the ocean
76 biological pump in delivering organic matter at depth. Such a mechanism was key to promote the
77 evolution of life in deep waters, allowing the development of the modern twilight zone ecosystem
78 (Boscolo-Galazzo, Crichton et al., 2021). The goal of this study is to combine the fossil record of
79 two ecologically complementary calcareous microplankton groups seldom analyzed together,
80 planktonic foraminifera and nannoplankton, and together with model simulations, help disentangle
81 the evolutionary drivers of modern deep-dwelling plankton. We use the planktonic foraminiferal
82 dataset from Boscolo-Galazzo, Crichton et al. (2021) and extend our analysis to calcareous
83 nannofossils in coeval sediment samples to assess their abundance and distribution pattern. We
84 compare the results from these two groups and contrast them against time and site-specific model
85 water column profiles for POC and oxygen (O₂) obtained from the cGENIE Earth System model.
86 Further, using stable isotopes, depth habitat reconstructions, abundance and biogeography data we
87 reconstruct the speciation mechanisms which led to the evolution of modern deep-dwelling
88 planktonic foraminiferal species.

89

90 **2. Methods**

91 **2.1 Planktonic foraminifera**

92 In this study we focus on the deep-dwelling groups of macroperforate planktonic foraminifera
93 of the hirsutellids, globorotaliids, truncorotaliids and globoconellids, which in the modern ocean
94 calcify and live mostly in the twilight zone of the ocean, i.e. between 200-1000 m (Birch et al.,

95

96 **Figure 1.** Depth-habitat reconstructions for middle Miocene to present planktonic foraminiferal

97 species at the investigated sites. Surface dwellers (species living at depths shallower than 200 m)

98 are indicated with a grey dot, deeper species are indicated with colored symbols. Relative size of

99 symbols represents the size fractions of the sample. Reproduced from Boscolo-Galazzo, Crichton

100 et al. (2021).

101

102 2012; Rebotim et al., 2017), and have a more complete fossil record than deep-dwelling
103 microperforate planktonic foraminifera (Kennett and Srinivasan, 1983).

104 Planktonic foraminiferal data and depth habitat reconstructions (Fig. 1) are from Boscolo-
105 Galazzo, Crichton et al. (2021). They were obtained from globally and latitudinally distributed
106 DSDP (Deep Sea Drilling Project)/ODP (Ocean Drilling Program)/IODP (Integrated Ocean
107 Drilling Program & International Ocean Discovery Program) sites and from cores drilled onshore
108 and offshore Tanzania, all characterized by abundant calcareous microfossils (Boscolo-Galazzo,
109 Crichton et al., 2021). The work was focused on seven target ages (15 Ma, 12.5 Ma, 10 Ma, 7.5
110 Ma, 4.5 Ma, 2.5 Ma, 0 Ma/Holocene). To avoid sample-aliasing, bulk sediment stable isotopes
111 were measured on an average of ten samples per target age at each site. The sample displaying
112 mean oxygen stable isotope values was chosen for subsequent analyses (Boscolo-Galazzo,
113 Crichton et al., 2021). Taxonomy follows: Berggren (1977), Kennett and Srinivasan (1983), Bolli
114 et al. (1989), Scott et al. (1990), Berggren (1992), Pearson (1995), Majewski (2010), Fox and
115 Wade (2013), Spezzaferri et al. (2015), Wade et al. (2018), Lam and Leckie, (2020a), with
116 phylogenetic genus names from Aze et al. (2011).

117 Ages were determined based on biostratigraphic analysis mostly following the biozonation
118 scheme by Wade et al. (2011).

119 Foraminiferal picking for stable isotope measurements were conducted from the size fractions:
120 180-250 μm , 250-300 μm , 300-355 μm (Boscolo-Galazzo, Crichton et al., 2021). Stable isotopes
121 were measured on an average of 15 different species per sample, using ~25 specimens for common
122 species, and as many specimens as possible for rare species. Stable isotopes were measured at
123 Cardiff University. Stable isotope results are shown in Fig. S1 to S9 in the Supplement. Only data
124 from the largest of the three measured size fractions are shown when data from more than one size

125 fraction are available. Data from size fractions other than those above are shown only when a
126 species did not occur within the preferred size interval. Foraminiferal abundance counts were
127 carried out in two size fractions, 180-250 μm and $>250 \mu\text{m}$, counting up to 300 specimens in each.
128 Total abundances were derived by summing up abundances from these two size fractions.

129 Boscolo-Galazzo, Crichton et al. (2021) reconstructed planktonic foraminiferal depth habitat
130 (Fig. 1) using a combined model-data approach, solving the paleotemperature equation of Kim and
131 O'Neill (1997) for each data point using measured foraminiferal $\delta^{18}\text{O}$, global ice volume estimates,
132 and the cGENIE modeled salinity field to determine local water $\delta^{18}\text{O}$, and then use the model
133 temperature-depth curve to determine depth. The full method is described in Boscolo-Galazzo,
134 Crichton et al. (2021).

135

136 **2.2 Calcareous Nannofossils**

137 Quantitative calcareous nannofossil data were collected from the same samples as used for
138 planktonic foraminiferal analysis or, when this was not possible, stratigraphically adjacent samples
139 (Table S1 in the Supplement). A cascading count technique was used to maximise nannofossil
140 diversity recovery and quantification of low abundance species (Styzen, 1997). Nannofossils were
141 counted per field of view (FOV) until a minimum of 400 specimens were achieved for each sample.
142 However, if a high abundance species exceeded an average of 25 specimens per FOV, it was
143 excluded from subsequent counts in that sample and its abundance scaled-up based on its average
144 abundance and the total numbers of FOV counted. Only specimens directly counted contributed
145 to the minimum count threshold of 400 specimens. An additional scan of two slide transects were
146 undertaken to record rare species not observed during the extended count and are included in the
147 total species richness and diversity analyses. Samples for nannofossil analysis were prepared using

148 the smear slide technique (Bown & Young, 1998). Calcareous nannofossils were observed using
149 both plane-polarised (PPL) and cross-polarised light (XPL) on a Zeiss Axioscope light-microscope
150 at x1000 magnification. Identification and taxonomy used herein follows Young et al. (1997) and
151 is coherent with the recent Neogene calcareous nannofossil taxonomy (Ciummelli et al., 2016;
152 Bergen et al., 2017; Blair et al., 2017; Boesiger et al., 2017; Browning et al., 2017; de Kaenel et
153 al., 2017).

