10 **Abstract.** The [warming of the Arctic](#) is [warming at double the average global rate](#), affecting the carbon cycle of tundra ecosystems.
11 Most research on carbon fluxes from Arctic tundra ecosystems has focused on abiotic environmental controls (e.g. temperature,
12 rainfall, or radiation). However, Arctic tundra vegetation, and therefore the carbon balance of these ecosystems, can be substantially
13 impacted by herbivory. In this study we tested how vegetation consumption by brown lemmings (*Lemmus trimucronatus*) can
14 impact carbon exchange of a wet-sedge tundra ecosystem near Utqiagvik, Alaska during the summer, and the recovery of
15 vegetation during a following summer. We placed brown lemmings in individual enclosure plots and tested the impact of
16 lemmings' herbivory on carbon dioxide (CO₂) and methane (CH₄) fluxes and the normalized difference vegetation index (NDVI)
17 immediately after lemming removal and during the following growing season. During the first summer of the experiment,
18 lemmings' herbivory reduced plant biomass (as shown by the decrease in the NDVI) and decreased [net](#) CO₂ uptake, while not
19 significantly impacting CH₄ emissions. [CH₄Methane](#) emissions were likely not significantly affected due to CH₄ being produced
20 deeper in the soil and escaping from the stem bases of the vascular plants. The summer following the lemming treatments, NDVI
21 and [net](#) CO₂ fluxes returned to magnitudes similar to those observed before the start of the experiment, suggesting recovery of the
22 vegetation, and a transitory nature of the impact of lemming herbivory. Overall, lemming herbivory has short-term but substantial
23 effects on carbon sequestration by vegetation and might contribute to the considerable interannual variability in CO₂ fluxes from
24 tundra ecosystems.

25 1 Introduction

26 The Arctic is warming at [twice-about three times](#) the rate of the global average (IPCC, [20142021](#)), impacting tundra vegetation
27 and the carbon cycle. Vegetation influences the carbon stored in the tundra ecosystem through the exchange of carbon dioxide
28 (CO₂) and methane (CH₄) from the soil into the atmosphere via respiration or by CO₂ uptake through photosynthesis. One of the
29 largest natural reservoirs of organic carbon in the world is stored within Arctic soils, containing approximately 1,300 Pg of [soil](#)
30 [organic](#) carbon (Hugelius et al., 2014). Once soils thaw, microbes can convert stored carbon into greenhouse gases that enter the
31 atmosphere, contributing to global warming (McGuire et al., 2009; Schuur et al., 2008). This positive feedback could have dramatic
32 effects on warming rates, and these effects are why most carbon cycle research in tundra systems focuses on abiotic controls on
33 carbon fluxes (Kwon et al., 2019; Oechel et al., 2014; Sturtevant et al., 2012; Zona et al., 2010). Most of the studies investigating
34 the patterns and controls on the carbon balance from Arctic ecosystems focused on the environmental controls on CO₂ and CH₄,
35 while overlooking the role of herbivory. Since herbivores remove photosynthetic tissues of vegetation, [herbivory should](#)
36 [substantially decrease](#) the ability of vegetation to photosynthesize and sequester CO₂ [should decrease substantially with herbivory](#)
37 (Metcalfe and Olofsson, 2015). The decrease in vascular plant cover should also decrease CH₄ emissions, given that aerenchyma

38 in sedges (*Carex aquatilis* is the dominant vascular plant and sedge in our study site.; Davidson et al., 2016) facilitate the escape
39 of CH₄ from deeper anoxic soil layers into the atmosphere (Dias et al., 2010; McEwing et al., 2015; ~~Dias et al., 2010; Ström et~~
40 ~~al., 2003; Whiting and Chanton, 1993).~~ Moreover, in addition to transport, vascular plants which only facilitate CH₄ transport
41 from deeper anoxic soil layers into the atmosphere, but also affects the release of labile carbon from photosynthetic tissues, which
42 in turn stimulates CH₄ emission (Bhullar et al., 2014; McEwing et al., 2015; Ström et al., 2003; Tan et al., 2015; ~~Whiting and~~
43 ~~Chanton, 1993).~~ Investigating the impacts of herbivory on Arctic vegetation and its recovery after herbivory ~~can~~ would contribute
44 to a refined refining the understanding of the response of tundra ecosystems to climate change.

45 Small rodents, especially lemmings, in the Arctic tundra of Alaska are important herbivorous consumers of plants and prey
46 species for larger animals (Le Vaillant et al., 2018).
47 Throughout the Arctic, few rodent species persist, of which lemmings are by
48 far the most abundant and widespread, and are consequently identified as keystone species in tundra environments (Krebs, 2011).
49 As dominant year-round grazers in the tundra, lemmings may heavily impact plant productivity (Olofsson et al., 2014). The site of
50 our research, Utqiagvik, Alaska, was an ideal site for studying the impact of lemmings on vegetation, as it has been
51 reported that brown lemmings (*Lemmus trimucronatus*) deplete 100 times more primary
52 production than caribou, a much larger herbivorous mammal that migrates throughout the Alaskan Arctic (Batzli et al., 1980). Due
53 to their life history characteristics and abundance, lemmings can have a significant influence on the surrounding environment.
54 Lemmings experience cyclic population dynamics where their population density oscillates, changing community interactions
55 (Soininen et al., 2017). Lemming grazing during population peaks can dramatically affect vegetation (Olofsson et al., 2012), and
56 therefore greenhouse gas fluxes from Arctic tundra; given the amount of vegetation consumed by lemmings, their presence could
57 have substantial impacts on the carbon balance of tundra ecosystems. However, despite the role of lemmings as keystone
58 herbivores, the direct impact of their vegetation consumption on the carbon cycle of Arctic tundra in Alaska is still largely
59 unknown, with few published studies evaluating the role of lemming herbivory on the Arctic carbon balance and vegetation
60 (Lara et al., 2017; Lindén et al., 2021; Metcalfe and Olofsson, 2015; Min et al., 2021).

61 Most of the studies
62 analyzing the effects of lemmings on vegetation focused on ecosystem functioning in the absence of lemmings (Lara et al., 2017;
63 Lindén et al., 2021; Min et al., 2021), the impacts of lemming waste products and carcasses on nutrient cycling and vegetation
64 (McKendrick et al., 1980; Roy et al., 2020), the disturbance to soil via turnover by burrowing and fecal production (McKendrick
65 et al., 1980), and recruitment and loss of forest vegetation (Ericson, 1977). This leaves a crucial gap in our understanding of how
66 one of the main herbivores in a rapidly changing ecosystem, such as the Arctic, may affect carbon cycling. Since population cycles
67 vary by species and region (Reid et al., 1995), qualitative predictions on how brown lemmings would alter Arctic vegetation and
68 carbon cycling are uncertain.

