**Correspondence:** Ulrike Löptien (ulrike.loeptien@ifg-uni.kiel.de)

**Abstract.** In recent years, upwelling events of low-oxygenated deep water have been repeatedly observed in Eckernförde Bight (EB) situated in the Baltic Sea, Germany. Many of these events were related to massive fish-kill incidents - with negative consequences for commercial fisheries and tourism. The aim of this study is to dissect underlying mechanisms and to explore the potential of existing monitoring programs to predict these events. Our main tool is an ultra-high spatially resolved general ocean circulation model which drives an elementary representation of the biogeochemical dynamics of dissolved oxygen (dubbed MOMBE and EckO<sub>2</sub>, respectively). In addition, we integrate artificial "clocks" that measure the residence time of the water in EB along with timescales of (surface) ventilation. We present an ensemble of hind cast model simulations, covering the period from 2000 up to 2018, designed to cover a range of poorly known model parameters for vertical background mixing (diffusivity) and local oxygen consumption within EB. Our results indicate that the dynamics of low (hypoxic) oxygen concentrations in bottom waters deep inside EB is, to first order, determined by the following antagonistic processes: (1) the inflow of low-oxygenated water from the Kiel Bight (KB) - especially from July to October and (2) the local ventilation of bottom waters by local (within EB) subduction and vertical mixing. Biogeochemical processes that consume oxygen locally, are apparently of minor importance for the development of hypoxic events. Reverse reasoning suggests that subduction and mixing processes in EB contribute, under certain environmental conditions, to the ventilation of the KB by exporting recently-ventilated waters enriched in oxygen. A detailed analysis of the 2017 fish-kill incident highlights the interplay between westerly winds importing hypoxia from KB and ventilating easterly winds which subduct oxygenated water. Finally, we explore the capabilities of - comparably computationally cheap - feed-forward artificial neuronal networks to forecast hypoxia deep in EB based on data at a monitoring site at the entrance of EB.

## 1 Introduction

The sheer size of our oceans currently adds stabilizing momentum to climate change. This effect is weaker at the oceanic boundaries, such as the shallow coastal regions, that are in closer proximity to disruptive anthropogenic drivers and may exhibit tipping points or thresholds which ones reached, unleash highly non-linear dynamics. Among such disruptive drivers are marine pollution, over-fertilization and overfishing. These can put local assets such as recreational use, fish yields or (blue) carbon sequestration at risk (see Figure 1 for a schematic of typical stressors and assets). Hence, there is growing societal need for projection tools that can provide a base for cost-efficient adaptation and mitigation strategies in a warming world.

This study documents the effort to improve the current process understanding and to develop a numerical tool suited to forecast lack of dissolved oxygen which causes intermittent and massive fish-kills in Eckernförde Bight (EB) (Figure 2). EB is an appendix to the Kiel Bight (KB) in the German part of the Baltic Sea (Figure 3). The reasons for choosing this site to develop a piloting workflow is threefold: First, EB is exemplary for specific coastal regions such as the East China Sea and Chesapeake Bay (see Fennel and Testa, 2019, for a comprehensive summary). Similarly to these regions, the Baltic Sea ranks among the largest anthropogenically-induced hypoxic areas in the world (Carstensen et al., 2014) and is infamous for vast hypoxic conditions. Second, EB has reached distressing levels of attention by the German local media, because mass fish-kill incidents caused by a lack of dissolved oxygen have been frequent during late summer during recent years. There is concern that this situation will deteriorate because, e.g., a warming climate reduces the capacity of sea water to hold dissolved oxygen because its solubility is inversely related with temperature. This concern triggered an interest in projection tools by a governmental stakeholder (*Landesamt für Landwirtschaft, Umwelt und ländliche Räume Schleswig-Holstein, LLUR*). Third, EB hosts the monitoring station *Boknis Eck* (Figure 4), one of the longest-operated time series stations worldwide (e.g. Lennartz et al., 2014). Consequently, EB is subject to an exceptional large base of observational data, facilitating the development of numerical models and piloting approaches in general.