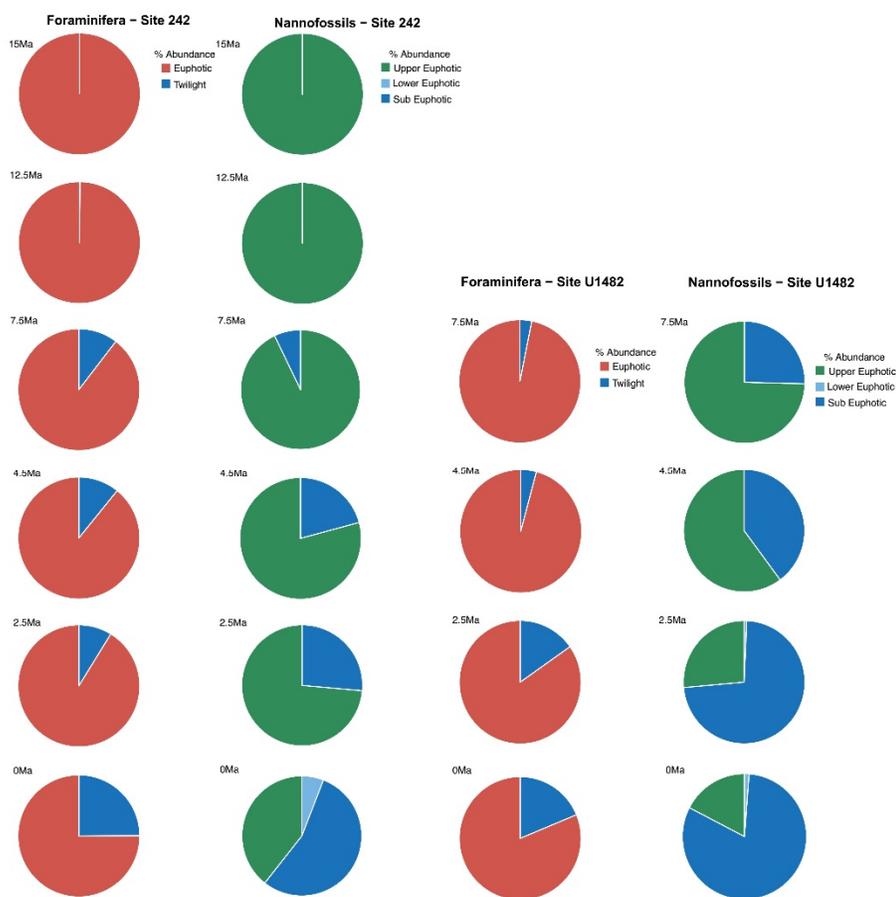

154 **2.3 Plankton Ecogroups**

155 In order to compare the datasets obtained from the planktonic foraminiferal and nannofossil
156 analysis, we grouped species into ecogroups based on depth-habitat preferences. Planktonic
157 foraminiferal ecogroups are defined based on paleodepth habitat reconstructions from Boscolo-
158 Galazzo, Crichton et al. (2021): the euphotic zone ecogroups includes species with an average
159 depth habitat shallower than 200 m (the bottom of the euphotic zone), the twilight zone ecogroup
160 includes species with an average depth habitat coinciding with the twilight zone (200-1000 m).
161 The twilight zone ecogroup is largely composed of species within the globocornellids, the
162 *Globorotalia merotumida-tumida* lineage, the hirsutellids and the truncorotaliids, but also includes
163 species from other genera, such as *Globigerinella calida*, *Globorotaloides hexagonus*, *G.*
164 *variabilis*, and *Pulleniatina obliquiloculata*. *Dentoglobigerina venezuelana* has a changeable
165 depth habitat through time (Matsui et al., 2016; Wade et al., 2018); following the depth habitat
166 reconstructions from Boscolo-Galazzo, Crichton et al., (2021) it was grouped as euphotic zone
167 species for target ages 15, 12.5, 7.5, 4.5 Ma and as twilight zone species for target age 10 Ma.
168 Species were excluded from the grouping when they are known to have a marked seasonality in
169 abundance and depth habitat (*Globigerina bulloides*, *Globigerinella praesiphonifera* and the

170 neogloboquadrinids) (e.g., Jonkers and Kucera, 2015; Greco et al., 2019), and if they were too rare
171 and depth habitat reconstruction was not possible (*Candeina nitida*).

172 Three ecogroups for calcareous nannofossils are used: upper-euphotic, lower-euphotic and
173 sub-euphotic. The upper-euphotic group is represented by: *Discoaster* spp., *Rhabdosphaera*
174 *xiphos*, *Reticulofenestra* spp. and *Gephyrocapsa* spp. (excluding *G. ericsonii*); the lower-euphotic
175 ecogroup contains: *Rhabdosphaera clavigera*, *Gephyrocapsa ericsonii* and *Ceratolithus* spp.,
176 finally the subeuphotic ecogroup includes: *Florisphaera profunda* and *Calciosolena murrayi*.
177 Because species specific stable isotope measurements and depth habitat reconstructions are
178 difficult for calcareous nannofossils, species depth-habitat preference was assigned based on the
179 literature (Poulton et al., 2017; Tangunan et al., 2018). In particular, Poulton et al. (2017) described
180 vertically separated coccolithophores communities sampled during a meridional cruise in the
181 Atlantic Ocean. Here we use their criteria for assigning nannofossil species into ecogroups,
182 whereby in the upper-euphotic zone ecogroup we include species found to live in waters with
183 >10% surface irradiance, in the lower-euphotic zone ecogroup we group species found to live in
184 waters with 10-1% irradiance, and in the sub-euphotic zone ecogroup we group species found to
185 live in waters with <1%, i.e. too low to support photosynthesis (Poulton et al., 2017). *Discoaster*
186 become extinct in the early Pleistocene, therefore, its depth habitat remains under debate as the
187 group has no extant relative (Schueth and Bralower, 2015; Tangunan et al., 2018). However,
188 geochemical evidence from oxygen isotope values of *Discoaster* and planktonic foraminifera
189 (*Globorotalia menardii*, *Dentoglobigerina altispira* and *Globigerinoides obliquus*), reveal
190 comparable values and signifies that *Discoaster* likely inhabited the upper euphotic zone
191 (Minoletti et al., 2001).

192 For each target age, the relative abundance of ecogroups was calculated summing up the
 193 abundance counts of all the individual species pertaining to an ecogroup at each site, hence,
 194 ecogroup abundance data represent global mean values. For both nannofossils and planktonic
 195 foraminifera, the percentage of each ecogroup per time bin was converted into pie-charts (Fig. 2-
 196 5). Diversity indexes for both foraminiferal and nannofossil ecogroup were calculated using the
 197 statistical software Past (Hammer et al., 2001) (Fig. 6).
 198

199
 200 **Figure 2.** Foraminiferal and nannofossil ecogroup abundance at Site 242 and U1482.

201

202

203 **2.4 cGENIE model**

204 We extracted model output for Particulate Organic Carbon (POC) and oxygen concentration
205 from the cGENIE simulations for each of the seven target ages as described fully in Boscolo-
206 Galazzo, Crichton et al. (2021). To facilitate a general discussion of near-surface changes, we
207 divided the data latitudinally by calculating the arithmetic mean for low latitudes ($<16^\circ$ latitude),
208 two mid-latitude bands (mid 1: 16° to 40° , mid 2: 40° to 56°) and high latitudes ($>56^\circ$). The
209 cGENIE simulations take account of changing boundary conditions including CO_2 forcing,
210 bathymetry and ocean circulation (Crichton et al., 2020). The model's ocean biological carbon
211 pump is temperature dependent, where temperature affects both nutrient uptake rates at the surface
212 and remineralization rates of sinking particulate organic matter down the water column (Crichton
213 et al., 2021).

214 **3. Results**

215 **3.1 Plankton Ecogroups**

216 For both calcareous nannoplankton and planktonic foraminifera, the variation in abundance
217 of euphotic zone and deeper-dwelling ecogroups show global patterns recognised across sites.
218 Additionally both group indicate a long-term directionality towards increased abundance of deep-
219 dwelling ecotypes. Among planktonic foraminifera, the twilight zone ecogroup increases in
220 abundance through time starting at 7.5 Ma (Fig. 6). The relative abundance of the twilight zone
221 ecogroup in the middle Miocene is 15% and it increases to $\sim 30\%$ in the Holocene time slice (Fig.
222 6). The average abundance of the euphotic zone species ecogroup in the middle Miocene is 85%
223 and it decreases through time until reaching 60% in the Holocene (Fig. 6). In the twilight zone
224 ecogroup we observe an increase in the total number of species from about 1-2 species at 15 Ma,
225 to 14 species in the Holocene (Fig. 6). In the middle Miocene this group comprised 1/6 of the total