69 In this study, we used enclosures to directly quantify impacts of lemming herbivory on tundra carbon cycling, both immediately
70 after disturbance and during the growing season following the disturbance to examine vegetation recovery after one year. Thus far,
71 very few studies (Johnson et al., 2011; Lara et al., 2017; Lindén et al., 2021; long-term enclosures) have investigated the effect of
72 lemming herbivory on the tundra carbon cycle, including the timing of recovery of vegetation after lemming disturbance. By using
73 enclosures to manipulate the number of lemmings per plot and observe a direct impact of lemming presence during peak annual
74 activity, our study quantified the short-term effects of vegetation removal from lemming herbivory on carbon fluxes and the timing
75 of vegetation recovery in the Alaskan Arctic.

76 The short-term effects of brown lemmings' herbivory on Arctic vegetation and carbon fluxes and their longer-term recovery
77 are critical to understand how lemmings might influence tundra environments. For this purpose, we measured the impact of brown

78 lemmings on vegetation in summer 2018 across a variety of plots in a wet-sedge tundra ecosystem in the Alaskan Arctic. Then, in
79 summer 2019, we measured ~~control and treatment~~the plots again to evaluate vegetation recovery from lemmings' grazing. The
80 goal of this experiment was to understand: (1) how brown lemmings affect vegetation through herbivory and disturbance, and
81 therefore how they could impact the Arctic tundra carbon cycle and photosynthetic capacity of vegetation, and (2) the rate of
82 vegetation recovery after brown lemming herbivory.

83 We hypothesized that lemmings, given their high rate of vegetation consumption, would have a negative impact on
84 net CO₂ sequestration by vegetation, but due to the rapid regrowth of the annual vascular plants they preferentially
85 consume, the vegetation would fully recover in terms of biomass and CO₂ sequestration the growing season following
86 grazing. We expected CH₄ emission to decrease in response to herbivory, given the reduction in the
87 biomass of vascular plants.
88 Our broader goals are to increase our understanding of how the foraging behaviors of these herbivores impacts CO₂ and CH₄ fluxes
89 Our broader goals are to increase our understanding of how the foraging behaviors of
90 these herbivores impacts CO₂ and CH₄ fluxes and the photosynthetic capacity of plants in the Alaskan
91 Arctic environment, which we hope will further public interest in the understanding of complex interactions in the Arctic and
92 relationships that may exist between climate change, herbivory, and predator-prey interactions.

93 2 Materials and methods

94 2.1 Study location

95 This study was carried out in Utqiagvik (formerly Barrow), Alaska (Fig. 1a). Located in the Arctic Coastal Plain, Utqiagvik is
96 comprised of polygonal ground (flat-, low-, and high-center ice-wedge polygons) that cover roughly 65% of the land cover
97 (Billings and Peterson, 1980). The major vegetation type at this site is graminoid-dominated wetlands, consisting of mosses,
98 lichens, graminoids (grasses), and wet sedges (Davidson et al., 2016).

99 The study area was located near the Barrow Atmospheric Baseline Observatory, an atmospheric monitoring site managed
100 by the National Oceanic and Atmospheric Administration (NOAA) (Fig. 1b), approximately 2 km south of the Arctic Ocean
101 (71°19'21.10" N: 156°36'33.04" W). This site was near a pre-established remote flux and
102 meteorological tower monitored by the Global Change Research Group (Goodrich et al., 2016) and has substantial lemming
103 populations relative to other Arctic tundra areas in Alaska (Ott and Currier, 2012).

104
 105 **Figure 1.** (a) The location of the study site, Utqiagvik (Barrow), in Alaska (© Google Maps 2018, imagery from TerraMetrics) represented by a
 106 red star, (b) location of the sampling site (© Google Maps 2018, imagery from TerraMetrics), (c) distribution of the sampling plots on an image
 107 created using the coordinates of the plots in R (Worldview-3 panchromatic imagery taken 24 July 2016, Maxar Technologies), (d) chamber used
 108 for the greenhouse gas flux measurements, (e) chamber covered by light-blocking material, and (f, g) enclosures installed at each of the plots
 109 during the manipulation experiment.

110 **2.2 Brown lemmings as a study species**

111 Within the Arctic ecosystem of Alaska there are two species of lemmings: brown lemmings (*L. trimucronatus*) and northern
 112 collared lemmings (*Dicrostonyx groenlandicus*). Brown lemmings tend to be distributed among lower and middle Arctic tundra
 113 subzones (Stenseth, 1999). Although both brown and collared lemmings are found in Utqiagvik, brown lemmings are more
 114 abundant in this region due to their preference for wetter habitats with relatively high-quality vegetation from lowlands (Batzli et
 115 al., 1983). Northern collared lemmings occupy drier habitats, and as a result are not as profuse and influential on vegetation in wet
 116 regions of the Alaskan Arctic such as Utqiagvik (Batzli et al., 1983; Krebs et al., 2011; Morris et al., 2000).

117
 118
 119
 120
 121
 122

123 **2.2.1 Brown lemming consumption**

124 Brown lemmings mostly consume graminoids in the summer and mosses in the winter (Batzli and Jung, 1980). Brown lemmings
 125 can consume much more than predicted by general trends of terrestrial vertebrates (EPPO, 1994), consuming up to eight times
 126 their body weight each day (Stenseth and Ims, 1993). Thus, their extreme capacity for consumption, of vegetation (combined with
 127 their elevated population density cyclic elevated population densities in the region.) Daily food intake of terrestrial vertebrates

128 ranges from 10% of body weight for heavier species, such as caribou, to 30% for species under 100 grams, such as lemmings
129 (EPPO, 1994). However, brown lemmings can eat much more than predicted from these general trends and can consume up to
130 eight times their body weight each day (Stenseth and Ims, 1993). Thus, even though lemmings weigh less than 100 grams (Huck
131 and Banks, 1982), their extreme capacity for consumption and elevated population density can result in high vegetation removal.
132 Additionally, during winter lemmings destroy or uproot up to 90-100% of surrounding aboveground biomass within their foraging
133 range (Stenseth and Ims, 1993). Arctic vegetation consumed by lemmings is generally nutrient-poor (Batzli et al., 1980). Brown
134 lemming digestive efficiency tends to be low, digesting only about 30 percent-% of ingested food (Batzli et al., 1980). Due to
135 consistent year-round activity and their small body size, lemmings also have a high metabolic rate. Low nutrient content, low
136 digestive efficiency, and a high metabolic rate result in lemmings requiring a high rate of food intake for survival.

