13

14 **Abstract.** Salt marshes and seagrass meadows can sequester and store high quantities of organic  
15 carbon (OC) in their sediments relative to other marine and terrestrial habitats. Assessing carbon  
16 stocks, carbon sources, and the transfer of carbon between habitats within coastal seascapes are  
17 each integral in identifying the role of blue carbon habitats in coastal carbon cycling. Here, we  
18 quantified carbon stocks, sources, and exchanges in seagrass meadows, salt marshes, and  
19 unvegetated sediments in six bays along the Pacific coast of California. The salt marshes studied  
20 here contained approximately twice as much OC as did seagrass meadows,  $23.51 \pm 1.77$  kg OC  
21  $m^{-3}$  compared to  $11.01 \pm 1.18$  kg OC  $m^{-3}$ , respectively. Both seagrass and salt marsh sediment  
22 carbon stocks were higher than previous estimates from this region but lower than global and  
23 U.S.-wide averages, respectively. Seagrass-derived carbon was deposited annually into adjacent  
24 marshes during fall seagrass senescence. However, isotope mixing models estimate that  
25 negligible amounts of this seagrass material were ultimately buried in underlying sediment.  
26 Rather, the vast majority of OC in sediment across sites was likely derived from  
27 planktonic/benthic diatoms and C3 salt marsh plants.

28

29 **Keywords:** Carbon cycling, lateral fluxes, seagrass meadow, salt marsh, carbon sequestration

30

31

## 32 1 Introduction

33 As carbon dioxide (CO<sub>2</sub>) concentrations in the oceans and atmosphere continue to rise,  
34 interest in measuring the relative quantities of carbon stored within natural ecosystems has  
35 increased. These assessments can help improve global and regional climate models, the  
36 prediction of future CO<sub>2</sub> concentrations related to sources and sinks, and our broader  
37 understanding of nature-based climate change solutions (Serrano et al., 2019). Coastal habitats  
38 including seagrasses, salt marshes, and mangroves have earned the moniker ‘blue carbon’

39 habitats for their ability to store disproportionately high levels of organic carbon (OC) in their  
40 sediments relative to other habitat types (McLeod et al., 2011). This can be attributed largely to  
41 the tendency for these habitats to exhibit high sediment accretion rates and low decomposition  
42 rates, driven by their exposure to permanent or regular inundation (Peck et al., 2020; Serrano et  
43 al., 2019). This value has led to increasing interest in blue carbon habitats, given their  
44 conservation can prevent significant emissions of carbon (Lovelock et al., 2017; Pendleton et al.,  
45 2012) and their restoration can lead to increased drawdown of atmospheric CO<sub>2</sub> (Freedman et al.,  
46 2009; Greiner et al., 2013).

47

#### 48 **1.1 Carbon stock assessments and their significance**

49 Despite global interest, many regions are still lacking basic information on carbon stocks  
50 and burial rates in blue carbon habitats. This information forms the foundation for more  
51 advanced scientific research and can be extremely valuable within management contexts to  
52 develop informed local and regional climate assessments. Salt marshes and seagrass meadows  
53 cover extensive portions of North America's west coast, yet their carbon stocks have been  
54 relatively understudied compared to other habitats in North America and other blue carbon  
55 habitats in different regions of the world (Ouyang and Lee, 2014; Postlethwaite et al., 2018).

56 Eelgrass (*Zostera marina*) is the dominant seagrass species in North America and  
57 occupies coastal waterways from Alaska to Mexico (Green & Short, 2003). Until recently,  
58 seagrass carbon stock data were almost entirely absent along the west coast of North America  
59 (See Capece et al., 2019; Kauffman et al., 2020; O'Donnell et al., 2017; Poppe & Rybczyk, 2018;  
60 Postlethwaite et al., 2018; Röhr et al., 2018). Of these studies, very few data came from Central  
61 or Southern California seagrass meadows, despite the fact that this region represents a key

62 temperate to subtropical transition in *Z. marina*'s range (Cabello-Pasini et al., 2003). As a result  
63 of the previous paucity of data from the west coast of North America, this region was not  
64 represented in previous global syntheses of seagrass carbon stocks (Duarte et al., 2010;  
65 Fourqurean et al., 2012; Mazarrasa et al., 2015). Existing work on global seagrass carbon storage  
66 identifies that two species of seagrasses in the Mediterranean (*Posidonia oceanica*) and Australia  
67 (*Posidonia australis*) store significantly more carbon than other seagrass species, including *Z.*  
68 *marina* (Fourqurean et al., 2012; Lavery et al., 2013; Prentice et al., 2020). These *Posidonia*  
69 species were overrepresented in some early assessments of total global seagrass carbon storage –  
70 making these global estimates unreliable when applied to management decisions or climate  
71 models (Johannessen & Macdonald, 2016; Kennedy et al., 2010). In reality, the geographic and  
72 interspecies variability in carbon stocks is likely greater than was initially anticipated (Macreadie  
73 et al., 2018; Postlethwaite et al., 2018).

74 Salt marsh carbon stocks are similarly understudied in western North America, with  
75 published carbon stock data from only four estuaries in the region and very minimal spatial  
76 coverage and analyses performed in three of these locations (Brevik and Homburg, 2004;  
77 Callaway et al., 2012; Kauffman et al., 2020; Patrick and DeLaune, 1990). Existing analyses of  
78 North American freshwater wetlands and salt marshes are typically dominated by studies along  
79 the east coast (Nahlik & Fennessy, 2016; Wilkinson et al., 2018; with the exception of Holmquist  
80 et al. 2018). Within west coast studies, considerable variation in carbon stocks is observed  
81 (Callaway et al., 2012; Chmura et al., 2003). Similar to seagrass meadows, these regions have  
82 distinctly different oceanographic and geomorphological regimes, which can drive differences in  
83 sediment carbon storage. Thus, seagrass and salt marsh carbon storage data collected from

84 understudied regions and across varying environmental gradients are necessary for understanding  
85 carbon stock variability and its drivers.

86

## 87 **1.2 Blue carbon sources and drivers**

88         Despite an increasing breadth of information on blue carbon habitats in the last decade, a  
89 number of questions remain before we can fully understand their role in regional carbon cycling  
90 and climate adaptation (Macreadie et al., 2019). We do not yet fully understand what drives  
91 variation in carbon stocks – a key aspect of ensuring the protection and enhancement of these  
92 carbon services in the future. Previous work demonstrates that numerous factors can control  
93 carbon accumulation in coastal sediments including overlying biomass, topography, hydrology,  
94 mineralogy, and remineralization rates (Kelleway et al., 2016; Lima et al., 2020; Mazarrasa et  
95 al., 2018; Prentice et al., 2019). In particular, sediment grain size has been demonstrated as a  
96 significant predictor of carbon stocks (Dahl et al., 2016; O'Donnell et al., 2017; Serrano et al.,  
97 2016), as it affects decomposition rates, which is likely related to the deposition of small  
98 particles and low resuspension from the attenuation of water flow by seagrasses (Bos et al.,  
99 2007; Conley et al., 2017; Gambi et al., 1990; Hendriks et al., 2008). Through similar pathways,  
100 fine, silty sediments trapped in tidal salt marshes can also increase carbon storage (e.g. Zhou et  
101 al., 2007).