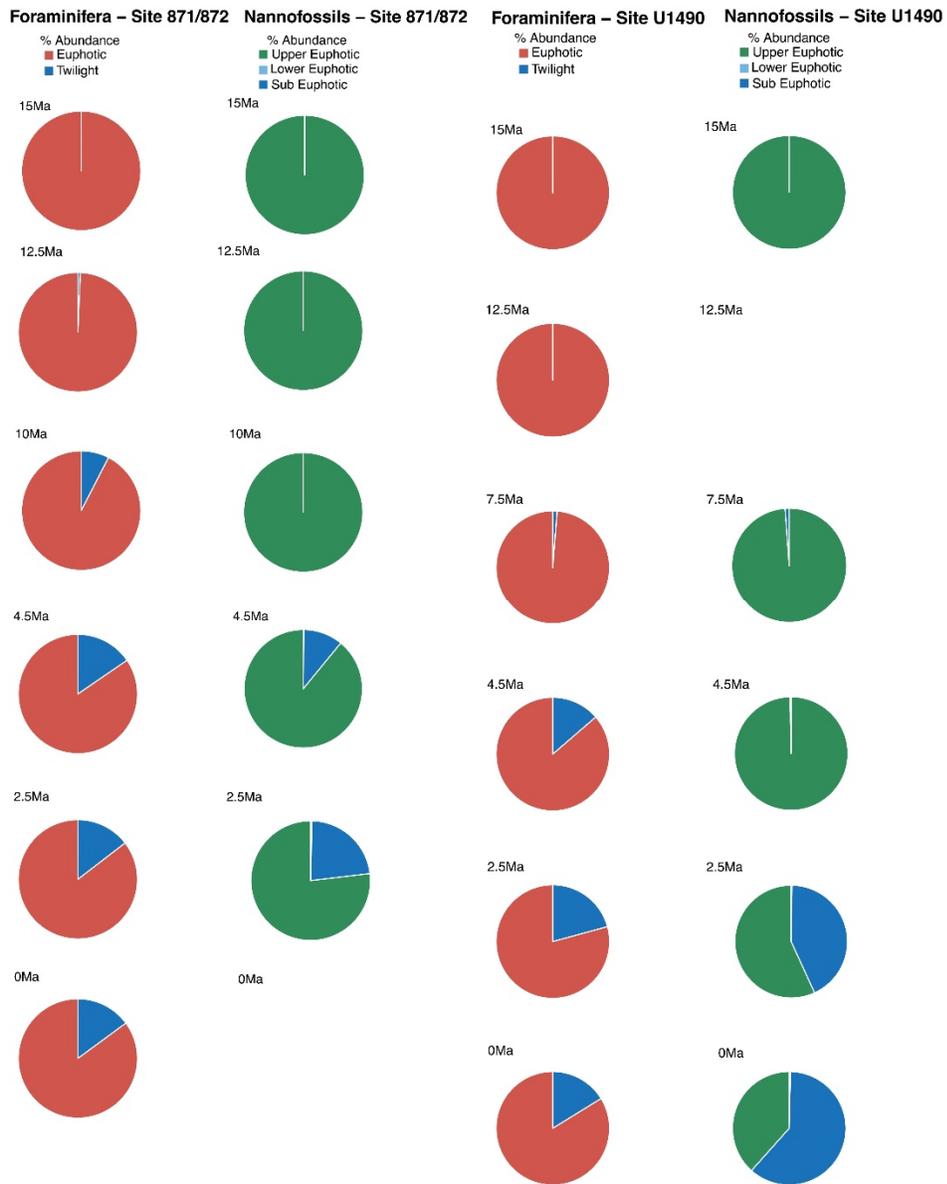

226 number of species in our samples, while in the Holocene it represents almost the half. All the
227 diversity indexes show a late Miocene to Holocene increasing trend for the twilight zone ecogroup
228 (Fig. 6).

229 Calcareous nannofossil assemblages are dominated by the upper-euphotic ecogroup from
230 15 to 10 Ma at all sites (Fig. 2-5). At 7.5 Ma the sub-euphotic ecogroup first becomes a significant
231 component of assemblages at Indian Ocean sub-tropical Sites U1482 and to some extent Site 242,
232 but it is not until the 4.5 Ma time slice that the sub-euphotic ecogroup becomes a significant
233 component of assemblages at the majority of locations (Sites 516, 871/872, 242, U1338, U1482,
234 U1489; Fig. 2-5). By the Holocene time slice, coccoliths of sub-euphotic species are dominant at
235 most locations, except at Eastern Equatorial Pacific Site U1338 (Fig. 6 and 4). At the southern
236 high latitude Site 1138 there is no significant contribution from coccoliths of either lower-euphotic
237 or sub-euphotic species at any point, although there is no data from the Pliocene to Holocene time
238 slices at this location (Fig. 5). Global average compositions of calcareous nannofossil assemblages
239 reflect the changes noted above, with a marked and rapid decline in the relative contribution of the
240 upper-euphotic ecogroup, and a corresponding increase in the sub-euphotic zone ecogroup through
241 the Pliocene and to Holocene (Fig. 6).

242 **3.2 Planktonic foraminiferal deep-dwelling species: depth habitat, abundance and** 243 **biogeography**

244 **3.2.1 Hirsutellids**

245 The only hirsutellid species occurring in our Miocene samples is *Hirsutella scitula*. At 15 Ma this
246 morphospecies is common only at Site 1138 (~8%), sporadically occurs at Site 516 (<1%) and is
247 absent at the other investigated sites (Fig. 7). Oxygen isotopes range from 0.5 to 1.3‰ (Fig. S1-

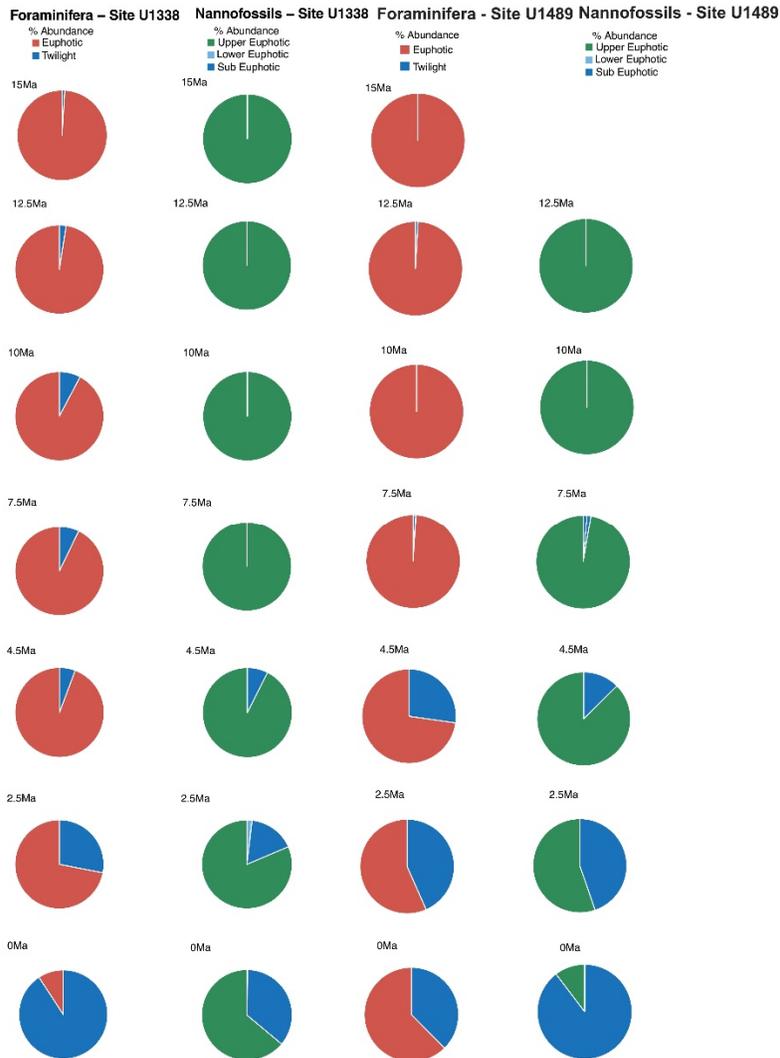

248
 249
 250
 251
 252
 253
 254
 255
 256

Figure 3. Foraminiferal and nannofossil ecogroup abundance at Site 871/872 and U1490.