Typical surface concentrations of dissolved oxygen are around few hundreds  $\text{mmol O}_2\text{m}^{-3}$ , predominantly set by physical solubility as a function of temperature and salinity (and rather constant atmospheric concentrations). At depth, however, oxygen sinks can accumulate oxygen deficits until critical thresholds for the survival of animal or even plants are undercut. Common denominations for critical thresholds are: *hypoxic*, *suboxic* and *anoxic* conditions. Their respective values are, however, fuzzy. Here, we follow Gray et al. (2002) and define the threshold values for hypoxia as a concentration of dissolved oxygen of  $2\text{mg O}_2\text{l}^{-1}$ , which corresponds to  $\approx 60\text{mmol O}_2\text{m}^{-3}$ . The relevance of this threshold is that it limits the survival of most fish (Hofmann et al., 2011). In addition we consider a second threshold of  $4\text{mg O}_2\text{l}^{-1}$  corresponding to  $\approx 120\text{mmol O}_2\text{m}^{-3}$ . This value is used as an indicator for the eutrophication of stratified water bodies (such as EB) by the Baltic Marine Environment Protection Commission (Helsinki Commission - HELCOM, 16th Meeting of the Intersessional Network on Eutrophication Helsinki, Finland, 29.-30. January 2020) and as such of relevance to the stakeholder LLUR.

Qualitatively, the mechanisms causing hypoxia are well known. Typically, dissolved oxygen concentrations are determined by antagonistic processes in the ocean: production of organic matter by autotrophs in the sun-lit surface ocean is associated with oxygen production while remineralization of sinking organic matter is typically associated with oxygen consumption by bacteria. Air-sea fluxes of oxygen may be in or outgoing, depending on whether the ocean's surface is over or undersaturated. Additional complexity is added by the ocean circulation which determines the timescales on which oxygen sources and sinks may accumulate before the antagonistic process kicks in. The difficulty lies in reliable quantification of sources and sinks of oxygen with hypoxia being essentially the result of the difference of two relatively large and uncertain numbers.

Hence, reliable projections of hypoxia necessitate an exceedingly exact quantitative understanding of oxygen sources and sinks in conjunction with ever changing ocean circulation and turbulent mixing. In a nutshell, concentrations are reset to saturation levels at the surface and reduced by respiratory processes at depth. Hence, respiration rates along with the transport timescales (that determine the time a water parcel may accumulate respiratory signals at depth - until it is pushed back up

to the well-ventilated surface layer) need to be known. Unfortunately, both, the respiration rates and transport timescales or subsurface residence timescales, are difficult and expensive to measure *in situ*. This makes this type of observations very rare - even in EB, which is renowned for its good observational data coverage. Our approach to overcome the respective limitations in this study is to integrate an ensemble of a high-resolution coupled ocean-circulation biogeochemical model configurations, that  
65 test through a range of mixing parameters (which determine residence timescales) and through respective parameter values for the biogeochemical oxygen sources and sinks. The ensemble is assessed with observations of salinity, temperature and dissolved oxygen measurements deep inside EB. The most realistic ensemble members are then analyzed in greater detail in order to dissect a mechanistic understanding of the processes involved in the dynamics of dissolved oxygen. Finally, we build an artificial neuronal network (ANN) in order to forecast dissolved oxygen concentrations deep in EB based on measurements  
70 at the entrance of EB. This approach yields a computationally cheap surrogate to the (relatively) computationally expensive coupled ocean-circulation biogeochemical model to the stakeholder (cf., Figure 5). Key predictors are identified by systematic feature selection.