102         The relative importance of each potential driver of carbon stock variability may be highly  
103 dependent on the environmental setting, species under study, and the interactive effects of these  
104 drivers. For example, in Australian salt marshes, overlying vegetation was shown to only  
105 significantly affect carbon stocks in sandy and mixed grain size sediments, having no effect on  
106 stocks in fine sediments (Kelleway et al., 2016). However, in other cases vegetation has been the

107 primary predictor of carbon stocks in salt marshes, irrespective of grain size (Lovelock et al.,  
108 2014; Saintilan et al., 2013). Similar region and species-specific complexities between carbon  
109 stocks, overlying vegetation, and mineralogy have been described in seagrass meadows (e.g.  
110 Lima et al., 2020; Serrano et al., 2016), meriting further investigation to understand these  
111 complex interactions.

112         Knowing the relative contributions of locally produced (autochthonous) and imported  
113 (allochthonous) carbon also elucidates the underlying mechanisms by which blue carbon habitats  
114 store and accumulate carbon. Overlying vegetation can significantly impact sediment carbon  
115 stocks; however, it is rarely the dominant source of carbon buried within blue carbon habitats  
116 (Kennedy et al., 2010; Lewis et al., 2020; Mazarrasa et al., 2015; Prentice et al., 2019). In many  
117 cases, contributions from terrestrial habitats, macroalgae, and suspended particulate organic  
118 material contribute as much or more to carbon buried in blue carbon sediments than do  
119 autochthonous sources (Drexler et al. 2020; Kennedy et al., 2010; Leorri et al., 2018; Ricart et  
120 al., 2020). Thus, local primary production could significantly contribute to net annual carbon  
121 drawdown within a given habitat yet play a minor role in carbon burial due to lateral export or  
122 remineralization of this carbon. Understanding this phenomenon elucidates the role of blue  
123 carbon habitats in broader, system-wide energy flows and carbon cycling (Hyndes et al., 2014;  
124 Ricart et al., 2015). For instance, much of the carbon from laterally exported biomass may be  
125 remineralized in the water column or as wrack in nearby habitats (Attard et al., 2019; Liu et al.,  
126 2019), serving an important ecological role and altering the production and biogeochemical  
127 cycles of recipient systems (Hyndes et al., 2014; Ince et al., 2007; Valiela and Cole, 2002).  
128 Given that blue carbon habitats are highly productive (Duarte & Cebrián, 1996), support high  
129 carbon burial (e.g. McLeod et al., 2011), and can co-occur within small geographic ranges

130 (Alongi et al., 2018; Bouillon & Connolly, 2009), laterally exported carbon from one blue carbon  
131 habitat may be entrapped and buried in a neighboring habitat. From this landscape-scale  
132 perspective, exchanges between blue carbon habitats could increase their capacity for carbon  
133 burial or alter the sources of buried carbon. While some coastal studies have estimated lateral  
134 carbon fluxes (Jiménez et al., 2017; Liu et al., 2019), very few studies place these lateral fluxes  
135 into landscape-scale contexts that also address carbon burial in recipient habitats (Bouillon &  
136 Connolly, 2009; Duarte & Krause-Jensen, 2017; Ricart et al., 2017).

137

138 The study presented here addresses this globally relevant topic of research in a relatively  
139 understudied region by answering the following questions:

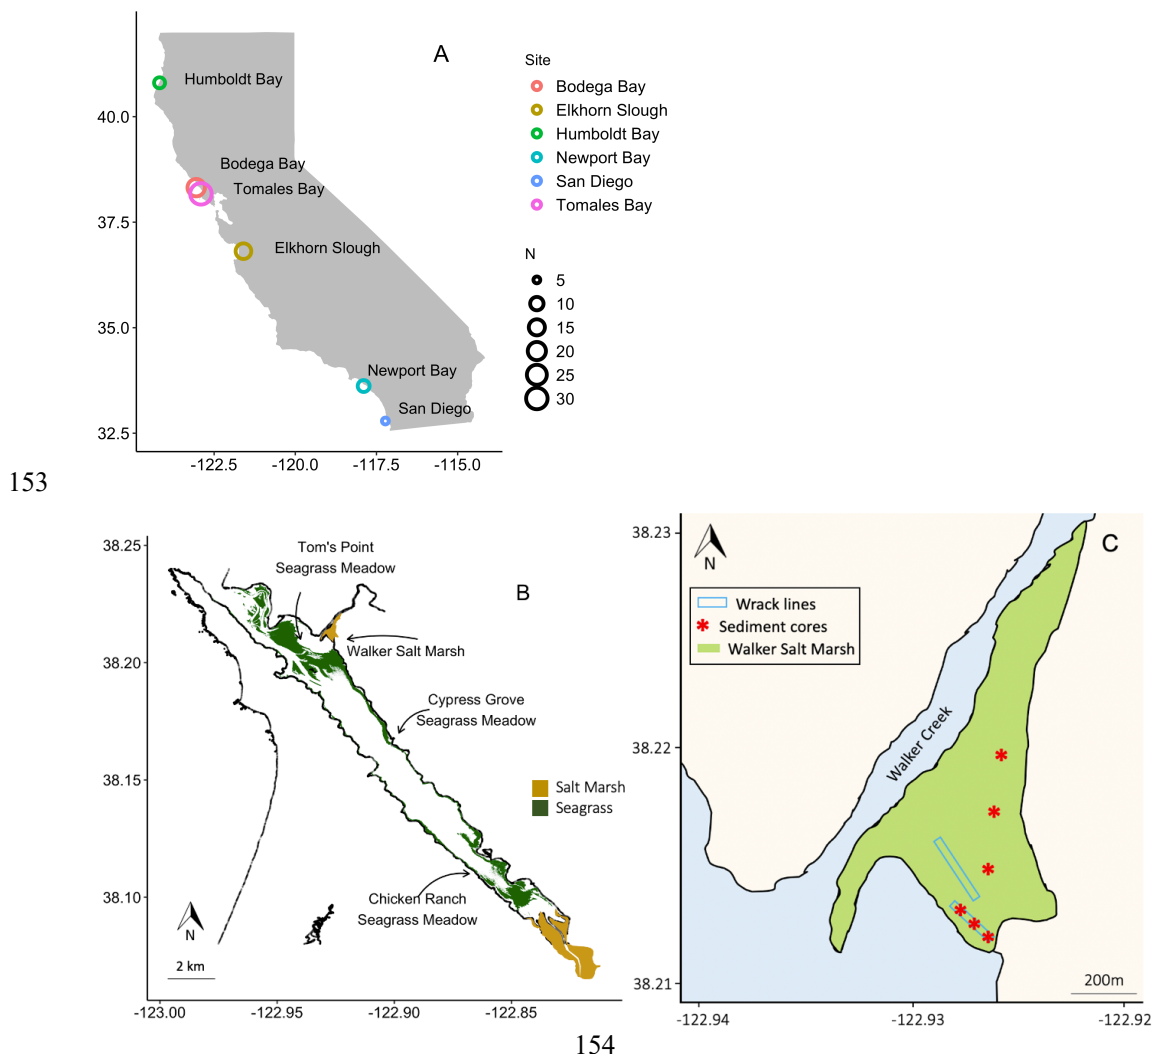

- 140 1) How much organic carbon is stored in seagrass meadow and salt marsh sediments across  
141 a California latitudinal gradient?
- 142 2) What are the sources of carbon buried within these sediments?
- 143 3) Is carbon exchanged between blue carbon habitats within the coastal landscape?