137 To reduce the risk of detection by predators (snowy owl, parasitic jaeger/arctic skua, arctic fox, and ermine), lemmings forage
138 on small areas near their burrows and maximize their foraging in these areas until their primary food source is depleted, at which
139 point they move to a new area of vegetation near a burrow or runway (Erlinge et al., 2011). This behavior shapes their foraging
140 habits and leads to a higher concentration of grazing on vegetation close to burrows and runways (Erlinge et al., 2011). As a result,
141 approximately 95-100 % of graminoid shoots are repeatedly clipped by lemmings occupying burrows and visiting runways in the
142 immediate vicinity of the vegetation, and as the distance from the burrows and runways increases, clipping becomes patchier and
143 the intensity of clipping on vegetation decreases (Batzli et al., 1980).

144 **2.2.2 Brown lemming population**

145 Populations of brown lemmings tend to reach peak densities every three to five years and then steeply decline (Stenseth, 1999).
146 Interactions between lemming populations as fast-growing consumers and plant populations as slowly recovering resources
147 represents a bitrophic system (Ims and Fuglei, 2005). In this system, vegetation could be heavily damaged by overgrazing during
148 peak years of lemming abundance.

149 Populations of brown lemmings tend to reach peak densities every three to five years and then steeply decline (Stenseth, 1999).
150 Interactions between lemming populations as fast-growing consumers and plant populations as slowly recovering resources
151 represents a bitrophic system (Ims and Fuglei, 2005). In this system, vegetation could be heavily damaged by overgrazing during
152 peak years of lemming abundances.

153 A report on the monitoring of lemming abundance and distribution (Ott and Currier, 2012) estimated brown lemming density
154 near Utqiaġvik in 2012 to range from five to 65 lemmings per hectare. However, basic population density estimates may
155 underestimate the impact lemmings have on some vegetation due to an increased concentration in grazing very close to burrows
156 and runways (Erlinge et al., 2011). Ott and Currier (2012) also used baited Sherman traps to estimate abundance, a live-trapping
157 technique that may lead to an underestimate of the actual population density for this species, as brown lemmings are not readily
158 recaptured using baited Sherman traps; we found manual capture techniques to be much more effective than baited traps.

159 **2.3 Sampling plan and experimental design**

160 ~~This experiment was~~We performed this experiment over two summer growing seasons. During the first season (summer 2018),
161 we used enclosures to ensure even lemming herbivory pressure in each of our experimental plots. We manually captured the
162 lemmings used in this first season shortly after peak growing season (3-10 August), coinciding with accelerated lemming
163 reproduction and peak population density. We captured the lemmings in close proximity to our sampling sites while conducting
164 visual encounter surveys, and secured them ,but we only captured lemmings during the first summer field season (4-10 August
165 2018), shortly after peak growing season. This period coincides with accelerated lemming reproduction and peak population

Formatted: Indent: First line: 0"

166 ~~day. We captured lemmings multiple times per plot, and the lemmings were released in the same plot as they were captured. We did not capture any lemmings that were sick, very slow, or noticeably pregnant.~~ We released or avoided capturing any sick, very slow, or noticeably pregnant lemmings. After capture, we relocated lemmings to
167 the study site and included them in the experimental plots. Like voles (close relatives of lemmings), lemmings have distinct
168 preferences for habitats containing their preferred food items (Batzli and Henttonen, 1990), which ~~this study~~ we specifically selected for
169 when designing the location of the experimental plots ~~in this study in order to be representative of realistic effects of lemming behavior in areas of tundra near their burrows and runways.~~

170 We established 10 plot sets for this experiment. Each of the 10 plot sets included a lemming plot paired to a control (no-
171 lemming) plot nearby (20 plots in 10 sets total) (Fig. 1c). Each plot contained the different vegetation types, mosses, lichens,
172 graminoids, and wet sedges, and was selected to be as similar to the other plot within the same set as possible in order to minimize
173 biases due to spatial heterogeneity in vegetation and other landscape characteristics influencing vegetation and carbon fluxes (a
174 more in-depth analysis of these vegetation types was completed by Davidson et al. in 2016). We placed plot sets approximately 3
175 m apart from each other. Control plots were located within 1 m of lemming plots in the same set to keep environmental factors as
176 similar as possible. Plots were 50 x 50 cm in size; in each plot we dug a galvanized hardware cloth with a ½ inch grid down through
177 the thawed soil to the permafrost and up to 60 cm above the surface (Fig. 1f and g). We selected the size of these plots to be
178 consistent with a similar lemming enclosure experiment by Eskelinen and Virtanen (2005) in Finland. This size is also similar, yet
179 a bit larger than the experimental plots in the study by Lara et al. (2017) near Utqiagvik, Alaska which used 30 x 30 cm chamber
180 bases within their enclosures. Control plots not only excluded lemmings for the duration of the experiment, but also served as a
181 control for the soil and vegetation disturbance resulting from digging galvanized hardware cloth into the soil. Plots that included
182 lemmings also included a top portion of hardware cloth that prevented lemmings from escaping via climbing and prevented
183 predators from removing the lemmings during the experiment. Inside each enclosure with a lemming was a locked-open Sherman
184 trap with cotton nestlets for protection from environmental elements.

185 Because rodents may experience physiological stress after being captured (Fauteux et al., 2018a), prior to the experiment we
186 kept the lemmings in small individual cages made of hardware cloth with a locked-open Sherman trap for shelter, cotton nestlets
187 for warmth, and vegetation for nutrition for at least an hour to help them acclimate. After this acclimation period, we placed the
188 lemmings in their individual plots for 16 hours. We based the duration of the experiment on field trials we carried out for several
189 weeks before the start of the experiment. These trials showed that 16 hours was enough time to observe an average impact on the
190 vegetation, visually similar to the effect lemmings have on areas near their burrows, but was not too long as to result in complete
191 vegetation consumption, unrepresentative of most areas where lemmings forage. Our field trials revealed that keeping lemmings
192 inside the enclosure for longer than 16 hours (which varied with lemming size) led to a complete vegetation removal, an extreme
193 scenario only observed in the very close proximity of the burrows, and not representative of most of their foraging areas. We
194 released the lemmings at the end of all these experiments in proximity to the locations where they were captured.