## 2 Methods

MOMBE (Modular Ocean Model Bight of Eckernförde) is a new configuration of a general ocean circulation model (GCM).  
75 The GCM is coupled to a simple representation of biogeochemical processes by introducing an additional passive tracer, that is advected and mixed just like the tracers temperature and salinity but, other than that, controlled by prescribed rates of oxygen production and consumption. Further, we introduce artificial tracers or "clocks" that estimate the residence times and the age (i.e. the time of last contact to the surface) of water parcels. This approach facilitates the dissection between local (i.e. inside EB) and remote (e.g., inflowing hypoxic deep water from the KB) processes that drive the oxygen dynamics. The following  
80 subsections describe the GCM, followed by a model evaluation in Section 3. The feed-forward neuronal networks designed to mimic the full-fledged coupled GCM at a station deep in the Bight are described in Section 4.4.

### 2.1 Model Configuration

We use the Modular Ocean Model framework MOM4p1 as released by NOAA's Geophysical Fluid Dynamics Laboratory (Griffies, 2009). The model code and configurations are almost identical to those described in Dietze et al. (2014) and Dietze  
85 et al. (2020). The few exceptions are listed in the following subsections. Section 2.1.1. describes the model grid, Section 2.1.2 the subgrid parameterizations, and Section 2.1.3 specifies the input data (boundary conditions). Section 2.1.4 documents the representation of sea ice, Section 2.1.5 introduces the implementation of the residence time and age tracers. The implementation of the oxygen module is documented in Section 2.1.6.

#### 2.1.1 Grid and Bathymetry

90 The bathymetric data are provided by the Federal Maritime and Hydrographic Agency (BSH, <https://www.geoseaportal.de/mapapps/resources/apps/bathymetrie/index.html?lang=de>). We use a bilinear scheme to interpolate these onto an Arakawa

B model grid (Arakawa and Lamp, 1977). There are  $165 \times 103$  grid boxes horizontally, each about  $100 \text{ m} \times 100 \text{ m}$  in size (Figure 4). The total wet area of the model is  $119 \text{ km}^2$ . The vertical resolution is 1 m, with a total of 31 layers. The average water depth is 11.7 m. The bathymetry was smoothed with a filter similar to the Shapiro filter (Shapiro, 1970). The filter weights are 0.25, 0.5 and 0.25. The filter essentially fills steep holes in the ocean floor which increases numerical stability of the GCM. The filter was successively applied three times, as this has proven (in Dietze and Krist, 2012; Dietze et al., 2014, 2020) to be a good compromise between unnecessary smoothing on the one hand and numerical instability on the other hand.

### 2.1.2 Subgrid Parameterisations

Even a horizontal resolution as high as 100 m horizontally and 1 m vertically fails to explicitly resolve all (turbulent) processes of relevance for transport and mixing of substances in EB. Hence, effects of unresolved small-scale processes have to be parameterized. We use parameterizations and setting identical to those applied by Dietze et al. (2014) in a high-resolution model configuration of the Baltic Sea. An exception is the parameter choice for the vertical background diffusivity: Holtermann et al. (2012) estimates from measurements for deep water processes in the central Baltic Sea a vertical diffusivity of  $10^{-5} \text{ m}^2 \text{ s}^{-1}$  (calculated from the propagation speed of a purposely-deployed dye-like substance). Closer to coast Holtermann et al. (2012) report much higher values. Because mapping this information on conditions in EB is difficult, we decided to test a range of vertical background diffusivities and to assess the respective model performances based on available observations. The considered diffusivities are:  $5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ ,  $1 \times 10^{-4} \text{ m}^2 \text{ s}^{-1}$  and  $5 \times 10^{-4} \text{ m}^2 \text{ s}^{-1}$ . This range comprises relatively low diffusivities, which are characteristic for the deep central Baltic Sea, and fairly high values, which are more representative for coastal mixing (as can be expected in the shallow Eckernförde Bight).