144

## 145 **2 Methods**

### 146 **2.1 Study Sites**

147 Sediment cores from salt marshes and seagrass meadows, along with neighboring  
148 unvegetated sediments (hereafter ‘bare sediment’ near seagrass meadows, and ‘pan’ near salt  
149 marshes) were collected from six bays across a latitudinal gradient in California (Fig. 1a). A total  
150 of 82 sediment cores were collected, 30 of which have been discussed previously (O’Donnell et  
151 al., 2017) and are included here for comparison. The number of cores collected in each site and  
152 general site characteristics are described in Table 1. While all sampled seagrass meadows were

153

154

155 **Figure 1:** Sediment cores were collected from six estuaries across a latitudinal gradient in  
156 California, where N = number of cores (A). Seagrass wrack deposition into Walker salt marsh  
157 from surrounding seagrass meadows (Merkel & Associates, 2017) was estimated, while sediment  
158 cores were taken from all four labeled habitats (B). Three sediment cores were collected beneath  
159 persistent wrack lines in Walker salt marsh, while three were collected from areas that do not  
160 receive regular, annual tidal deposition of wrack (C).

161

162 dominated by a single seagrass species (*Zostera marina*), salt marshes contained a mixed

163 community of halophytes, predominantly composed of pickleweed (*Sarcocornia pacifica*), and

164 to a lesser extent salt grass (*Distichlis spicata*) and marsh jaumea (*Jaumea carnosa*). Bare  
165 sediment cores were collected in unvegetated sediment nearby each seagrass meadow at a  
166 minimum of 20 meters away from the meadows and from similar depths. Pan cores  
167 were collected from patches of unvegetated sediment (2-4m diameter) found within the salt  
168 marsh interior, a natural and semi-permanent feature of salt marsh habitats formed by elevational  
169 depressions (Escapa et al., 2015). None of our sampling sites were actively restored and, to our  
170 knowledge, have persisted through time.

171 We estimated OC stocks in seagrass, salt marsh, pan, and bare sediments (see details below).  
172 In addition, we analyzed sediment OC sources for two individual salt marshes in Elkhorn Slough  
173 ('Elkhorn salt marsh') and Tomales Bay ('Walker salt marsh'), and we examined carbon  
174 exchange between a single seagrass meadow and the neighboring Walker salt marsh. Walker salt  
175 marsh is located approximately 5.5 km from the mouth of Tomales Bay and is in close proximity  
176 to extensive meadows of *Z. marina* – the dominant seagrass in each of the meadows sampled  
177 (Fig. 1b). This marsh lies where the mouth of Walker Creek meets bay waters, and thus can  
178 receive terrestrial and riverine inputs, while simultaneously receiving marine inputs from tidal  
179 exchange.

Bay	Coordinates	Number of cores	Site description
Humboldt Bay	40°48'12 N, 124°10'52 W	Seagrass: 4 Bare sediment: 3	A large semi-enclosed bay with a narrow mouth, stabilized by jetties. Primary freshwater sources come from the Elk River and its tributaries, with Freshwater Creek inputs entering the bay near the sampling site. Freshwater input is small relative to tidal flushing but can locally effect sedimentation rates within the bay (Schlosser and Eicher, 2012)
Bodega Harbor	38°19'60 N, 123°02'53 W	Seagrass: 15 Bare sediment: 3	There are no significant rivers or creeks that provide freshwater or sediment inputs. Sediment input in Bodega Bay is largely controlled by jetties at the mouth of the harbor and is influenced by its history of routine dredging to maintain shipping channels and

			control wind-blown sand entering from nearby dunes
Tomales Bay	38°10'17 N, 122°54'46 W	Seagrass: 15 Bare sediment: 9 Salt Marsh: 6	A long, narrow bay that receives periodic freshwater inputs from two primary tributaries, Walker Creek and Lagunitas Creek, which peaks seasonally during winter storms.
Elkhorn Slough	36°49'15 N, 121°45'06 W	Salt Marsh: 11 Pan: 3	Receives periodic freshwater inputs from the Old Salinas River and Bennett and Moro Coho Sloughs. After a long history of increasing sediment deposition and slowing tidal flow to the bay, levee breaches and removals in 1953 rapidly converted it to a higher tidal energy, erosional system, as it remains today (Van Dyke and Wasson, 2005). As a result, the extent of 'high-quality' salt marsh in 2000 was 23% of what it had been a century earlier (Van Dyke and Wasson, 2005)
Newport Bay	33°38'07 N, 117°53'17 W	Seagrass: 4 Bare sediment: 4	An urban bay, that receives terrestrial and urban inputs from the San Diego Creek Watershed. After a long history of high sedimentation and water quality nutrient impairments from urban and agricultural sources, a program was implemented in 1998 to meet water quality targets. Since its commencement, both sedimentation and nutrients in the bay have significantly decreased (County of Orange, 2019).
Mission Bay	32°47'24 N, 117°13'40 W	Seagrass: 3 Bare sediment: 2	An urban, enclosed bay, that receives terrestrial and urban input from the San Diego River watershed and the Rose Creek tributary. Experiences long residence times and is primarily controlled by tidal flushing processes rather than the minimal freshwater inputs (Cyronak et al., 2018; Largier et al., 1997)

180  
 181 **Table 1:** The location and a brief description of each bay sampled is included here, along with  
 182 the total number of cores collected from each habitat type in each of these bays.  
 183

184 **2.2 Carbon stocks**

185 All sediment cores were sampled by manually inserting transparent, open-barrel PVC pipes  
 186 (20 cm length, 5.08 cm diameter). Compaction occurred in 19% of cores, and a compaction  
 187 factor was applied when calculating carbon stocks according to Howard et al. (2014). Once

188 extracted, cores were capped and transported to the laboratory upright to prevent mixing of  
189 sediment layers. Cores were then immediately extruded into sections at 2 cm intervals. Coarse  
190 living plant material (> 1cm) was manually removed. Each section was dried at 60°C and  
191 weighed, and dry bulk density (DBD) was determined by dividing dry bulk mass by the volume  
192 of sampling interval.

193 Each section was then homogenized and divided into three subsamples of 10 g each, and the  
194 remaining sample was archived. One of the three subsamples was acidified using 1.12 M HCl to  
195 remove and measure total inorganic carbon (Milliman 1974). The second subsample was  
196 analyzed for total organic material (TOM) by loss-on-ignition method for 4 hours at 550° C  
197 (Dean 1974). Total C content (%) and  $\delta^{13}\text{C}$  were additionally determined on a set of 44 of the  
198 acidified subsamples randomly selected across each habitat type using an elemental analyzer  
199 (PDZ Europa ANCA-GSL, SD  $\pm$  0.25 %) integrated with a continuous flow isotope ratio mass  
200 spectrometer (PDZ Europa 20-20, SD  $\pm$  0.2 ‰) at the UC Davis Stable Isotope Facility.  $\delta^{13}\text{C}$   
201 ratios are expressed in parts per thousand (‰) relative to VPDB (Vienna Pee Dee Belemnite)  
202 according to standard notation ( $\delta^{13}\text{C} = [(R_{\text{sample}} / R_{\text{standard}}) - 1] \times 1000$ , where R is the ratio  
203  $^{13}\text{C}/^{12}\text{C}$ ). Organic carbon in each core section was then estimated using a power model developed  
204 between measured TOM and measured OC in this set of subsamples (as in Craft et al., 1991).  
205 Specifically, the equation  $y = 0.22x^{1.1}$  was applied ( $r^2 = 0.84$ ; Fig. S1). A power model was  
206 selected over a linear model for these data to avoid negative estimates of carbon stocks at low  
207 levels of TOM (Fig. S1). Carbon stocks were determined by multiplying DBD ( $\text{g cm}^{-3}$ ) by %  
208 OC.