195 The subsequent season (summer 2019), we re-visited the sample plots to measure the impact of
196 lemmings one year after their grazing (24 June-7 August). During this season, we did not capture any
197 lemmings, nor did we perform any additional manipulation. To be able to assess longer-term impacts of the
198 manipulations carried out the previous summer, we collected measurements
199 throughout the following summer (Table 1) to represent pre-, early, and peak growing season (hereafter
200 defined as “rounds”). Sampling was carried out to monitor the timing of regrowth of photosynthetic tissue and recovery of the
201 plants at different times of the season in 2019: 24-29 June (round one: pre-growing season), 9-19
202 July (round two: early growing season), and 29 July-7 August (round three: peak
203 growing season).
204

	Data Collected	Frequency of Measurement
Summer 2018	CO ₂ fluxes (NEE) and CH ₄ fluxes, NDVI, air temperature, soil temperature, soil moisture, thaw depth, motion camera footage	Before (pre-herbivory) and after (post-herbivory) lemming treatment (N=10 before and N=10 after for each treatment, for a total of N=40 per NEE, CH ₄ fluxes, NDVI; N=40 for air temperature; N=40 for soil temperature; N=100 for soil moisture; N=20 for thaw depth)
Summer 2019	CO ₂ fluxes (NEE, ER, GPP) and CH ₄ fluxes, NDVI, air temperature, soil temperature, soil moisture, thaw depth	Different times of the season (pre-, early, peak growing season) (N=10 for each round and treatment, for a total of N=60 per NEE, ER, GPP, CH ₄ fluxes, NDVI; N=60 for air temperature; N=300 for soil temperature; N=240 for soil moisture; N=240 for thaw depth)

Table 1. Types of data collected and when they were measured during summer 2018 and summer 2019. All data were collected while lemmings were not in the present inside the experimental plots, except for the motion camera footage. NEE is defined as net ecosystem exchange, ER as ecosystem respiration, GPP as gross primary production, and ER as...and NDVI as the normalized difference vegetation index is the Normalized....

There could have been other sources of herbivory (such as caribou), but these sources are not as frequent in these northernmost areas of the Arctic Coastal Plain. Additional sources of disturbance to vegetation could originate from a drastic change in environmental conditions, such as extreme temperatures, extremely dry conditions, etc.; however, these would not selectively remove the vascular plants while not affecting the moss layer, which is what we observed in this experiment.

2.4 Greenhouse gas fluxes and environmental conditions-variables measurements

We used a Los Gatos Research (LGR) Ultraportable Greenhouse Gas Analyzer (UGGA Model 915-0011) to measure CO₂ and CH₄ concentrations (currently, global mean atmospheric concentrations for CO₂ and CH₄ are approximately 417 ppm and 1909 ppb, respectively; NOAA GML, 2022) and air temperature over time in all plots during both summer seasons (2018 and 2019). We measured CO₂ and CH₄ concentrations one day after lemming removal from the plots in summer 2018 (exact time varied based on weather conditions and when plots were measured in temporal relation to other plots) and during the different rounds of the growing season in summer 2019. To collect measurements, we built a clear plexiglass acrylic chamber (Davidson et al., 2016; McEwing et al., 2015) to enclose the plots once the aboveground portion of the caging had been detached and the lemming had been removed (Fig. 1d). This chamber was placed on a metal frame positioned in the ground outside of the plots and had clear polyvinyl material weighed down by heavy metal chains to produce a seal inside the chamber. These measurements were performed in a closed loop, where tubes connected the chamber to the gas analyzer and then air was circulated back to the chamber. We positioned a small fan inside the chamber to ensure appropriate air mixing. The We collected greenhouse gas concentrations were collected in the absence of lemmings.

We used the rate of concentration change to calculate carbon fluxes using the chamber volume and area covered by vegetation (i.e. responsible for the carbon emission or uptake) as a function of time, as described in McEwing et al. (2015). The CO₂ concentration change allowed us to calculate the net balance between the carbon uptake from photosynthesis and the carbon loss from respiration, also defined as the net ecosystem exchange (NEE), before and after manipulations as previously described (summer 2018) and to track the seasonal development of NEE during the following summer (2019). In the subsequent summer (2019), we used a light-blocking material to cover the chamber (Fig. 1e) for determining CO₂ ecosystem respiration (ER) and gross primary production (GPP) from NEE, calculated following Eq. (1):

$$GPP = NEE - ER \quad (1)$$

and using the sign convention suggested by Chapin et al. (2006). Since plant growth and photosynthetic uptake is restricted to the summer months in these Arctic ecosystems, we used GPP to indicate "the total amount of CO₂ 'fixed' by land plants per unit time

238 [through the photosynthetic reduction of CO₂ into organic compounds” \(Gough, 2011\) during the time of measurements, rather than](#)
239 [as an annual measurement.](#)

240 We also measured a variety of environmental variables before and after each portion of the experiment (summer 2018) and
241 during each round (summer 2019). These environmental variables included air temperature recorded by the LGR gas analyzer, soil
242 temperature measured with a Thomas Scientific Traceable Kangaroo thermometer, soil water content recorded by a FieldScout
243 Soil Moisture Meter, and thaw depth using a metal probe marked every 5 cm. We examined these variables as controls that may
244 explain shifts in CO₂ and CH₄ fluxes within the study area and to monitor if plots in each of the sets were experiencing similar
245 abiotic conditions. This assured potential differences in carbon fluxes were due to our manipulation, and not different
246 environmental conditions of various plots.

247 2.5 Camera [footage](#) and hyperspectral measurements

248 We quantified the impact of lemming herbivory and burrowing on vegetation using a Spectra Vista Corporation (SVC)
249 Spectroradiometer HR-512i, which measures spectral reflectance and records a picture of the vegetation being scanned. The
250 spectrometer yielded hyperspectral measurements for vegetation in the 338.9-1075.1 nm spectral range with 512 bands and a
251 bandwidth of ≤ 1.5 nm. [We used](#) the internal global positioning system (GPS) of the spectroradiometer [to](#) record geographic
252 coordinates (latitude and longitude) for all plots to an accuracy of 2.5 m. [We](#)
253 [collected](#) hyperspectral measurements [in the absence of lemmings.](#)

254 We measured total reflected spectral exitance from a blank white reference panel right before sampling each plot set
255 (approximately every 20-30 scans, or 10-15 minutes) to estimate spectral irradiance based on reflectance calibration information
256 provided for the reference panel. We recorded spectral surface reflectance before and after each experimental treatment (summer
257 2018) and at different times during the season in the following summer (2019) and used it to calculate narrow-band normalized
258 difference vegetation index (NDVI) to compare the photosynthetic capacity of vegetation in the plots. NDVI is calculated as the
259 normalized difference between reflectance in the near infrared wavelengths (800.5 nm) and red wavelengths (680.2 nm). Lower
260 values of NDVI indicate no living vegetation and higher values indicate more green biomass.

261 [We recorded a time-lapse of various parts of the experiment using a](#) Brinno MAC200DN Outdoor Camera
262 to collect motion-sensor video footage of lemming activity. The camera also allowed for
263 re-visitation and surface cover characterizations of the plots to classify and quantify vegetation types within each plot and assess
264 how grazing had affected vegetation. We did not systematically record all trials on video, but instead used this technology as a
265 qualitative tool to visually document the activity of the lemmings.