257 S2). Depth-habitat reconstructions for Site 1138 are unattainable from $\delta^{18}\text{O}$ data due to the
258 overprinting effect of subpolar front shifts at this location, but habitat reconstruction at Site 516
259 suggests a paleodepth habitat shallower than 200 m. By 12.5 Ma, *H. scitula* appears at Site U1338
260 and U1489 in very low abundance (<0.5%) (Fig. 7). At Site U1489 the species was so rare that it
261 was encountered when picking for stable isotopes and no more when counting for species
262 abundances, despite the use of different splits of the residue. No differences were observed
263 between 12.5 and 10 Ma in the biogeography of *H. scitula* (Fig. 7). However, by 7.5 Ma, *H. scitula*
264 occurs at all our low latitude sites (Fig. 8) with oxygen isotopes ranging from -0.5 to 2.0‰ (Fig.
265 S3-S9), which according to depth habitat reconstructions translates to 250 and 500 m water depth
266 (Boscolo-Galazzo, Crichton et al., 2021). This is similar to that of *Globorotaloides hexagonus*
267 (Fig. 1), the only twilight zone dweller we observed at tropical sites at 15 Ma, displaying stable
268 isotopes ranging from 0 to 1‰, which translates to depths around 300-500 m. In the late middle
269 Miocene the stable isotope values of *G. hexagonus* increase to 2-2.5‰ (Fig. S3-S9). Similarly, the
270 oxygen isotope values of tropical *H. scitula* increased through time, reaching 2-3‰ in the youngest
271 target ages. In line with this, the reconstructed depth habitat of *H. scitula* and *G. hexagonus*
272 increases through time in a stepwise fashion, and in the Holocene it reaches down to 800-1500 m
273 (Fig. 1) (Boscolo-Galazzo, Crichton et al., 2021). *Hirsutella scitula* becomes gradually more
274 common at low latitude sites through the Miocene-Pliocene, although it never becomes abundant.
275 In our record, *Hirsutella margaritae* and *H. theyeri* first appear in the early Pliocene at a depth
276 between 200-300 m (Fig. 1) (oxygen isotopes range -1 to -0.5‰), similar to that of *H. hirsuta*
277 (oxygen isotopes range 0 to 1‰) when it first appears in the Holocene (Fig. S3-S9).

290 3.2.2 Truncorotaliids

291 The earliest appearances of *Truncorotalia crassaformis* in our record corresponds to our 4.5 Ma
292 time slice at Site 1138 in the Indian Ocean sector of the Southern Ocean where it represents >20%
293 of the assemblage, and in coeval sediments at mid-latitude Site 516 in the southwest Atlantic,
294 where it represents ~9% of the assemblage (Fig. 9), with oxygen isotopes ranging from 1.5 to 3.0‰
295 (Fig. S1-S2). At Site 516 we observe the co-occurrence of *T. oceanica* (~14%) and *T. crassaformis*
296 in the early Pliocene (4.5 Ma), and of *T. viola* (~5%) and *T. crassaformis* (~13%) in the late
297 Pliocene (2.5 Ma) (Fig. 10). We did not observe *T. oceanica* and *T. viola* anywhere else. *T.*
298 *oceanica* and *T. crassaformis* display almost overlapping $\delta^{18}\text{O}$ values and depth habitat (Fig. S2)
299 but *T. crassaformis* has 0.5‰ lower $\delta^{13}\text{C}$ values. Oxygen stable isotope data (1‰; Fig. S2) and
300 habitat reconstructions for Site 516 indicate that a subsurface habitat (>200 m) was already
301 occupied by *T. crassaformis* at the beginning of its evolutionary history (Fig. 1). The late Pliocene
302 appearance of *T. viola* at Site 516, which differs from *T. crassaformis* in having a more convex
303 umbilical side, a triangular outline and a subacute profile, is associated with a shift to more positive
304 oxygen isotope values of *T. crassaformis* (1.5‰) and to slightly greater depths (Fig. 1).

305 We find *T. crassaformis* by the late Pliocene at our investigated tropical and subtropical
306 sites (2.5 Ma, Site U1338, U1489, 872, U1490, 242, U1482) (Fig. 10-11), with oxygen isotope
307 values ranging from 1.0 to 2.0‰ which translate to depth habitats of 400-600 m (Boscolo-Galazzo,
308 Crichton et al., 2021; Fig.1). The appearance of *T. crassaformis* at our low latitude sites is coeval
309 with the appearance in our record of *Truncorotalia tosaensis*, morphologically transitional
310 between *T. crassaformis* and *T. truncatulinooides* (Lazarus et al., 1995) (Fig. 10). *Truncorotalia*
311 *tosaensis* displays oxygen isotopes values ranging from 0 to 0.5‰ (Fig. S1-S9), which translate to
312 300-350 m depth (Fig. 1). Consistent with earlier findings (Jenkins and Srinivasan 1986; Lam and

313 Leckie 2020b; Lazarus et al., 1995), we record the first occurrence of *T. truncatulinoides* in the
314 late Pliocene in the south-west Pacific (2.5 Ma, Site U1482), and only later in the North Pacific (0
315 Ma, Site 872), Indian Ocean (0 Ma, Site 242) and South Atlantic (0 Ma, Site 516) (Fig. 11).
316 *Truncorotalia truncatulinoides* records oxygen isotope values ranging from -1 to 2‰, more
317 negative than coeval *T. crassaformis* (Fig. S3-S9). *Truncorotalia truncatulinoides*, although
318 reported in the modern tropical ocean as one of the species living at the greatest depths, occupies
319 a shallower depth habitat than *T. crassaformis* when it first appears in our tropical to subtropical
320 records (2.5 Ma).

332

333

334 3.2.3 Globorotaliids

335 With globorotaliids here we refer to the *Globorotalia merotumida-tumida* lineage composed by *G.*
336 *merotumida*, *G. plesiotumida*, *G. tumida* and *G. ungulata* (Kennett and Srinivasan, 1983). This
337 group first appears with *Globorotalia plesiotumida* in our 10 Ma time slice at Site 871 (Fig. 7). At
338 all the investigated low latitude sites, we find *G. tumida* by 4.5 Ma with abundances between 2-
339 24% (Fig. 9). *Globorotalia plesiotumida* co-occurs with *G. tumida* only at Sites 872 and 242
340 corresponding to our 4.5 Ma time slice (Fig. 9; Fig. S9). In our records, *G. tumida* consistently
341 displays oxygen isotope values between -1 to 0‰ (Fig. S3-S9), and an average depth habitat
342 around 250 m, with a shallowest occurrence at 50 m and a deepest occurrence around 600 m (Fig.
343 1). Similar oxygen isotope values and depth habitat preference are recorded for *G. plesiotumida*
344 and *G. ungulata* (Fig. 1 and Fig. S3-S9).

345 3.2.4 Globoconellids

346 In our records, *Globoconella miozea* is a dominant component of planktonic foraminiferal
347 assemblage at Site 1138 at 15 Ma (65%) and occurs in moderate abundance at Site 516 (5%) (Fig.
348 7). The distribution of globoconellids appears restricted to southern high to mid-latitudes during
349 the middle Miocene and the late Miocene to Pliocene. At Site 1138 globoconellids decrease in
350 abundance through time, with *Globoconella panda* the only late Miocene (7.5 Ma) species (<1%;
351 with $\delta^{18}\text{O}$ of 3‰), followed only by *Globoconella inflata* in the Holocene (4.2%; with $\delta^{18}\text{O}$ of
352 3.5‰) (Fig. 11). On the contrary, at Site 516 globoconellids increase in abundance through time
353 becoming a characteristic feature of the planktonic foraminifera assemblage as noted in previous
354 studies of this area (Berggren, 1977; Norris et al., 1994) (Fig. 7-11). In the Holocene *G. inflata* is
355 most abundant at mid-latitude Site 516 (22.7%; with $\delta^{18}\text{O}$ of 1‰), but also occurs in the subtropical
356 (<0.5%; with $\delta^{18}\text{O}$ of 0.9‰) and subpolar Indian ocean (4.2%; with $\delta^{18}\text{O}$ of 3.5‰) (Fig. 11; Fig.