209 In each core section, the proportion of fine sediments – the silt and clay fraction (<63  $\mu\text{m}$ ),  
210 hereafter “mud” – was quantified. The grain size analysis was conducted by mass loss in the

211 third subsample from each section in 70 of the 82 total cores. The subsample was rinsed through  
212 a 63  $\mu\text{m}$  sieve with deionized water, and the remaining sediments were dried at 60°C and re-  
213 weighed.

214

## 215 **2.2 Carbon sources and exchange**

216 We applied mixing models to assess salt marsh sediment carbon sources to understand  
217 within-estuary exchange of carbon in the sampled habitats. Two separate mixing models were  
218 produced in 1) Elkhorn salt marsh in Elkhorn Slough and Walker salt marsh in Tomales Bay, and  
219 2) salt marsh sediments under seagrass wrack, versus not under wrack in Walker salt marsh. At  
220 Walker salt marsh, a total of six sediment cores were collected. Three of these sediment cores  
221 were collected from the interior marsh, while three were collected from underneath a seagrass  
222 wrack line along the tidal edge of the marsh (Fig. 1c). *Z. marina* in this region is known to  
223 undergo a period of senescence as photoperiod shortens in the fall, as is common in all temperate  
224 seagrasses (Fourqurean et al., 1997). Historical imagery of the site shows persistent seagrass  
225 wrack concentrated along these tide lines that consistently appears in early fall as seagrass  
226 senesces (Fig. S2; Google Earth, 2020). The biomass of seagrass wrack along this tide line at the  
227 time of core collection was quantified along an 80 m transect within the marsh by collecting all  
228 seagrass present in a 1 m<sup>2</sup> quadrat every 10 meters. This material was taken back to the lab,  
229 sorted into above ground biomass (AGB) and below ground biomass (BGB), rinsed, dried  
230 (60°C), and weighed. Biomass data from seagrass in nearby meadows was previously published  
231 (see O'Donnell et al., 2017) and is used here for reference. Sediment cores collected from  
232 beneath wrack lines were sectioned at 2 cm intervals, analyzed for total OC and  $\delta^{13}\text{C}$  content  
233 according to the methods described above. Total nitrogen content was also determined on an

234 unacidified portion of the same 44 sediment subsamples used in carbon analyses  
235 (ThermoFinnigan Flash 1112 Series elemental analyzer,  $SD \pm 0.02\%$ ). Data from Walker salt  
236 marsh are also displayed as ‘shallow’ (surface sediment to 10 cm deep) and ‘deep’ (10 cm and  
237 deeper), to facilitate interpretation of changes with depth.

238 The contributions of carbon sources to each core section were then estimated with a mixing  
239 model using  $\delta^{13}\text{C}$  and N:C ratios as tracers. Given  $\delta^{15}\text{N}$  can be altered during early diagenesis  
240 (e.g. Benner et al., 1991), we selected  $\delta^{13}\text{C}$  and C:N ratios as the primary geochemical tracers,  
241 and therefore did not include fractionation factors into the model (Craven et al., 2017). N:C  
242 ratios are utilized rather than C:N ratios because mixed fractions returned by the model are based  
243 on the denominator, and thus  $^{13}\text{C}/^{12}\text{C}$  and N:C both estimate the fractional contribution of  $^{12}\text{C}$   
244 (Craven et al., 2017; Perdue and Koprivnjak, 2007). However, C:N ratios are used in text and  
245 figures given this format is more typically presented in the literature. We used a Bayesian mixing  
246 model SIAR 4.2 (Parnell and Jackson, 2013) to estimate the contributions of four source groups  
247 selected according to the dominant plant and algal species observed within the selected salt  
248 marshes. The four sources included C3 salt marsh plants (*Sarcocornia sp.*, *Grindelia stricta*), C4  
249 salt marsh plants (*Distichlis spicata*), seagrass (*Z. marina*), and plankton/benthic diatoms.  
250 Representative geochemistry for all of these sources (aside from seagrass) have been published  
251 previously and were used here, from samples collected in San Francisco Bay, approximately 60  
252 km south of Walker salt marsh (see Cloern et al., 2002 for full methods). All salt marsh sediment  
253 cores were collected from areas of the marsh that were dominated by these four species, and as  
254 such, other marsh species were not considered (e.g. *Spartina sp.*). While lower densities of other  
255 C3 marsh plants may have been present in some cored sites, the variability demonstrated by the  
256 selected source samples likely encompasses much of this variability given the utilization of the

257 same photosynthetic pathway (Cloern et al., 2002). Plankton samples were collected from  
258 estuarine water samples while benthic diatom samples were collected from both salt marsh  
259 surface sediments and neighboring mudflats (Cloern et al., 2002). Isotopic signatures from the  
260 benthic diatoms and estuarine plankton measured here are distinct from the other selected  
261 sources but overlap with one another (Cloern et al., 2002). Thus, we pooled these data and refer  
262 to this source as ‘diatoms’ hereafter, acknowledging that this also encompasses contributions  
263 from other planktonic and benthic sources. Seagrass geochemistry was estimated from seagrass  
264 leaves collected from meadows near the selected salt marshes in Newport Bay, Tomales Bay,  
265 and Bodega Bay (Fig. 1a; Capece et al., 2019).

266

### 267 **2.3 Statistical Analyses**

268 To evaluate decay of carbon through time, we tested for significant changes in OC in each  
269 habitat type with core section depth (a proxy for time) by fitting data to a generalized linear  
270 mixed model (GLMM) using maximum likelihood with ‘depth’ and ‘site’ as fixed effects and  
271 ‘core’ as a random effect, using a gamma distribution and log link function to account for non-  
272 normality. In sites and habitats that demonstrated significant OC changes with depth, the rate of  
273 decay was estimated from the slope of its associated model. In all analyses to follow, OC across  
274 all sections in each core were averaged, and statistics were performed on these core averages.  
275 After inspecting data for normality and homogeneity of variance, differences in OC and grain  
276 size between habitat types and between sites were analyzed using simple linear models (SLM;  
277 significance defined by  $\alpha = 0.05$ ). Specifically, these data were fit to a linear model using  
278 ordinary least squares with ‘site’ and ‘habitat’ (i.e. seagrass, salt marsh, bare sediment, pan) as  
279 fixed effects, including their interaction. The relationships between TOM (%) and grain size

280 were analyzed using simple linear regressions, whereby a grain size filter was selectively applied  
281 to determine the point at which the relationship between the two was no longer significant ( $p <$   
282  $0.05$ ). Differences in  $\delta^{13}\text{C}$  (‰) or C:N ratios between sediment depth ('surface' versus 'deep'),  
283 and between sediments collected under wrack versus not under wrack, were also tested with  
284 SLMs using ordinary least squares with 'depth' or 'under wrack' as fixed effects. When  
285 necessary, data were log transformed. Tukey's post-hoc analyses were conducted for multiple  
286 comparisons. All statistical analyses were performed in R software (R Core Team, 2018).