266 2.6 Statistical analyses

267 We used the statistical program R, version 3.5.1 (R Core Team, 2019), for our statistical analyses. [For the 2018 data, we](#) ~~W~~ [tested](#)
268 [for normality using a Shapiro-Wilk normality test. in 2018](#) ~~The 2018 data to be~~ [were](#) normally distributed (NEE $P = 0.489$, NDVI
269 $P = 0.816$), except the CH₄ data ($P < 0.001$), which were right-skewed, so we log-transformed the CH₄ data to help normalize them
270 ($P = 0.284$). [After this transformation, we used a linear mixed-effects models \(with the package “nlme”; \(Pinheiro et al., 2018\) to](#)
271 [test for the significance in the differences between the different treatments. For the 2019 data, we used both a linear mixed-effects](#)
272 [models with the package “nlme” and non-parametric Kruskal–Wallis tests; statistics](#) ~~because we could not make all the data normal~~
273 [using the same transformation method \(log transformation, square root transformation\) for every round during the season. We also](#)
274 [tested for equal variance using an F-test and found there was no significant difference between the variances \(treatments\) in 2018](#)

275 (NEE $P = 0.172$, CH₄ flux $P = 0.810$, NDVI $P = 0.100$) and 2019 (NEE $P = 0.441$, ER $P = 0.650$, GPP $P = 0.852$, CH₄ flux $P =$
276 0.346 , NDVI $P = 0.951$).

277 We tested multiple variations of the [linear mixed-effects models](#) using the [methods for model selection](#) in ecology described
278 in Zuur et al. (2009). We then plotted the models to examine the residuals of the data and found them to not appear heteroscedastic.
279 For the 2018 models, we used treatment (control, lemming plots), time (before, after experiment), and their interaction as fixed
280 factors in the models; for the 2019 models, we used treatment (control, lemming plots), round (pre-, early, and peak growing
281 season), and their interaction as fixed factors in the models. In all analyses we used the plot identification (1C, 1E, 2C, 2E, etc.)
282 nested within the plot set (1-10) as random factors. Mixed models allow us to account for temporal and spatial pseudoreplication
283 and to test the significance of the interactions among factors. When fixed factors were significant, we conducted a pairwise analysis
284 via a Tukey post-hoc test (with the package “emmeans”; Lenth et al., 2019) to investigate the interacting effects in the model.

285 To identify the effect of the manipulation on [carbon fluxes](#) and [NDVI](#), we applied the linear
286 mixed-effects models and tested for differences in each environmental variable before and after lemming exposure in summer
287 2018. We then used the statistical analyses to help us explore if the post-lemming experimental plots showed a
288 significant change in [carbon fluxes and NDVI](#) when compared to pre-lemming experimental plots (2018),
289 and if the [carbon fluxes and NDVI](#) varied between treatments the following growing season (2019). Our analysis
290 of the NDVI from spectral indexes provided us with information on changes in plant biomass before and after each
291 manipulation in summer 2018 and vegetation regrowth in summer 2019.

292 3 Results

293 3.1 Environmental variables

294 Environmental controls on CO₂ and CH₄ fluxes such as air temperature, soil temperature, thaw depth, and soil moisture were
295 similar between the control and experimental plots in 2018 (Fig. [A1a-h](#)) and 2019 (Fig. [A1i-p](#)). During summer 2018, air
296 temperature ($P = 0.542$), soil temperature ($P = 0.960$), thaw depth ($P = 0.683$), and soil moisture ($P = 0.619$) were not significantly
297 different between control plots and lemming plots. During summer 2019, measurements of the control and lemming plots were not
298 significantly different for air temperature ($P = 0.887$), soil temperature ($P = 0.060$), thaw depth ($P = 0.512$), and soil moisture (P
299 $= 0.387$).

300

301

302 3.2 Carbon fluxes

303 3.2 Carbon fluxes in the treatment plots

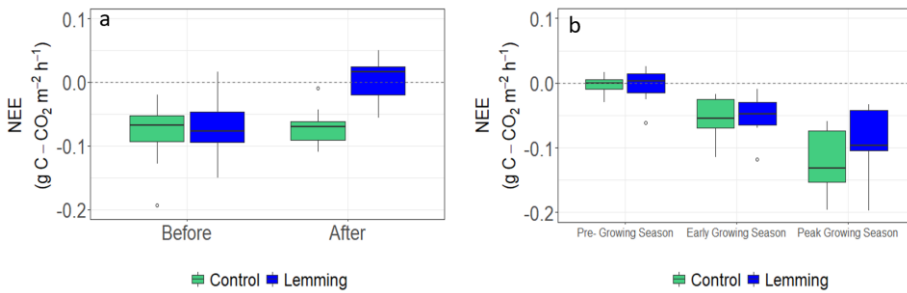

304 The presence of lemmings significantly impacted CO₂ fluxes (i.e. NEE) during summer 2018 when the
305 lemming enclosure treatment was implemented. Before the treatment, calculated NEE (Fig. 2a) and CH₄ fluxes (Fig. 3a)
306 for the control and lemming plots were similar. After we removed lemmings from experimental plots, net
307 CO₂ uptake decreased significantly ($P < 0.001$, Fig. 2a)
308 . In this context, net CO₂ uptake by vegetation, or carbon dioxide
309 sequestration, is the removal of CO₂ from the atmosphere and its storage in the above- and belowground biomass through
310 photosynthesis after accounting for the carbon loss through respiration. Therefore, when lemmings consume the
311 photosynthetic tissues of the vegetation (aboveground biomass), the vegetation is no longer able to
312 uptake CO₂ from the atmosphere, and NEE (the net ecosystem exchange equivalent to the net CO₂ fluxes) approaches either zero
313 or becomes less negative (a negative sign implies more carbon removal from the atmosphere).

314 By

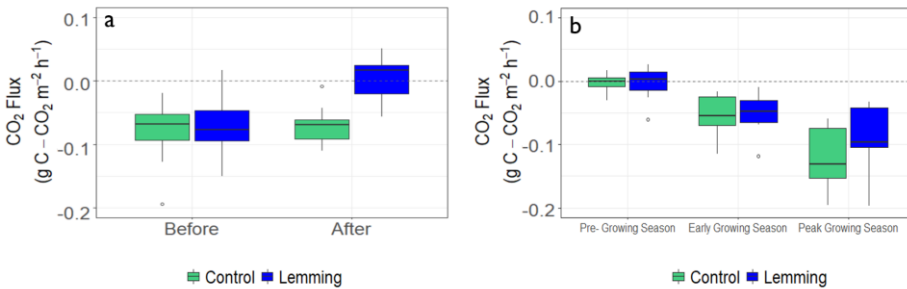

315 the end of summer 2018, the effect of brown lemmings' herbivory changed the mean NEE for lemming plots from -0.074
316 ± 0.012 gC-CO₂m⁻²h⁻¹ (i.e. net CO₂ sequestration) to 0.003 ± 0.012 gC-CO₂m⁻²h⁻¹ (i.e. net CO₂ fluxes were around zero
317). Contrary to what we expected, CH₄ flux values did not significantly differ between control plots and plots subjected
318 to lemmings' herbivory ($P = 0.989$, Fig. 3a).