357 S1-S3). Depth habitat reconstructions for the globoconellids show a deepening trend through time
358 although less marked compared to those of other deep-dwelling groups considered in this study
359 (Boscolo-Galazzo, Crichton et al., 2021; Fig. 1). At Site 516, the depth habitat is just above 200 m
360 for middle Miocene *Globoconella miozea* ($\delta^{18}\text{O}$ 0.9‰), just below 200 m for late Miocene *G.*
361 *miotumida* and *G. conomiozea* ($\delta^{18}\text{O}$ 1‰), and around 350 m for late Pliocene *Globoconella*
362 *puncticulata* ($\delta^{18}\text{O}$ 1.6‰) the precursor of *G. inflata*, which shows a similar depth habitat at this
363 site ($\delta^{18}\text{O}$ 1-1.2‰; Fig. S2), (Fig. 1). At Site 242 the average depth reconstruction for the Holocene
364 *G. inflata* is of ~450 m ($\delta^{18}\text{O}$ 0.9‰; Fig. S3), similar to that of *T. crassaformis* and *T.*
365 *truncatulinooides* (Boscolo-Galazzo, Crichton et al., 2021; Fig. 1).

366 **4. Discussion**

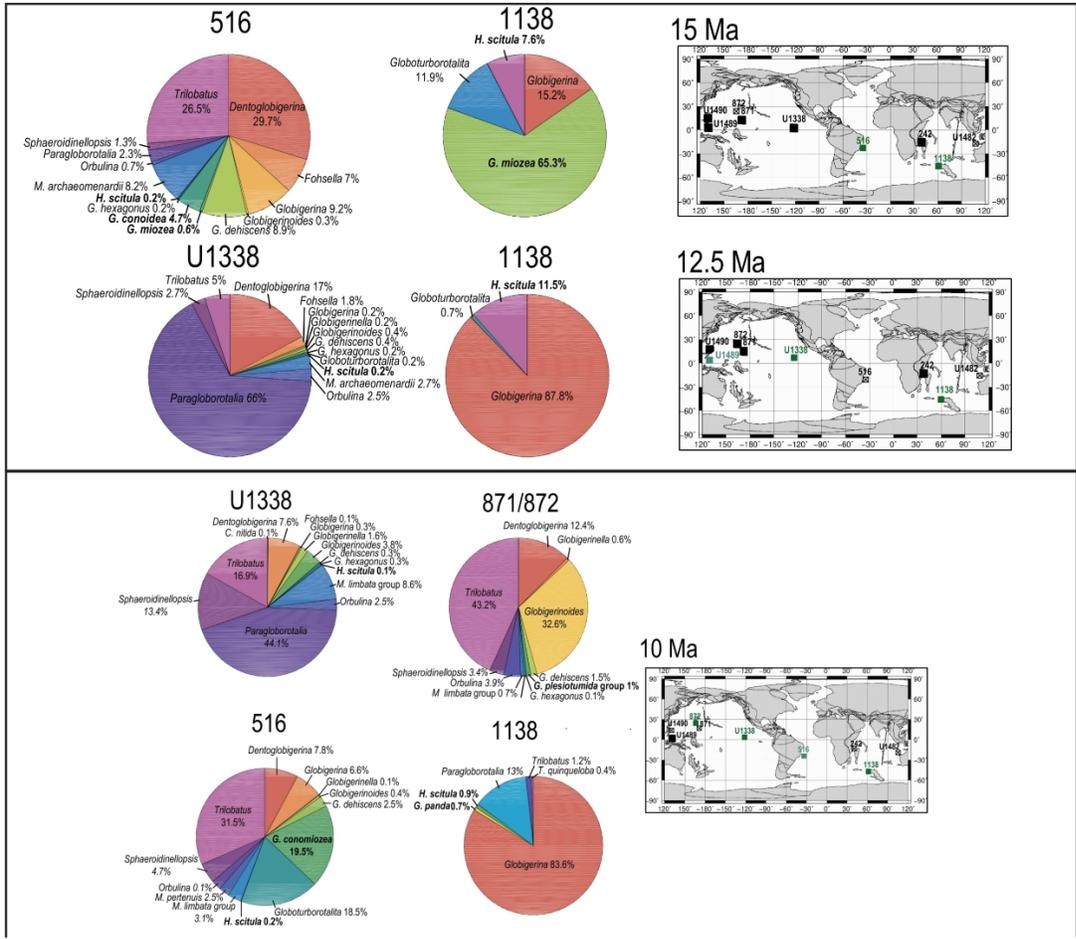

367 **4.1 Evolution of a deep-plankton ecological niche linked to late Neogene cooling**

368 We observe a trend of increasing ecological importance of deep-dwelling species in both
369 calcareous nannofossil and foraminiferal communities from the late Miocene to Recent. The
370 foraminiferal twilight zone ecogroup shows a marked increase in abundance and diversity at 7.5
371 Ma, at the same time as the first significant appearance of the sub-euphotic ecogroup within
372 coccolithophore assemblages, and coinciding with a possible acceleration of global cooling
373 (Cramer et al., 2011; Crichton et al., 2020). Fossil deep-dwelling coccoliths are dominated by one
374 species, *Florisphaera profunda*, which is often very abundant in Plio-Pleistocene sediments. This
375 makes our sub-euphotic ecogroup a low diversity – high abundance assemblage, whose origin
376 significantly impacts the relative abundance balance between ecogroups, but with little change in
377 diversity metrics towards the modern. Although there are morphological variants of *F. profunda*
378 in the modern oceans, potentially representing sub-species or pseudo-cryptic species (Quinn et al.,
379 2005), these are not distinguished in fossil assemblages and documenting their divergence times

380 requires either further molecular genetic or detailed morphological analyses. The one clear signal
381 in our diversity analyses is a late Miocene – early Pliocene peak in upper-euphotic species richness,
382 followed by a marked decline through the late Pliocene to the Holocene. The late Miocene-
383 Pliocene peak diversity is present in previous global compilations of total nannofossil diversity
384 (Bown et al. 2004; Lowery et al. 2020), but here we show that this signal is driven by first a
385 diversification and then progressive extinction almost entirely within upper-euphotic taxa.

386 Modern planktonic foraminifera evolved in two main diversification pulses in the middle Miocene
387 (16-14 Ma) and during the late Miocene-Pliocene transition (6-4.5 Ma) (Kennett and Srinivasan,
388 1983; Kucera and Schönfeld, 2007). Our species abundance and diversity data show that this
389 diversification was mostly driven by the origin of lineages of deep/subsurface dwelling species
390 (Fig. 7-11 and Fig. 6). Diversity among euphotic zone species remained constant from the middle
391 Miocene to the early Pliocene, then declined (Fig. 6). This pattern, similar to calcareous
392 nannofossils, may explain early records pointing to a decrease in Pliocene to Recent planktonic
393 foraminiferal diversity (Wei and Kennett, 1986).

394 The observed evolutionary patterns in planktonic foraminifera and coccolithophores can
395 be explained by the development of environmental conditions favourable to deep living plankton

396

397

398 **Figure 7.** Abundance and biogeography of planktonic foraminiferal species at 15, 12.5, and 10
 399 Ma. In the pie-charts twilight zone planktonic foraminiferal species are in bold. Sites where
 400 twilight zone planktonic foraminifera were found are highlighted in green in the maps. The crossed
 401 square symbol in the maps indicate that the time interval of interest was not recovered for a given
 402 site. Continental configuration follows: Ocean Drilling Stratigraphic Network (GEOMAR, Kiel,
 403 Germany).