287

### 288 3 Results

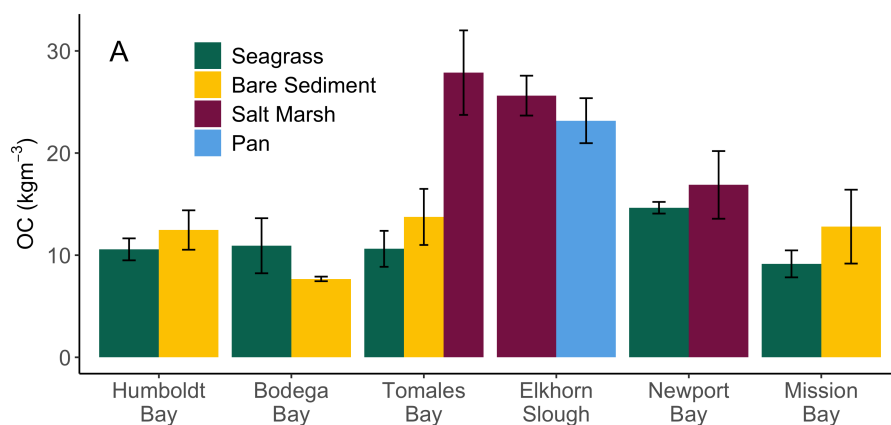

#### 289 3.1 Carbon Stock Assessments

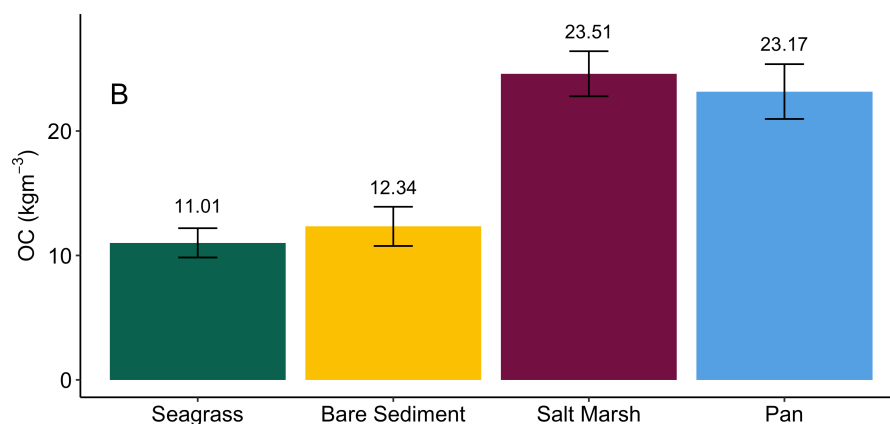

**Figure 2 (left):** Down core trends (surface = 0 cm) in average ( $\pm$  SE) OC ( $\text{kg m}^{-3}$ ) for each habitat type and site. Data show an insignificant decline in OC through time (downcore) in all sites except Newport Bay salt marshes.

309 Down core OC demonstrates high variability, resulting in few significant differences in  
310 OC with depth (Fig. 2). Specifically, only Newport Bay salt marsh sediments exhibited  
311 significant loss of OC down core, which declined at a rate of  $0.95 \text{ kg C m}^{-3} \text{ per cm}$  (Fig 2e;  
312 GLMM, T-value = -4.7, SE = 0.01,  $p < 0.05$ ). Significant differences between OC stocks  
313 emerged when cores were compared between habitats, with salt marshes containing significantly  
314 more carbon than both bare sediment and seagrass meadows (Fig. 3b; SLM,  $p < 0.01$ , F-statistic  
315 = 13.3, DF = 3). Specifically, salt marsh sediments contained  $23.51 \pm 1.77 \text{ kg OC m}^{-3}$ , while  
316 seagrass meadows contained  $11.01 \pm 1.18 \text{ kg OC m}^{-3}$  (Fig. 3b; mean  $\pm$  SE). Seagrass meadow  
317 carbon stocks were not significantly different than those of nearby bare sediments (Tukey's post-  
318 hoc analysis,  $p > 0.05$ ), which contained an average of  $12.34 \pm 1.57 \text{ kg OC m}^{-3}$ . Pan sediments  
319 also contained higher carbon than did seagrass meadows (Tukey's post-hoc analysis,  $p > 0.05$ ).  
320 A full list of carbon stocks is displayed in Table S1. Tukey's post-hoc analysis indicates that in  
321 Tomales Bay, salt marshes contained significantly more carbon than seagrass meadows (Fig. 3a;  
322  $p < 0.05$ ) while bare sediment and seagrass carbon stocks did not significantly differ from one  
323 another ( $p > 0.05$ ). We did not detect any other significant differences when comparing carbon  
324 stocks across habitat types within each individual site (Tukey's post-hoc analysis,  $p > 0.05$ ).

325

326

327 **Figure 3:** Average ( $\pm$  SE) total organic carbon (OC) stocks ( $\text{kg m}^{-3}$ ) across all cores collected  
328 from each habitat type within each site in this study (A). Average ( $\pm$  SE) total organic carbon  
329 stocks ( $\text{kg m}^{-3}$ ) across all cores collected within each habitat type in this study (B).  
330

331 We observed a very strong relationship between grain size and storage of organic material,  
332 especially at lower TOM (%) values (Fig. 4). Specifically, the observed linear relationship  
333 between grain size and TOM is strongest when sediment is 8.5% TOM or less (linear model,  $r^2 =$   
334  $0.95$ ,  $p < 0.05$ , F-statistic = 4957, DF = 269). However, as the proportion of fine sediments in  
335 each sample increases, the relationship between grain size and TOM weakens, with no  
336 significant relationship between the two in sediments consisting of more than 36% mud (SLM,  $p$   
337  $> 0.05$ , F-statistic = 3.9, DF = 232). Our results indicate that grain size was similar between sites  
338 (SLM,  $p > 0.05$ , F-statistic = 2.7, DF = 3) but differed between habitat types (Fig. 5a; SLM,  $p <$   
339  $0.05$ , F-statistic = 5.7, DF = 3), with salt marsh sediments demonstrating significantly greater %  
340 mud than both seagrass and bare sediment (Tukey's post-hoc analysis,  $p < 0.05$ ). Recognizing  
341 that the sample size of pan cores was low, pan sediments displayed comparable % mud to salt  
342 marsh sediments but there were no significant differences between pan grain size and the other  
343 habitat types' grain sizes (Tukey's post-hoc analysis,  $p > 0.05$ ). Tukey's post-hoc analyses did

344 not indicate any significant differences in grain size between habitat types within each site (Fig.  
345 5a;  $p > 0.05$ ).

346

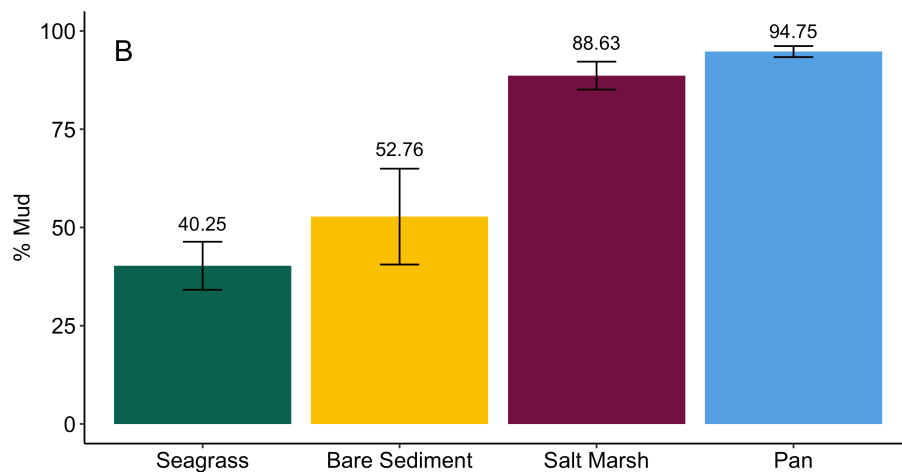

347 **Figure 4:** Biplot showing the relationship among total organic material (TOM) (%) of each 2-cm  
348 core section from each habitat type plotted against sediment grain size (% Mud).