Formatted: Subscript

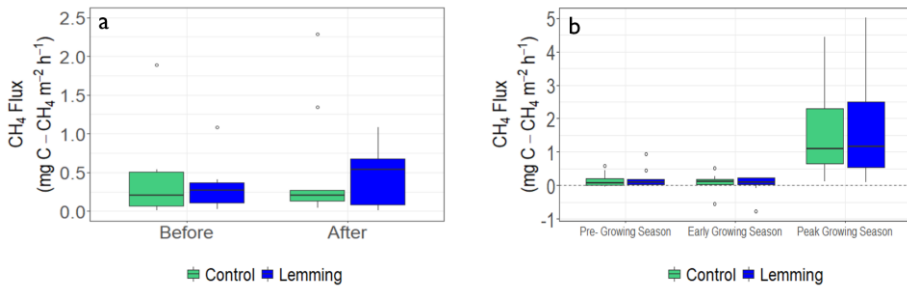

319 In summer 2019, we measured NEE and CH₄ fluxes again, and additionally calculated ER and GPP. During this second summer
 320 of measurements, results of the linear mixed-effects models for NEE, ER, GPP, and CH₄ fluxes were all not significantly different
 321 between control and lemming plots (NEE $P = 0.834$, Fig. 2b; ER $P = 0.742$, Fig. 4a; GPP $P = 0.716$, Fig. 4b; CH₄ flux $P = 0.869$,
 322 Fig. 3b). These results were consistent with those of the Kruskal–Wallis test, which found there was no significant difference
 323 between the treatments in 2019, either by testing the data set all together (NEE $P = 0.769$, ER $P = 0.221$, GPP $P = 0.513$, CH₄ flux
 324 $P = 0.824$) or separating it for different times of the season (rounds) and testing each time separately (pre-growing season: NEE P
 325 $= 0.245$, ER $P = 0.672$, GPP $P = 0.296$, CH₄ flux $P = 0.728$; early growing season: NEE $P = 0.853$, ER $P = 0.600$, GPP $P = 0.558$,
 326 CH₄ flux $P = 0.638$; peak growing season: NEE $P = 0.293$, ER $P = 0.366$, GPP $P = 0.212$, CH₄ flux $P = 0.970$).

327
 328
 329 **Figure 2.** Box and whisker plots of 2018 and 2019 NEE for the control and lemming plots. Negative flux
 330 values indicate carbon sequestration/uptake from the atmosphere by vegetation through photosynthesis and positive flux values indicate carbon
 331 emission/loss into the atmosphere. (a) Median NEE for plots before and after the experiment in summer 2018 ($T = 4.62$, $P < 0.001$), and
 332 (b) median NEE for plots during the three rounds of measurements in summer 2019 ($T = 0.21$, $P = 0.834$).

333

334 **Figure 3.** Box and whisker plots of 2018 and 2019 CH₄ fluxes for control and lemming plots. Negative flux values indicate uptake from the
 335 atmosphere and positive flux values indicate emission to the atmosphere. (a) Median CH₄ flux for plots before and after the experiment in summer
 336 2018 ($T = 0.01$, $P = 0.989$), and (b) median CH₄ flux for plots during the three rounds of measurements in summer 2019 ($T = -0.17$, $P = 0.869$).

337

338

339 **Figure 4.** Box and whisker plots of ER and GPP for control and lemming plots
 340 during the three rounds of data collection in summer 2019. Positive flux values indicate a positive respiration (carbon loss into the atmosphere)
 341 and a positive carbon uptake by vegetation through photosynthesis. (a) Median ER ($T = -0.34$, $P = 0.742$), and
 342 (b) median GPP ($T = -0.37$, $P = 0.716$). The signs of ER and GPP are always positive, but if ER is more than
 343 GPP, then the ecosystem is a carbon source into the atmosphere (with a positive sign of NEE).

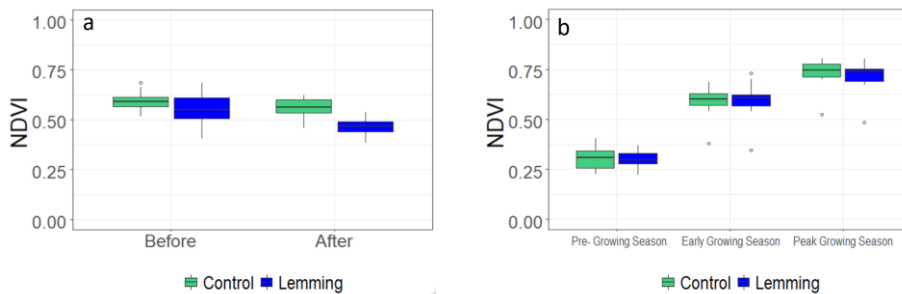

344 3.3 Hyperspectral surface reflectance and NDVI

345 Spectral reflectance derived from spectroradiometric radiances generally increased across visible and near infrared wavelengths
 346 after lemmings' vegetation removal (Supplementary Fig. S1). Before placing lemmings in enclosures, control and lemming plots
 347 exhibited similar surface reflectance values, while reflectance curves showed more substantial separation after lemming removal
 348 (Supplementary Fig. S1). Analyzing the surface reflectance of the same control and lemming plots re-visited in summer 2019
 349 revealed that the reflectance values for these different treatments were alike in each plot set, similar to what was observed before
 350 the beginning of the manipulation experiment (Supplementary Fig. S2b).

351 To better quantify the changes in reflectance, we calculated the NDVI in all the control and treatment plots in both summer
 352 2018 and 2019. Following lemming removal in the first summer, lemming plots had significantly lower NDVI than the control
 353 plots ($P = 0.015$, Fig. 65a), consistent with the decrease in green biomass observed in the photographs collected before and after
 354 placing the lemmings in the treatments' enclosure (Supplementary Fig. S1), and with the decreases in net CO₂ uptake (see NEE
 355 close to zero after lemming vegetation consumption; Fig. 32a). The effect of brown lemmings' herbivory changed the mean NDVI
 356 for lemming plots from 0.551 ± 0.021 to 0.465 ± 0.021 . During the second summer, median NDVI values of all plots were similar

Formatted: Tab stops: 6.5", Left

357 (Fig. 65b). Results of the linear mixed-effects model reveals that dDuring this time, there was no significant difference in NDVI when
 358 comparing control plots to lemming plots ($P = 0.692$), which is consistent with the results of the Kruskal–Wallis test that found
 359 there was no significant difference between the treatments in 2019 either by testing the data set all together ($P = 0.694$) or separating
 360 it for different times of the season (rounds) and testing each time separately (pre-growing season: $P = 0.260$, early growing season:
 361 $P = 0.418$, peak growing season $P = 0.283$). There was a significant difference between rounds ($P < 0.001$). The significant difference in NDVI across the rounds ($P < 0.001$), which
 362 is consistent coincides with the increased green biomass observed in collected photographs from pre- to early to peak growing season
 363 (Supplementary Fig. S2a).