### 2.1.3 Boundary Conditions

The atmospheric boundary conditions of our model are set by a reanalysis from the Swedish Meteorological and Hydrological Institute (SMHI). We use the results of the reanalysis framework as a means to interpolate (patchy) observations in time and space. The underlying atmospheric model features a horizontal resolution of 11 km. For the period 2000 to 2015 we use RCA4 (Samuelsson et al., 2015, 2016). RCA4 data is available only until 2015. Hence, for the period 2016 to 2018 we switched to another product: UERRA (regional reanalysis for Europe; <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-uerra-europe-complete?tab=overview>). UERRA is more advanced but does not include "spectral nudging" to the large-scale atmospheric circulation. This detail may allow for unrealistic shifts in the trajectories of low pressure systems. Fortunately, for the time and location under consideration here, a rough comparison with the observations from Kiel lighthouse (in position  $54.3344^\circ \text{N}, 10.1202^\circ \text{E}$ ) showed a generally good agreement between reanalysis and direct observations (not shown).

Our model configuration features rigid walls in the east, where EB is connected to the KB. We mimic the respective water exchange by restoring to prescribed temperature, salinity and sea surface height values at the model boundaries. For sea surface height we restore to prescribed values taken from an oceanic reanalysis carried out with MOMBA (Dietze et al., 2014). MOMBA differs from MOMBE in that it covers the entire Baltic Sea with a horizontal resolution of 1 nautical mile while MOMBE introduced here covers the EB only - albeit with much higher resolution (100 m). For the sake of consistency,

125 MOMBA has been integrated for the entire hindcast period 2000-2018 using the atmospheric forcing described above (which differs from Dietze et al., 2014). For temperature, salinity and oxygen we restore MOMBE at its horizontal boundaries with Kiel Bight to interpolated measurements from Station *Boknis Eck* at the entrance of EB (Lennartz et al., 2014, <http://www.bokniseck.de/>, <http://doi.pangaea.de/10.1594/PANGAEA.855693>).

#### 2.1.4 Sea Ice

130 The focus of our investigation are ice-free seasons. We will show in Section 4.1 that the memory of the system under consideration, as given by residence times in Eckernförde Bight, is less than a month. This suggests that sea-ice dynamics are rather irrelevant to the processes and seasons examined here. Even so, for the sake of completeness, we report that our ocean component is coupled to a dynamical sea ice module, the GFDL Sea Ice Simulator (SIS). SIS uses elastic-viscous-plastic rheology adapted from Hunke and Dukowicz (1997). We use the exact same settings described in Dietze et al. (2020) (which are  
135 identical to the settings in Dietze et al. (2014), except for switching to levitating sea ice).

#### 2.1.5 Artificial Clocks

In order to facilitate the dissection of local versus remote processes influencing the oceanic oxygen concentrations in EB, we introduce two artificial tracers or "clocks" to the ocean circulation model (following and approach similar to Dietze et al., 2009). Both clocks behave like dyes in that they are subject to transport processes just like like temperature, salinity and  
140 dissolved oxygen. In addition to being transported, the clocks continuously count up time in every grid box. The first clock is reset to zero whenever a water parcel reaches the ocean surface. Thus, it measures the time elapsed since a water parcel had been in contact with the atmosphere. This time is also referred to as the age of the water. The second clock is reset to zero at the eastern boundaries of the model domain. Thus, it measures the time elapsed since water entered EB. This time is also referred to as the residence time of water in EB.

145 The ratio between residence time and age is a measure of the importance of local processes versus remote processes: if a water parcel remains much longer in EB than the time has passed since the water parcel has been ventilated locally in EB, then this may be an indication of the dominance of local (inside EB) biological respiratory processes. Conversely, if the residence time is much shorter than the age, then the interplay between the inflowing water and the local ventilation of this water (by "upwelling" or mixing to the surface, where it is exposed to air-sea gas exchange) dominates.