356 (B).  
357

### 358 3.2 Carbon Sources and Exchange

#### 359 3.2.1 Wrack Deposition

360 While we conducted only one ground survey of seagrass wrack lines within Walker salt  
361 marsh in October 2019, historical aerial imagery was utilized to verify that these wrack lines  
362 appear reliably in this season in similar locations each year (Fig. S2). This phenomenon can be  
363 viewed as far back as 2002, before which images are of low quality or unavailable (Google  
364 Earth, 2020). These wrack lines typically persist throughout the winter, becoming indiscernible  
365 via aerial imagery by spring. Previous data collected by the authors (O'Donnell et al., 2017)  
366 demonstrated this senescence within the nearby Tom's Point seagrass meadow (Fig. 1b), where  
367 average summer seagrass biomass was  $440 \pm 59.4 \text{ g m}^{-2}$  and winter biomass was  $115 \pm 16.5 \text{ g m}^{-2}$   
368 (AGB and BGB, mean  $\pm$  SE; Table 2). Within the neighboring Walker salt marsh, fall estimates  
369 of wrack demonstrated that  $106 \pm 24.6 \text{ g m}^{-2}$  of seagrass (dry weight) was deposited along tide  
370 lines (Table 2). While both seagrass AGB and BGB are included in this value, seagrass BGB

371 only accounted for 3.5% of total seagrass biomass measured (Table 2). Analysis of seagrass  
372 leaves collected from Tomales Bay demonstrated that seagrass material was composed of 31.6%  
373 of OC. Thus, we estimate Walker salt marsh receives  $33.4 \pm 7.6$  g OC m<sup>-2</sup> in the form of seagrass  
374 along wrack lines each year.

	Seagrass (winter) (g/m <sup>2</sup> )	Seagrass (summer) (g/m <sup>2</sup> )	Wrack (g/m <sup>2</sup> )	Wrack carbon (gC/m <sup>2</sup> )
<b>AGB</b>	58.6 ± 14	361.3 ± 47.8	102.8 ± 24	32.5 ± 7.6
<b>BGB</b>	57.1 ± 4.6	79 ± 15.5	3.7 ± 2.6	1.2 ± 0.8
<b>Total</b>	115.7 ± 16.5	440.3 ± 59.4	105.7 ± 24.6	33.4 ± 7.8

375

376 **Table 2:** Living seagrass above ground biomass (AGB) and below ground biomass (BGB) was  
377 collected in Tom's Point seagrass meadow (Fig. 1b) in both summer and winter (g m<sup>-2</sup>). Total  
378 seagrass wrack delivered to Walker salt marsh was quantified as AGB and BGB (g m<sup>-2</sup>) and  
379 converted to carbon (g C m<sup>-2</sup>) using a 31.6% carbon conversion rate.  
380

### 381 3.2.2 Sediment Carbon Sources

382 In Walker salt marsh, surface (< 10 cm) wrack sediments had higher  $\delta^{13}\text{C}$  values than  
383 sediments collected from the interior of the marsh (non-wrack sediments) and thus were more  
384 similar to the  $\delta^{13}\text{C}$  values of seagrass (Fig. 6; SLM,  $p < 0.05$ ; F-statistic = 27.3; DF = 18).  
385 Shallow wrack sediments had an average  $\delta^{13}\text{C}$  of  $-22.5 \pm 0.38$  ‰, while non-wrack sediments  
386 had an average  $\delta^{13}\text{C}$  of  $-24.9 \pm 0.26$  ‰ (mean ± SE). However, when both shallow and deep  
387 (>10cm) sediments were included, wrack sediment  $\delta^{13}\text{C}$  did not significantly differ from non-  
388 wrack sediments (SLM, DF = 31, F-statistic = 0.34,  $p > 0.05$ ). C:N sediment ratios did not  
389 significantly differ from one another regardless of collection depth or location (SLMs,  $p > 0.05$ ).  
390 When data were applied to a mixing model, apparent discrepancies in seagrass-derived carbon  
391 contributions between shallow and deep, and wrack and non-wrack sediments were insignificant

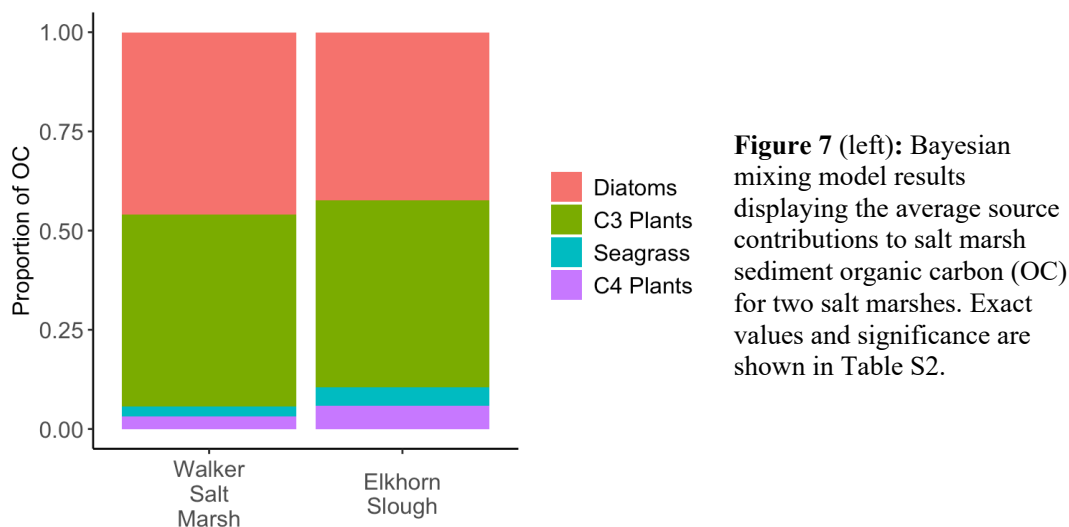

392 (SIAR mixing model, Table S2). Similarly, no significant quantity of seagrass-derived carbon  
393 was detected in Elkhorn salt marsh sediments (SIAR mixing model, Table S2). Rather, models  
394 estimate that sediments were derived from an estimated 47% salt marsh C3 plants and 42%  
395 diatoms in Elkhorn Slough, and 49% salt marsh C3 plants and 46% diatoms in Walker salt marsh  
396 (Fig. 7; Table S2). Thus, regardless of site, depth, or the presence of wrack, model results  
397 estimate no significant storage of seagrass-derived carbon in sediment (Table S2). Instead, C3  
398 plants and diatoms are the only two significant contributors to underlying carbon storage across  
399 salt marshes in all locations.