364
 365 **Figure 5.** Box and whisker plots of 2018 and 2019 NDVI values for control and lemming plots. (a) Median NDVI for plots before and after the
 366 experiment in summer 2018 ($T = -3.69$, $P = 0.015$), and (b) median NDVI for plots during the three rounds of measurements in summer 2019 (T
 367 $= 0.41$, $P = 0.692$). Higher vascular plant green biomass in the pre-lemming treatment plots presented NDVI values in the 0.6 to 0.7 range,
 368 whereas post-lemming treatment plots in 2018 exhibit NDVI values around 0.5.

369 4 Discussion

370 We found, within a short-term enclosure experiment, that brown lemmings' herbivory significantly decreased net CO₂ uptake
 371 immediately after consumption of vegetation, while surprisingly not affecting CH₄ fluxes. Consumption of photosynthetically
 372 active plant tissue by lemmings impacted the ability of the vegetation to sequester CO₂, nullifying CO₂ uptake by tundra vegetation.
 373 The lack of significant difference in the evaluated environmental variables (air temperature, soil temperature, soil moisture, thaw
 374 depth) between the control and lemming treatment plots suggests that these factors did not play a significant role in the difference
 375 in net CO₂ fluxes before and after the treatments during the first summer, but that the decline in CO₂ flux values was due to
 376 vegetation removal by lemmings. Unfortunately, the design of this experiment, mostly focusing on the aboveground measurements
 377 (except for the soil temperature, soil moisture, and thaw depth), did not allow for identifying the contribution of belowground
 378 increased decomposition from the aboveground vegetation removal. However, as we did not notice an increase in CH₄ emission
 379 with vegetation removal (which could have increased with an increase as an indirect effect of an increase in sugars related to
 380 increased soil microbial respiration), we could assume that the direct effect of the removal of photosynthetic plant tissue was the
 381 main mechanisms explaining the decrease in the ability of the ecosystem to sequester carbon. Therefore, we believe the main
 382 source of disturbance that would result in that the removal of vascular plants in these wet tundra ecosystems is from lemming
 383 herbivory was the main driver explaining the decrease in the ability of these ecosystems to uptake carbon. There could be other
 384 sources of herbivory (such as caribou), but they are not as frequent in these northern areas of the Arctic Coastal Plain and would
 385 not have been able to access the vegetation within the galvanized hardware cloth enclosures. Additional sources of disturbance to
 386 vegetation could originate from a drastic change in environmental conditions, such as extreme temperatures, extremely dry

Formatted: Subscript

387 [conditions, etc.; however, these would not selectively remove the vascular plants while not affecting the moss layer, which is what we observed in this experiment.](#)

388 Notably, lemmings' herbivory did not affect CH₄ fluxes, even though plant transport of CH₄ is a critical pathway for emission
389 in tundra ecosystems (Lai, 2009; McEwing et al., 2015); plants offer substrate for methanogenesis and increase CH₄ transport
390 (Bridgman et al., 2013). The lack of a significant effect on CH₄ fluxes may be due to the location of vegetation removal on
391 consumed plants. Kelker and Chanton (1997) showed the location of the clipping of vegetation affects the CH₄ emissions;
392 belowground clipping at the root-shoot or porewater-root boundary is more likely to impact CH₄ emission, but aboveground
393 clipping is less likely to affect CH₄ emission. This differential effect is likely related to the location of CH₄ escape through
394 vegetation, which is just at the root-shoot or porewater-root boundary (Kelker and Chanton, 1997). Clipping has an effect not only
395 on gas transport, but also on substrate availability. Vegetation can have an impact on stimulating CH₄ through labile carbon exuded
396 by the roots (McEwing et al., 2015; [Ström et al., 2003](#); [Zona et al., 2009](#)). [Labile carbon fuels methanogenesis, aiding in CH₄](#)

415 Measurements collected the summer following our herbivory experiment (2019), revealed that the vegetation recovery after
416 brown lemming disturbance was rapid. In 2019, vegetation quickly regrew to a condition comparable to that found in 2018, prior
417 to lemming consumption. [Since lemmings mostly consume vascular plants, such as graminoids and sedges, in the summer and](#)
418 [avoid non-vascular and slower growth vegetation, such as mosses and lichens \(Batzli et al., 1980\), the preferential consumption](#)

421 [vegetation preferences. An in-depth analysis of the vegetation types found in our plots was completed in a previous study by our](#)
422 [team \(Davidson et al., 2016\)](#).

423 As expected, the biomass of vegetation decreased during summer 2018 due to the impact of lemming consumption
424 (Supplementary Fig. S1). The control and experimental plots before the lemming treatment had relatively high and similar mean
425 NDVI values (Supplementary Fig. S1), suggesting their biomass had similar values (Goswami et al., 2015). Vegetation removal
426 by brown lemmings significantly lowered the mean NDVI of the plots subjected to lemming herbivory. By summer 2019, the mean

427 NDVI value of these same lemming plots indicated that the vegetation was fully recovered from the lemmings' impact the previous
428 summer.

429 While our experiment showed a potentially substantial impact of lemming herbivory on the CO₂ fluxes from these tundra
430 ecosystems, we did not address the impact of varying degrees of intensity of herbivory and population cycling of brown lemmings
431 on carbon fluxes and photosynthetic capacity of different vegetation communities. Roy et al. (2020) found that herbivore presence
432 can alter communities of vegetation differently, as herbivores play a role in regulating a variety of plant species. These herbivores
433 can lead to significant changes in the abundance of vegetation types, allowing for the potential of the tundra during the peak
434 growing season to switch between a carbon source to sink in the absence of herbivory (Min et al., 2021). Since brown lemmings
435 rely on a high rate of food intake to sustain growth and reproduction (Batzli et al., 1980) and experience population cycles with
436 distinct seasonal and multiannual density fluctuations (Reid et al., 1995; Stenseth, 1999), rapid consumption of plant matter by
437 lemmings as sustenance during population peaks may significantly contribute to shifts in plant communities and, thus, carbon cycle
438 changes.