404

405

406

407

408 with cooling. For the deep-dwelling planktonic foraminifera, survival requires the availability of
409 food at depth, and with the exception of few species adapted to oxygen minimum zones (Davis et
410 al., 2021), the absence of severe oxygen depletion. In the published literature there is a general
411 tendency for planktonic foraminiferal $\delta^{18}\text{O}$ values to be tightly grouped during times of warm
412 climate, becoming more spread-out during cooling episodes, for instance the transition from mid-
413 to late Cretaceous (Ando et al., 2010) and early to middle Eocene (John et al., 2013). In light of
414 our findings such tight $\delta^{18}\text{O}$ values, may indicate times when food and oxygen availability at depth
415 were limited, allowing planktonic foraminifera to live at shallower depths only. Because our data
416 are restricted to certain time slices and locations, we only capture a part of the overall pattern for
417 the Neogene, but other examples of depth-related evolution in the Neogene include the *Fohsella*
418 *peripheroronda* – *F. fohsi* lineage in the middle Miocene (Hodell and Vayavananda, 1993; Norris
419 et al., 1993) and the appearance of various deep-dwelling digitate species in the Plio-Pleistocene
420 (Coxall et al., 2007).

421 Deep-dwelling coccolithophores, most notably *Florisphaera profunda*, require dissolved
422 macronutrients (N, P) and at least some degree of light penetration (Quinn et al., 2005; Poulton et
423 al., 2017). The requirement for light penetration to depth is most clearly shown by the absence
424 of *F. profunda* beneath high surface productivity regions where nutrients are not limited at depth
425 but light is rapidly attenuated by more abundant mixed layer microplankton (Beaufort et al., 1999).
426 For coccolithophores, the cooling-driven shift from nutrient recycling within to below the mixed
427 layer, may have provided the ecological driver for species to live in deeper, more nutrient-rich
428 waters, but, as mixed layer waters cleared, also allowed the irradiance necessary for photosynthesis
429 to penetrate to these new deeper habitats. Additionally, the capability of coccolithophores to absorb

430 carbon and nutrients from seawater under low light conditions (Godrjian et al., 2020; 2021) may
431 have also aided in the occupation of new deep water niches.

432 Our model outputs from cGENIE is consistent with this interpretation, organic matter
433 export (POC at 40 m in Fig. 12) reduced with cooling, suggesting an overall decrease in primary
434 productivity at all 4 latitudinal bands considered in this study. Fewer particles in surface waters
435 would have allowed greater light penetration (Fig. 12), at the same time, the model indicates
436 enhanced organic matter delivery at >200 m with cooling. Greater organic matter delivery below
437 the euphotic zone, suggests a deeper remineralization depth and increased dissolved nutrients
438 availability at depth. This is most clearly shown in the modelled low and mid latitudes near-surface
439 waters. Oxygen availability also increased, particularly below 100 m depth in low latitudes and
440 further down the water column, below 200 m depth (Fig. 12).

441 Nonetheless, planktonic foraminifera and nannoplankton have distinct trophic statuses
442 (zoo- versus phytoplankton), further coccolithophore species require light for their dominantly
443 photosynthetic mode of life. In our data, such differences between the requirements of zoo- and
444 phytoplankton deep-dwellers is clearly observed in the biogeographic patterns. Sub-euphotic
445 coccolithophores are consistently more abundant in low nutrient sub-tropical locations (e.g. DSDP
446 Site 242 and IODP Site U1482; Fig. 2). The end-member of this biogeographic difference is ODP
447 Site 1138, in the Southern Ocean. Here, twilight foraminifera dominate most time intervals,
448 presumably due to high export production. However, lower-euphotic and sub-euphotic
449 coccolithophores are effectively excluded, due to turbid, high-productivity surface waters (Fig. 5).
450 This pattern is also supported through a comparison of high to low productivity tropical sites in
451 the Holocene – the Eastern Equatorial Pacific Site U1338 has abundant twilight foraminifera, but
452 relatively low abundances of sub-euphotic coccolithophores (Fig. 4), whereas the more

453 oligotrophic Site U1482 (Fig. 2) has lower abundances of twilight foraminifera and higher
454 abundances of sub-euphotic coccolithophores.

455 Despite these ecological differences between zoo- and phytoplankton, we suggest there is
456 a shared environmental driver for the evolution of deep-dwelling coccolithophores and planktonic
457 foraminifera linking the evolution of deep-dwelling specialists in each group. Efficient near-
458 surface recycling of organic carbon in past warm climates, such as the middle Miocene (Fig. 12),
459 precluded the occupation of the deep habitat for both groups by reducing both organic carbon
460 transfer (food limitation for foraminifera and for foraminiferal preys such copepods) and light
461 penetration (photosynthesis for coccolithophores) to depth (Fig. 2-6). Global cooling since the
462 middle Miocene (Kennett and Von der Borch, 1985; Kennett and Exon, 2004; Cramer et al., 2011;
463 Zhang et al., 2014; Herbert et al., 2016; Sosdian et al., 2018; Super et al., 2020), however, led to a
464 decreased export of organic matter and a deepening of the mean organic matter remineralization
465 depth, which in turn favoured the evolution of deep water niches in planktonic foraminifera (Fig.
466 1) and nanoplankton via increased availability of organic matter, oxygen, and likely nutrients at
467 depth (Fig. 12), and clearing of surface waters.

468

469 **4.2 Mechanisms of speciation of deep-dwelling planktonic foraminifera**

470 The hirsutellids gave rise to a large late Neogene radiation among planktonic foraminifera,
471 leading to the origin of modern phyletic groups such as the menardellids, globoconellids,
472 truncorotaliids, and the globorotaliids of the *Globorotalia merotumida* - *tumida* lineage (Kennett
473 and Srinivasan, 1983; Scott et al., 1986; Aze et al., 2011). The majority of the modern
474 representatives of these groups are lower euphotic zone to twilight zone species. The hirsutellids
475 originated about 18 Ma (Wade et al., 2011) from *Globorotalia zealandica* (Kennett and Srinivasan,

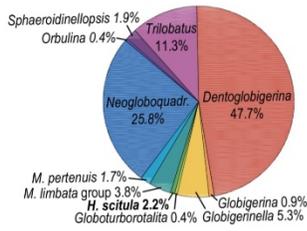

476 1983), the first representative of the group being *Hirsutella praescitula* (Kennett and Srinivasan,
477 1983; Aze et al., 2011). Extant hirsutellids include *H. scitula*, *H. hirsuta* and *H. theyeri*; genetic
478 data available for *H. hirsuta* indicate a single genotype (Schiebel and Hemleben, 2017). Modern
479 *H. scitula* and *H. hirsuta* are deep water forms. Depth habitat reconstructions show *H. scitula* at
480 the greatest water depth (Boscolo-Galazzo, Crichton et al., 2021; Fig. 1), consistent with it being
481 reported to have a deeper average depth habitat than *H. hirsuta* in the modern ocean (Birch et al.,
482 2013; Stainbank et al., 2019), where it feeds on suspended organic matter (Itou et al., 2001).
483 *Hirsutella hirsuta* has been reported to feed on dead diatoms and to predominantly live at depths
484 around 250 m (Schiebel and Hemleben, 2017), consistent with our habitat reconstructions placing
485 *H. hirsuta* and other hirsutellids shallower than *H. scitula*, between the bottom of the euphotic
486 zone and the upper twilight zone. Our depth habitat reconstruction for *H. scitula* at Site 516 for
487 the 15 Ma time slice, indicates an initial euphotic zone depth habitat preference for this species.
488 By the 7.5 Ma time slice, we find *H. scitula* at most of our low latitude sites, at depth comprised
489 between 300-500 m (Fig. 1). We suggest that the spread of *H. scitula* from high-mid latitudes
490 towards the tropics after the middle Miocene warmth (Fig. 7-11) tracks increasing availability of
491 POC and oxygen at depth (Boscolo-Galazzo, Crichton et al., 2021; Fig. 12), allowing this species
492 to find food in deep tropical twilight zone waters, profiting from a new ecological niche. We
493 suggest that moving from a surface to a deep-water habitat was for *H. scitula* an ecological
494 innovation which allowed the species to move outside its high-mid latitude areal, consistent with
495 observations from the modern ocean documenting *H. scitula* dwelling at progressively deeper
496 depth from high to tropical latitudes (Schiebel and Hemleben, 2017). The proceeding ocean
497 cooling (and increasing efficiency of the biological pump) explains the stepwise depth habitat
498 increase of *H. scitula* through time at tropical and subtropical sites (Fig.1): more food became