400

401 **Figure 6:** Points represent the  $\delta^{13}\text{C}$  and C:N ratios of Walker Salt Marsh sediment data, collected  
402 from underneath persistent wrack lines (blue) and from areas free of wrack (red) (Fig. 1c).  
403 Sediment subsamples collected from the surface to 10cm deep are labelled as surface samples  
404 (square) and below 10cm are labelled as deep samples (circle). Colored boxes represent sources  
405 (means  $\pm$  SD) from diatoms (purple), seagrass (green), C4 salt marsh plants (red), and C3 salt  
406 marsh plants (yellow).  
407

**Figure 7 (left):** Bayesian mixing model results displaying the average source contributions to salt marsh sediment organic carbon (OC) for two salt marshes. Exact values and significance are shown in Table S2.

## 421 4 Discussion

### 422 4.1 Carbon Stocks

423 The lack of clear downcore trends suggests relative OC stability with depth and through time  
424 (Fig. 2). This is further supported by the persistence of this pattern in seagrass and bare sediment  
425 sites where longer cores were available (Fig. S3). In the only site with significant downcore OC  
426 losses (Newport Bay salt marsh), this pattern may be explained by historic hydrographic  
427 changes. Specifically, previous sediment profiles from this region also found finer surface  
428 sediments above coarser materials – associated with the conversion from an erosional to a  
429 depositional system in the early 20<sup>th</sup> century due to urbanization of the surrounding area  
430 (Trimble, 2003). This change in grain size downcore may drive the associated OC loss down  
431 core, discussed further below. Although we did not quantify sediment carbon accumulation rates  
432 here, previous work in Tomales Bay seagrass meadows indicate rates of 11.37 - 15.16 g C m<sup>-2</sup> yr<sup>-1</sup>  
433 (O'Donnell et al., 2017). By these accumulation rate estimates, we estimate the top 20 cm of  
434 sediment sampled here accumulated over approximately 100-130 years. Given the relatively

435 slow accumulation rates and lack of down core trends, we interpret that our data represent  
436 realistic stock assessments for each respective habitat and location, rather than being reflective of  
437 shallow surface sediment carbon stocks.

438 Determining drivers of OC storage variation across habitats is notably complex, where a mix  
439 of factors such as grain size, elevation, hydrodynamic energy, and vegetation type may influence  
440 underlying sediment OC storage (Kelleway et al., 2016; Lima et al., 2020; Miyajima et al.,  
441 2015). Here, sediment grain size and its associated drivers allow us to further examine variation  
442 in sediment OC storage variation. Specifically, grain size likely contributed to the observed inter-  
443 habitat differences in OC storage, given its strong correlation with TOM. Despite no significant  
444 differences in grain size between habitat types within each site (likely due to high grain size  
445 variability and low relative sample sizes), apparent qualitative differences elude to possible  
446 explanations of stock differences. For example, seagrass sediments had lower % mud than salt  
447 marsh sediments in Tomales Bay, a trend that was reversed in Newport Bay (Fig. 5a; Table S1).  
448 Similarly, seagrass sediments did not always contain a higher % mud than neighboring bare  
449 sediments, contrary to what is typically reported (Bos et al., 2007; Conley et al., 2017; Mazarassa  
450 et al., 2015), which may explain their apparent lack of sediment OC differences. Overall, salt  
451 marshes had greater OC storage and smaller average grain size than seagrass meadows. The  
452 periodic, lower energy inundation of the sampled marsh and pan habitats may facilitate the  
453 observed smaller grain sizes – by preventing the resuspension of small particles that might occur  
454 in higher hydrodynamic energy or submerged systems (Christiansen et al., 2000; Yang et al.,  
455 2008). In marsh and pan habitats, biological factors such as primary production and  
456 decomposition rates may become more important drivers of carbon burial than would be true in  
457 dominantly sandy sediments (Miyajima et al., 2017). Yet despite the absence of vegetation in

458 pan sites, we did not observe significant differences in carbon stocks between pan sediments and  
459 surrounding salt marsh sediments. This could be attributed to 1) significant carbon contributions  
460 from surrounding salt marsh biomass to pan sites overtime, 2) historical marsh recovery along  
461 pan edges and subsequent burial of vegetation captured in pan cores, 3) variable decomposition  
462 rates in both pan and salt marsh sediments, or 4) because the expected effect of canopy-  
463 vegetation on salt marsh sediment is too small relative to other drivers, producing statistically  
464 insignificant results. In sum, although seagrasses and salt marshes can facilitate carbon storage  
465 by altering grain size distributions, hydrodynamics and geomorphology play a critical role in  
466 grain size distributions and therefore, carbon storage. The hydrographic changes in Newport Bay  
467 salt marshes associated with decreased grain sizes further emphasize this point – drawing  
468 attention to the importance of watershed and sediment management to regional carbon storage.  
469 Furthermore, although grain size is clearly a key driver in carbon storage, our data demonstrate  
470 that it becomes of limited use as a predictor of carbon stocks after the proportion of mud exceeds  
471 36% (Fig. 4). This demonstrates that using grain size as a cost-effective way to estimate carbon  
472 stocks (as has been suggested, e.g. Serrano et al., 2016) only appears possible in sandy and  
473 mixed grain size sediments within the sites studied here. Stocks in fine sediment sites above this  
474 threshold cannot be estimated using grain size alone – a management-relevant finding for efforts  
475 to incorporate habitat-specific carbon storage into regional climate plans.

476

#### 477 **4.2 Global and Regional Comparisons**

478 With recent meta-analyses on coastal carbon stocks in salt marshes and seagrass meadows,  
479 we can compare our data to global and regional averages (no sufficient syntheses of pan or bare

480 sediment carbons stocks were identified). We find that carbon storage in California seagrass  
 481 sediments studied here is lower than global estimates yet is higher than regional estimates of *Z.*

Study	Habitat Type/Species	Location(s)	Value (Mg C <sub>org</sub> ha <sup>-1</sup> )
Seagrass			
This study	Seagrass ( <i>Z. marina</i> )	California	110 ± 11.8
Kauffman et al. (2020)	Seagrass ( <i>Z. marina</i> )	* U.S. west coast	80 ± 12
Prentice et al. (2020)	Seagrass ( <i>Z. marina</i> )	U.S. west coast	65.12
Rohr et al. (2018)	Seagrass ( <i>Z. marina</i> )	* U.S. west coast  * Temperate Northern Hemisphere	69.4 ± 8.4  108.9 ± 39.56
<sup>1</sup> Fourqurean et al. (2012)	Seagrass	Global	<sup>1</sup> 139.7
Salt Marsh			
This study	Salt marsh dominated by <i>Sarcocornia pacifica</i> , <i>Distichlis spicata</i> and <i>Jaumea carnosa</i>	California	235 ± 17.7
Kauffman et al. (2020)	Salt marsh dominated by <i>Distichlis spicata</i> and <i>Sarcocornia perennis</i>	* U.S. west coast	190 ± 16
Holmquist et al. (2018)	Tidal wetlands (mixed, dominated by estuarine emergent vegetation)	* Conterminous U.S. tidal wetlands	270 ± 1.4

482  
 483 **Table 3:** Summary of previously reported carbon stock assessments in seagrass meadows and  
 484 tidal wetlands, all normalized to the top 1m of sediment. Studies that included any data from  
 485 California are denoted by an asterisk. Values are reported as mean ± SE, unless otherwise noted.  
 486 <sup>1</sup>Fourqurean et al. (2012) value represents median OC storage.  
 487

488 *marina* from the U.S. west coast (Table 3). Early estimates from the US west coast were  
 489 markedly low, with one study of *Z. marina* from British Columbia measuring average stocks of  
 490 1.34 kg C m<sup>-3</sup> with a maximum OC of 1.3%, compared to the 11.01 ± 1.18 kg C m<sup>-3</sup> and a  
 491 maximum OC of 7.0 % estimated here (Postlethwaite et al., 2018). While estimates from studies  
 492 averaging over broader U.S. West coast regions are higher than this Canadian case study (Table  
 493 3), the data presented here are still higher than regional estimates, suggesting possible latitudinal

494 difference in carbon storage between the northern and southern regions of the North American  
495 west coast. This is not unsurprising given the variation in environmental and geomorphic  
496 conditions over this large stretch of coastline, which likely influence the carbon storage capacity  
497 along with the factors discussed here such as hydrodynamics or grain size conditions.