439 Since lemming population densities vary in response to multiple environmental factors (Fauteux et al., 2015;
440 Soininen et al., 2017), predicting a 'normal' level of herbivory for this species is very challenging. Reports on estimated
441 brown lemming density have found their local density to range from five to 65 lemmings per hectare (Ott and Currier, 2012;
442 Alaskan Arctic) and about zero to nine lemmings per hectare (Fauteux et al., 2015; Canadian Arctic), which is variable and may
443 be an underestimate due to the use of live-trapping, as mentioned previously. Moreover, in addition to space, it is important to
444 consider time: we only kept lemmings inside the plots for 16 hours and there was no effect of lemming herbivory for the remainder
445 of the experiment. The most relevant comparison we could find to define the degree of herbivory observed was the effect on
446 vegetation near lemming burrows and runways in a similar ecosystem (Erlinge et al., 2011; Siberian tundra). Given the sparsity of
447 available literature and data from these understudied Arctic ecosystems, it is difficult to
448 categorize our lemming treatment as having some sort of 'normal' or 'heavy' impact on
449 vegetation, which would be required to explore legacy effects of lemming herbivory.

450 Lemming populations may also vary in response to regulation by predators
451 (Fauteux et al., 2018b).
452 Given the substantial impact of lemming herbivory on the tundra carbon balance, indirect cues indicating predatory risk could
453 Given the substantial impact of lemming herbivory on the tundra carbon balance, indirect cues indicating predatory risk could
454 Given the substantial impact of lemming herbivory on the tundra carbon balance, indirect cues indicating predatory risk could
455 Given the substantial impact of lemming herbivory on the tundra carbon balance, indirect cues indicating predatory risk could
456 Given the substantial impact of lemming herbivory on the tundra carbon balance, indirect cues indicating predatory risk could
457 Given the substantial impact of lemming herbivory on the tundra carbon balance, indirect cues indicating predatory risk could
458 herbivory on the tundra carbon balance, indirect cues indicating predatory risk could change lemming foraging
459 behavior, and in turn alter their effect on vegetation. The influence of predator-prey interactions on herbivory, and how they further
460 impact vegetation and carbon fluxes in the Arctic tundra should be quantified by future studies to better understand
461 multifaceted interactions in the Arctic (see supplementary materials).

462 5 Conclusions

463 We show that there is an immediate effect of lemmings on plant biomass and net CO₂ uptake by Arctic vegetation, but not on CH₄
464 flux in areas where lemmings forage. However, impacts on vegetation are temporary, and plant biomass and net CO₂

465 ~~uptake~~vegetation can recover to ~~its~~ previous conditions by the end of the subsequent growing season. To further our understanding
466 of the complex interactions in the Arctic, it is vital to also explore the longer-term feedbacks that may exist between climate change,
467 herbivory, and predator-prey interactions. The effects of warming on snow cover and plant growth, as crucial environmental
468 resources to lemmings, could lead to drastic population changes for lemmings, and the longer-term effect of lemmings' herbivory
469 on vegetation might not be captured by a short-term manipulation. It is also critical to link the long-term lemming population
470 fluctuations to potential shifts in vegetation and climate change. Additionally, climate change is likely to also alter the abundance,
471 behavior, or even occurrence of predators of lemmings, which may in turn impact lemming abundance and foraging behaviors. For
472 these purposes, longer-term and broader scale ecological data would be particularly valuable to build on the short-term effect
473 highlighted in this study.

474 Overall, our study suggests that brown lemmings have the ability to significantly alter vegetation by consuming photosynthetic
475 tissue, which hinders the sequestration by the vegetation and shifts CO₂ fluxes in the areas surrounding their burrows and runways.
476 We report that this effect is short-lived due to the preferential consumption by lemmings of plant species that quickly regrow and
477 recover by the next growing season. However, the duration of the impacts of lemming herbivory may change in different
478 vegetation communities, as various plant species might be affected differently. Thus, it is relevant to examine the effects
479 of lemmings on a wide range of ecosystems to make regional estimates of their short-term influence on net CO₂ fluxes and NDVI.
480 Future research should also more carefully quantify the interactions between lemmings, their predators, and carbon cycling in the
481 Arctic tundra ecosystem, which might explain some of the substantial interannual variability in the tundra CO₂ fluxes not
482 explained by environmental variables alone.

483 *Code availability.* R codes generated for data analysis during this study will be archived to the ORNL DAAC repository by the corresponding
484 author upon the journal's request.

485 *Data availability.* Data on carbon fluxes, hyperspectral surface reflectance, and environmental variables analyzed during this study will be
486 archived to the ORNL DAAC repository by the corresponding author upon the journal's request. All relevant data are included as figures in the
487 paper, and raw data may be made available upon request.

488 *Author contribution.* Study conception and design were carried out by Jessica Plein, Rulon Clark, Walter Oechel, and Donatella Zona. Material
489 preparation, data collection, and data processing were completed by Jessica Plein. Data scripts and codes were written by Jessica Plein, Kyle
490 Arndt, and Donatella Zona. Data analysis was performed by Jessica Plein and Donatella Zona. The drafts of the manuscript were written
491 by Jessica Plein and all authors commented on previous versions of the manuscript. All authors read and approved the final manuscript.

492 *Competing interests.* The authors declare that they have no conflict of interest.

493 *Acknowledgements.* We thank the Global Change Research Group for equipment use, field support, and suggestions on the project design. We
494 also thank Nicholas Barber for help with statistical analyses, George Aguiar at Archipelago Farms for reindeer urine collection (see supplementary
495 materials), and Lupita Barajas, Marco Montemayor, Thao Tran, and Brian Graybill for their efforts with field set-up/take-down and
496 measurements. The authors would also like to thank the Polar Geospatial Center for the geospatial support. We express gratitude to NOAA for
497 providing access to their observatory site, and especially Bryan Thomas for his expertise and guidance at the site. We thank the -Ukpeaġvik
498 Iñupiat Corporation (UIC) for the use of their laboratory, radios, and storage. The authors are also thankful to the Iñupiat people for sharing their
499 culture and home with us, and Bryan Thomas from NOAA for his expertise and guidance at the site. The research was conducted on both the

500 privately owned National Oceanic and Atmospheric Administration (NOAA) and Ukpqaġvik Inupiat Corporation (UIC) locations, and we thank
501 NOAA for providing access to their site and UIC for the use of their laboratory. Welfare of animals indicated in Alaska Department of Fish and
502 Game permits 18-167 and 19-131 and Institutional Animal Care and Use Committee (IACUC) Animal Protocol Form #16-08-014C.

503 *Financial support.* This research has been supported by the National Science Foundation Office of Polar Programs (grant no. 1702797) and
504 National Aeronautics and Space Administration (grant no. NNX16AF94A).