499 available at increasingly greater depth in association with improved oxygen availability (Fig. 12),

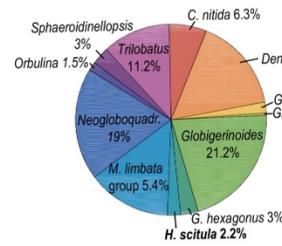

500 allowing the species to expand its habitat

 519 Continental configuration follows: Ocean Drilling Stratigraphic Network (GEOMAR, Kiel,
 520 Germany).

525 vertically other than geographically. At low latitude sites this was accompanied by speciation, with
526 the appearance of *Hirsutella margaritae* and *H. theyeri* in the early Pliocene, and of *H. hirsuta* in
527 the Holocene. These new species display depth habitats shallower than *H. scitula* at their
528 appearance. Hence, we suggest that it was the occupation of a new deep water habitat in tropical
529 waters that triggered speciation from *H. scitula* through depth sympatry, i.e. genetic isolation
530 attained in the same area but at different depths (Weiner et al., 2012). Earlier studies on speciation
531 among planktonic foraminifera based on the fossil record, highlighted a predominance of
532 sympatric speciation, possibly linked to changes in ecology (Norris et al., 1993; Lazarus et al.,
533 1995; Pearson et al., 1997). This has more recently been supported by genetic analysis, which
534 reveals a consistent depth separation between intra-specific genotypes at a global scale, suggesting
535 that depth sympatry could be a universal mechanism generating diversity among microplankton
536 (Weiner et al., 2012).

537 Truncorotaliids start their evolutionary history at ~4.31 Ma (Raffi et al., 2020), when
538 *Truncorotalia crassaformis* splits from *Hirsutella cibaoensis* (Kennett and Srinivasan, 1983; Aze
539 et al., 2011), one of the first new species originating from *H. scitula* after its spread to low latitudes
540 (Kennett and Srinivasan, 1983). Our reconstructed geographic and temporal distribution for *T.*
541 *crassaformis* suggests that the early Pliocene split from the hirsutellids happened in cold subpolar
542 water. By the early Pliocene *Truncorotalia crassaformis* was an abundant component of the
543 subpolar assemblage at Site 1138 (>17%) and had already successfully spread to middle latitudes
544 (>8%) but does not occur in our low latitude samples (Fig.9).

545

547

 557 Ma. In the pie-charts twilight zone planktonic foraminiferal species are in bold. Sites where
 558 twilight zone planktonic foraminifera were found are highlighted in green in the maps. The crossed
 559 square symbol in the maps indicate that the time interval of interest was not recovered for a given
 560 site. Continental configuration follows: Ocean Drilling Stratigraphic Network (GEOMAR, Kiel,
 561 Germany).

562

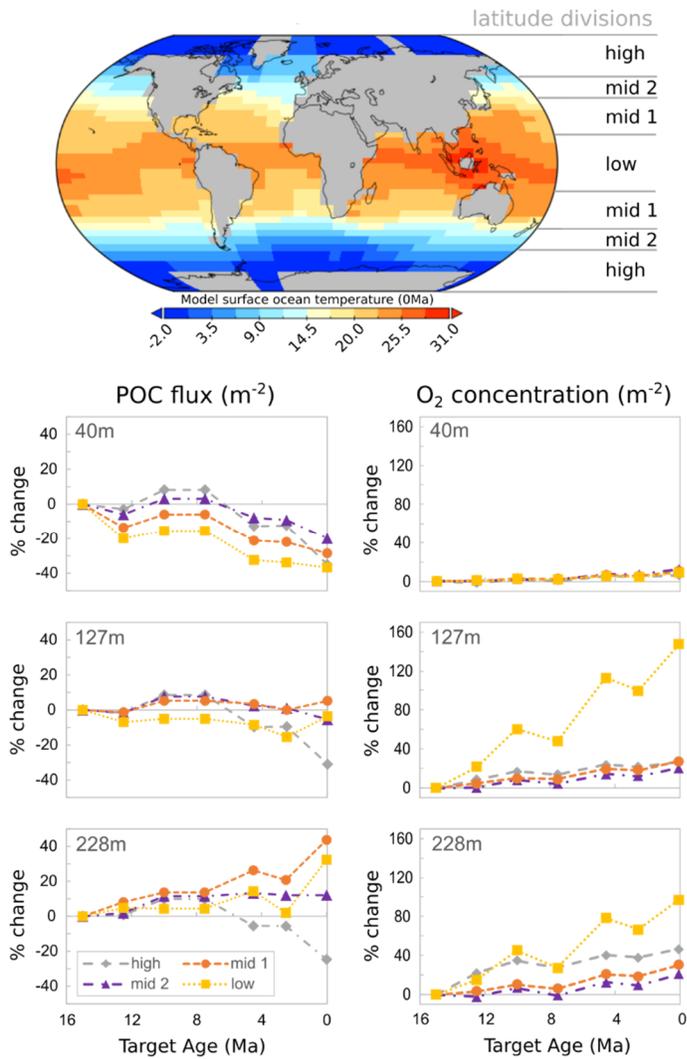

563 Although modern planktonic foraminifera have a high dispersal potential (Darling et al., 2000;
564 Norris and De Vergas, 2000), our data suggest that the evolution of *Truncorotalia crassaformis*
565 from the hirsutellids might have happened through allopatry, with low latitude population of *H.*
566 *cibaoensis* becoming isolated from subpolar populations and eventually evolving into *T.*
567 *crassaformis* (e.g., following the development of diachrony reproductive seasons in high and low
568 latitude populations). Similar to *H. scitula*, from subpolar latitudes, *Truncorotalia crassaformis*
569 appears to have subsequently spread to lower latitudes occupying progressively deeper habitats
570 (Fig. 1; Fig. 7-11), and originating numerous daughter species, some of which are intermediate
571 morphospecies with limited geographic distributions no longer extant today (Lazarus et al., 1995).
572 At Site 516 we find *Truncorotalia viola*, with lighter $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values than *T. crassaformis*
573 (Fig. S2), pointing to a clear ecological differentiation. Together with the marked morphological
574 differentiation between the two, this suggests *T. viola* may have been a different biological species.
575 *Truncorotalia truncatulinoides*, the most representative species of this group, appears to have
576 originated from *T. crassaformis* at about 2.7 Ma in the tropical southwest Pacific, and subsequently
577 spread in the global ocean (Dowsett, 1988; Lazarus et al., 1995). According to our reconstruction,
578 depth sympatry associated with gradual morphological changes characterizes speciation among
579 the truncorotaliids, as depth habitat deepening of the ancestor/precursor is clear in the transition *T.*
580 *crassaformis*-*T. viola* and *T. crassaformis*-*T. tosaensis*-*T. truncatulinoides* in our record (Fig. 1).
581 The possibility to colonize deeper water habitats may have led to progressive reproductive
582 isolation between “deeper” and “shallower” populations of *T. crassaformis*, resulting in biological
583 speciation. Depth sympatry as speciation mechanism for the truncorotaliids was already proposed
584 by Lazarus et al. (1995) based on biogeography, but without a definitive test.