498 Recent studies of the U.S. west coast and of conterminous U.S. tidal wetlands allow for  
499 comparison with salt marsh data collected here. Much like with seagrass meadows, California  
500 salt marsh carbon storage was also higher than previous estimates from the U.S. west coast  
501 (Kauffman et al., 2020; Table 3). Both the data presented here as well as those from Kauffman et  
502 al. (2020) (Table 3) were collected from similar marsh zones and species compositions, reducing  
503 some potential for these factors to result in the observed differences in carbon stocks. Previous  
504 work has found that high-marsh zone sediments are likely to contain greater OC than mid- and  
505 lower-marsh zones, and that less inundation can facilitate increased root productivity and  
506 increased OC (the sites presented here would be considered ‘lower-marsh zones’) (Blum, 1993;  
507 Connor et al., 2001; Zhou et al., 2007). Moreover, sediments beneath other common marsh  
508 species in this region (e.g. *Spartina sp.*) were not sampled, yet may have differing productivity  
509 levels, resulting in OC stock differences. This may contribute to the variation between our  
510 estimated salt marsh carbon stock and that of conterminous U.S. tidal wetlands (Holmquist et al.,  
511 2018), which includes a variety of habitat types including forested and shrub-dominated tidal  
512 wetlands.

513

#### 514 **4.1 Carbon Sources and Exchanges**

515 Across both salt marshes assessed in this study, diatoms and C3 plants were the dominant  
516 carbon sources in sediment. Although the isotopic signatures resulting from C4 and seagrass

517 sources are poorly resolved, lack of a significant signature from either source allows for  
518 interpretation. Specifically, neither C4 plants nor seagrasses significantly contributed to the OC  
519 sources in sediment. Thus, despite similar isotopic signatures, if some seagrass-derived organic  
520 matter was buried under wrack sediments, we would expect to see higher  $\delta^{13}\text{C}$  values in wrack  
521 sediments with depth. The insignificant differences in  $\delta^{13}\text{C}$  between wrack and non-wrack  
522 sediments suggest that seagrass is not ultimately being buried, but rather, carbon derived from  
523 C3 plants and diatoms are ultimately retained in sediment.

524 Several underlying causes may lead to this high proportion of diatom and C3-derived carbon  
525 (Fig. 7). The recalcitrance of both autochthonous and allochthonous material in sediment can  
526 vary depending on the material's composition (e.g. Burdige, 2007), and thus knowing the  
527 sources and composition of deposited material aids in understanding its chance of long-term  
528 burial. In seagrass meadows, previous work demonstrated that seagrass BGB likely contributes  
529 most to autochthonous carbon burial when compared to AGB, due to higher proportions of  
530 refractory compounds and decreased grazing pressure (Trevathan-Tackett et al., 2017). This may  
531 serve to explain our lack of seagrass signal in salt marsh sediments under wrack. Seagrass wrack  
532 material deposited on top of the salt marsh is predominantly AGB, likely breaking down or being  
533 transported elsewhere before any appreciable portion reaches long-term sediment carbon pools.  
534 Instead, the dominant C3 signal is likely driven by the presence of pickleweed species  
535 (*Sarcocornia sp.*), which have a considerable portion of below ground biomass. Despite the  
536 presence of salt grass (*Distichlis spicata*), the lack of C4-derived carbon in sediment may be due  
537 to a few potential factors: 1) salt grass is less common relative to pickleweed within our sites, 2)  
538 based on our field observations, root systems of salt grass do not seem to penetrate as deeply or  
539 contain as much BGB as do those of pickleweed, and 3) salt grass contains less woody tissue

540 than pickleweed, making it less refractory (Jepson Flora Project, 2020). In the case of diatom and  
541 planktonic sources, their significant presence in sediment may be due to a greater abundance  
542 overall, or due to complex preservation pathways such as the facilitation of carbon burial by  
543 binding sediments through extracellular polymeric substances (Drexler et al., 2020; Macreadie et  
544 al., 2019; Oakes and Eyre, 2013).

545 From the seasonal senescence indicated by seagrass meadow biomass data (Table 2), we  
546 infer that a significant amount of seagrass AGB biomass is either degraded within the meadow or  
547 exported for remineralization or deposition elsewhere. Given that strong tidal flows can occur  
548 within meadows and that high densities of seagrass wrack were observed in a neighboring salt  
549 marsh, lateral export of AGB from the meadow is likely. Nonetheless, the majority of OC  
550 deposited into the marsh in the form of seagrass wrack is likely remineralized over the course of  
551 the year – with wrack decomposition outpacing a sediment accumulation rate that might support  
552 carbon preservation. While wrack remineralization can support local estuarine food web  
553 metabolism, it can also produce emissions (Jiménez et al., 2017; Liu et al., 2019). However,  
554 these emissions are small when compared to the levels of carbon sequestration within the marsh  
555 – if all of the seagrass wrack along the wrack lines was remineralized annually, this degradation  
556 would only contribute  $33 \pm 7.8 \text{ g C m}^{-2}\text{yr}^{-1}$  to the atmosphere (Table 2). For comparison, dating  
557 (primarily  $^{137}\text{Cs}$ ) from salt marshes nearby estimate carbon accumulation as  $174 \pm 45 \text{ g C m}^{-2}\text{yr}^{-1}$   
558 (Ouyang & Lee, 2014). Thus, even along wrack lines, carbon accumulation far outpaces carbon  
559 release from breakdown of allochthonous material. Although estimates of decomposition and  
560 accumulation rates in this site could further inform these concepts, the slow annual cycle of  
561 seagrass wrack deposition and disappearance observed in the aerial imagery (Fig. S2), and the

562 lack of seagrass-derived carbon in underlying sediment make a compelling case that little of this  
563 material is ultimately buried.

564

## 565 **5 Conclusions**

566 We find that California salt marshes can store approximately twice as much carbon than do  
567 seagrass meadows within this region. Grain size – an easier metric to quantify than carbon stock  
568 – can be used to estimate regional carbon storage in sandy and mixed-grain size sediments. This  
569 information can serve to inform local and regional management plans in efforts to prioritize and  
570 quantify carbon storage across these habitat types. While seagrass meadows may act as local  
571 sinks for carbon, they also export substantial amounts of AGB annually, which can be rapidly  
572 remineralized and converted to CO<sub>2</sub>, rather than buried in neighboring blue carbon habitats. Both  
573 C3 salt marsh plants and diatoms contributed to the OC pools in all three salt marshes under  
574 study – likely due to their prevalence within our sites and their resistance to degradation. This  
575 comprehensive study assesses several key research needs in blue carbon science informing  
576 current efforts to prioritize and quantify carbon storage across these habitat types.

577