#### 150 2.1.6 Oxygen

Our dissolved oxygen module is dubbed *EckO<sub>2</sub>*-module (from **Eckernförde O<sub>2</sub>**). The module is very similar to the approach of Bendtsen and Hansen (2013) dubbed OXYCON. A schematic representation of *EckO<sub>2</sub>* is given in Figure 6. Following Bendtsen and Hansen (2013), the local development over time of dissolved oxygen,  $\frac{\partial O_2}{\partial t}$ , is defined by:

$$\frac{\partial O_2}{\partial t} + A(O_2) = D(O_2) + S(O_2), \quad (1)$$

155 where  $A$  and  $D$  denote the divergence of the three-dimensional advective and diffusive fluxes as calculated by the GCM.  $S$   
denotes biogeochemical oxygen sources and sinks given by the model parameters  $opro$  at the sunlit sea surface, by  $orewa$  at  
depth below the compensation depth  $z_{co}$ , and by  $orese$  in the lowermost wet model grid box. These parameters determine how  
much oxygen is generated by primary production ( $opro$ ) and how much is consumed at depth ( $orewa$ ) and in the sediment  
( $orese$ ). The respective parameter choices are based on literature values listed in Table 1. Following Babenerd (1991) and  
160 based on Ærtebjerg et al. (1981) and Jacobsen (1982) we assume that the subsurface oxygen consumption rates are rather  
uniform throughout KB, EB and up into the Danish Straits. This assumption is necessitated by our lack of direct measurements  
of consumption rates in EB.  $EckO_2$  prescribes climatological monthly mean consumption rates.

## 2.2 Observations

We use data from the regular monitoring program of the LLUR. Respective approx. monthly observations of salinity, temper-  
165 ature and oxygen covered the entire hind-cast period at the monitoring station *Buoy 2a* (location marked in Figure 4).

## 3 Model Evaluation

Among the challenges in simulating oxygen dynamics is that both biotic parameters (determining oxygen respiration (Sec-  
tion 2.1.6)), and the antagonistic abiotic parameters (that control ventilation with surface water high in oxygen such as e.g.  
vertical diffusivity (Section 2.1.2)) are uncertain. Our approach is to run an ensemble of simulations encompassing a plausible  
170 range of settings. These settings are listed in Table 2. We compare low, medium and high levels of diffusivity (tagged *HighMix*,  
*MedMix*, *LowMix*, respectively) and a best guess of local biotic processes versus ignoring local biotic processes altogether  
(tagged *Rem*, indicating "remote" forcing of hypoxia only). This section identifies the most realistic simulation(s).

Figure 7 shows Taylor diagrams which compare simulated and observed temperature, salinity and oxygen. The simulations  
with high diffusivity (*HiMix* and *HiMixRem*) feature the lowest performance in reproducing the observed variability of temper-  
175 ature, salinity and oxygen. This is consistent with an assessment of simulated velocities by Marlow (2020). The more realistic  
simulations *LoMix* and *HiMix* are very similar - irrespective of whether we account for local sources and sinks of oxygen or  
not. We conclude (from Figure 7) that the lower values for the diffusivity are more realistic and that local sources and sinks  
of oxygen are apparently of minor importance within EB. This suggests that hypoxic events in EB are "imported" rather than  
driven by local oxygen consumption.

180 Figure 8 shows simulated and observed oxygen concentrations at the bottom of the monitoring station *Buoy 2a* for the years  
2000 - 2015. Shown are the respective months April to October. November to March are omitted because these months feature  
high concentrations of dissolved concentrations beyond our scope of interest. The overall impression is that the model retraces  
the dynamics of temperature, salinity and oxygen reasonably well. Figure 9 provides a more quantitative estimate of the fidelity  
in reproducing hypoxic events (as defined by the  $120 \text{ mmol O}_2 \text{ m}^{-3}$  introduced in Section 1) at the monitoring station *Buoy 2a*.  
185 It shows sensitivity and specificity achieved with the simulations *LoMix* and *MedMix* that account for local sources and sinks

of oxygen: *LoMix* typically simulates  $\approx 70\%$  true positives and  $\approx 10\%$  false positives. *MedMix*, in comparison, simulates only several % false positives but fails to identify every third event ( i.e.,  $\approx 70\%$  true positives).