585 In the modern ocean the *Globorotalia merotumida-tumida* lineage is represented by *G.*
586 *tumida* and *G. ungulata*, distributed in tropical to temperate regions. Genetic analysis has revealed
587 that they are two distinct biological species with a single genotype each (Schiebel and Hemleben,
588 2017). Little is known about the ecology of these two species, although *G. tumida* is known to
589 dwell in subsurface waters at the deep chlorophyll maximum (Schiebel and Hemleben, 2017).
590 According to the phylogeny of Aze et al. (2011), *Menardella menardii* gave rise to the
591 *Globorotalia merotumida-tumida* lineage around 9 Ma. However, *Menardella menardii* is absent
592 in our late Miocene samples while other menardellids such *Menardella limbata* and *M. pertenuis*
593 are common at several of our investigated middle latitudes to tropical sites. By 4.5 Ma,
594 *Globorotalia tumida* had evolved and is common at all of our low latitude sites (Fig. 9), while *M.*
595 *menardii* is extremely rare, occurring only at Sites U1338 and U1490 (0.1%), becoming more
596 common only by the Holocene. Based on this biogeographic pattern, we propose that the *G.*
597 *merotumida-tumida* lineage originated from a late Neogene menardellid, such for instance *M.*
598 *limbata* which is morphologically very similar to *G. merotumida*. Given that *G. plesiotumida* and
599 *G. tumida* display a deeper habitat (> 200 m) than *M. limbata* and other Miocene menardellids
600 (100-200 m), we suggest that such transition may have happened through depth sympatry in
601 tropical waters, with forms which remained reproductively isolated in the twilight zone generating
602 the *G. merotumida-tumida* lineage. Morphometric measurements on *M. limbata* and *G.*
603 *merotumida* shells are required to test for an evolutionary relationship between these two species.
604 According to our depth habitat reconstruction, *G. plesiotumida* and *G. tumida* occupied a similar
605 depth habitat at 4.5 Ma, so it is not clear from our dataset which evolutionary mechanism may
606 have led to the origination of the latter from the first. Hull and Norris (2009) analyzed speciation
607 within this lineage and suggested that the evolution from *G. plesiotumida* to *G. tumida* happened

608 abruptly within 44 kyr. *Globorotalia ungulata*, appears in our record by the late Pliocene and often
609 display a habitat shallower than *G. tumida*, suggesting depth sympatry as the evolutionary
610 mechanism leading from *G. tumida* to *G. ungulata*. However, because depth habitat
611 reconstructions for these two species are more variable and shallower than that of other twilight
612 zone species, more data are required to more conclusively infer speciation mechanisms.

613 The globoconellids originated in the late early Miocene (~17 Ma) with *Globoconella*
614 *miozea*, which is considered to descend directly from *Hirsutella praescitula* (Kennett and
615 Srinivasan, 1983; Scott et al., 1990; Norris et al., 1994; Aze et al., 2011). *Globoconella miotumida*
616 originated in the middle Miocene and, after the extinction of *G. miozea* at about 10 Ma, remained
617 the only representative of the globoconellids until the latest Miocene. At this time, the evolutionary
618 turnover within the group accelerated and a number of different morphospecies originate from *G.*
619 *miotumida* and go extinct very rapidly, until the appearance in the late Pliocene of *G. inflata* which
620 persists until today (Wei and Kennett, 1988; Wei, 1994; Aze et al., 2011). Compared to other
621 Neogene to Recent taxa, the globoconellids display a more restricted geographic distribution
622 throughout their evolutionary history. They tend to be common at mid latitude hydrographic fronts
623 (Schneider and Kennett, 1999; Schiebel and Hemleben, 2017; Lam and Leckie, 2020; Brombacher
624 et al., 2021), except *G. puncticulata* and *G. inflata*, which extend into low latitude regions (Norris
625 et al., 1994). The geographic distribution of globoconellids as shown here suggests that this group
626 was already specialized to live at hydrographic fronts in the middle Miocene, possibly feeding on
627 phytoplankton. Starting at ~5.5 Ma, cooling and the possibility to feed on sinking detritus in deeper
628 waters (Boscolo-Galazzo, Crichton et al., 2021) may have stimulated evolutionary turnover within
629 this otherwise rather static group. The closely spaced temporal succession of morphospecies at this
630 time may reflect ongoing evolutionary experiments in an attempt to profit from new ecological

631 possibilities opening up at depth and outside the area of the group. The depth habitat
 632 reconstructions for *G. puncticulata* and *G. inflata* suggests that from the Pliocene this group started

633
 634 **Figure 12.** cGENIE model output for changes in Particulate Organic Carbon (POC) flux, and
 635 dissolved Oxygen in near-surface ocean waters from the middle Miocene to Present, with a
 636 temperature-dependent biological carbon pump. Inset map shows the modelled Present surface
 637 ocean temperatures. Depths are the middle of cGENIE's top three ocean layers.
 638

639 to progressively adapt to greater depths, consistent with the distinctive change in morphology
640 between *G. sphericomiozea* (and other Miocene globoconellids) and its Pliocene descendants *G.*
641 *puncticulata* and *G. inflata* (Kennett and Srinivasan, 1983), as well as with previous stable isotope
642 reconstructions for these species (Schneider and Kennett, 1996). We suggest that an evolutionary
643 transition began with the morphospecies *G. puncticulata*, transitional between *G. sphericomiozea*
644 and *G. inflata* and led to the late Pliocene speciation of *G. inflata*. It is not clear from our data
645 whether depth sympatry or allopatry allowed the speciation of *G. inflata*, as *G. puncticulata* and
646 *G. inflata* show similar depth habitat in our record. It may have been a combination of the two,
647 given *G. inflata* genotypes display a characteristic allopatric distribution in the ocean (Morard et
648 al., 2011).

649 Our data indicate that combining stable isotopes and model-derived water column temperature
650 is a promising approach to quantify the depth habitat of extinct planktonic foraminiferal species.
651 When combined with abundance and biogeographic data, depth habitat reconstructions offer
652 insights into speciation mechanisms not resolvable with the use of one technique alone (e.g., stable
653 isotopes). Our reconstructions indicate that both allopatry and depth sympatry played a role in the
654 origin of modern deep-dwelling planktonic foraminiferal species. Both allopatry and depth
655 sympatry appear to have been involved with the cladogenesis of the truncorotaliid and the
656 globorotaliid lineages, while depth sympatry seems to be mostly involved for intra-lineage
657 speciation.

658 **5. Conclusions**

659 Our global abundance and biogeographic data combined with our depth habitat
660 reconstructions allow us to piece together the environmental drivers behind speciation in two of
661 the most extensively studied group of pelagic microfossils, planktonic foraminifera and calcareous

662 nannofossils over the last 15 million years. The evolution of the new Neogene deep-water lineages
663 of the hirsutellids, globorotaliids, globoconellids and truncorotaliids, and of nanoplankton lower-
664 euphotic zone and sub-euphotic zone species, resulted in the vertical stratification of species seen
665 in the modern ocean, in particular at low latitudes. For planktonic foraminifera such vertical
666 stratification of species, hundreds of meters below the surface, originated through depth sympatry
667 as well as cladogenesis of new lineages via both sympatry and allopatry.

668 Our study places the evolution of modern plankton groups in the context of large scale
669 changes in ocean macroecology driven by the global climate dynamics of the past fifteen million
670 years. The late Miocene to present evolutionary history of planktonic foraminifera and
671 nanoplankton was linked, wherein increased efficiency of the biological pump with cooling since
672 the middle Miocene was a shared evolutionary driver. Lower rates of organic matter
673 remineralization in the upper part of the water column allowed the creation of new ecological
674 niches in deep waters, by increasing food delivery and oxygen at depth for heterotrophic planktonic
675 foraminifera, and by clearing surface waters and augmenting the concentration of macronutrients
676 at depth for nanoplankton.