## 4 Results

As a first step, we explore the simulated residence and ventilation timescales (Section 4.1) which provide a base for understanding the dynamics behind our hind cast, presented in Section 4.2. A complementary case study of the intense hypoxic event 2017 (related to the mass fish kill incidence depicted in Figure 2) is presented in Section 4.3. Section 4.4 describes the application of artificial intelligence for feature selection and extraction of the predictive capability of monitoring data at Station *Boknis Eck* at the entrance of EB to forecast hypoxia within EB at the monitoring station *Buoy 2a*.

### 4.1 Residence and Ventilation Times

The estimates of *residence* and *ventilation times* are calculated with "artificial clocks", as described in Section 2.1.5. Both model versions *LoMix* and *MedMix* show similar results: the water with the longest residence time is found at the end of EB in the interior close to the city Eckernförde (Figure 10). Typical values are of the order of one month for both exemplary months, August and October. Overall, *MedMix* shows lower values than *LoMix* indicating that vertical diffusive processes promote the horizontal exchange of water between EB and KB. This makes sense because the longest residence times can be found at the surface (Figure 11), suggesting that, on average, water enters the Bight at depth and leaves the Bight at the surface. A stronger vertical diffusivity is then associated with an accelerated rate of surface water renewal by deep water with shorter residence times.

The distribution of ventilation times or age is similar to that of residence times in that the highest values are generally found within the Bight towards Eckernförde (Figure 12). The horizontal gradient is more pronounced in the simulation with lower mixing, while higher prescribed vertical background mixing equalizes the effective ventilation processes horizontally. In terms of vertical distribution age has, in contrast to the residence time, high values at depth and low at the surface - where it is reset to zero (Figure 13).

In summary, we find that residence times and age are of similar magnitude. This suggests that the first order control of processes that determine oxygen concentrations in EB is an antagonistic interplay of inflowing water (generally low in oxygen) and the local aeration by vertical exchange with oxygenated surface waters. Biogeochemical processes in the interior of EB are apparently of minor importance for the oxygen dynamics within EB.

### 4.2 The Typical Seasonal Cycle inside EB

Figure 8 shows a comparison between the observed and simulated temporal evolution of dissolved oxygen concentrations at the bottom of the monitoring station *Buoy 2*. Most prominent is a pronounced seasonal cycle. The generic explanation for such seasonal cycles in such latitudes is that temperatures and biomass production in the surface waters ramps up in spring - driven by enhanced levels of photosynthetically available radiation (note, however that there is an ongoing discussion on this

issue Behrenfeld, 2010; Arteaga et al, 2020; Smetacek, 1985). The biomass eventually sinks to depth where it degrades and issues oxygen consumption. Later in the season, the water column stratifies and the surface layer heats up, effectively creating a barrier to the exchange of bottom water (deprived in oxygen) and the oxygenated surface waters. As autumn approaches, the surface ocean cools again and weakens the stratified barrier to vertical mixing. This facilitates the wind-driven mixing events that come along with more unstable autumn weather. In winter, convective mixing homogenizes the entire (rather shallow) water column vertically (e.g., Fennel and Testa, 2019; Petenati, 2017). Apparently the model captures this dynamic well, i.e., the ensemble mean of *LoMix* and *MedMix* features a high visual correspondence between the respective curves in Fig. 8 (see Figure 7 for more quantitative estimate).

Based on the hind cast simulation from 2000-2015 hypoxic events at Station *Buoy 2a* are most common in August and October with a local minimum of occurrences in September (Figure 14). This is inconsistent with the generic explanation outlined above, where a period of ever decreasing levels of dissolved oxygen ends in autumn when increasing winds and a pronounced air-sea heat transfer promotes net ventilation. So why do hypoxic conditions deep in EB at Station *Buoy 2a* become more frequent after the September setback, despite increasing winds and decreasing thermal stratification? The histograms of bottom oxygen concentrations observed at Station *Boknis Eck*, situated at the entrance to EB (and used to prescribe the conditions of water flowing into EB in the model), suggest: particularly low oxygen concentrations are more frequent in October than in August (Figure 15). Hence, water entering EB from KB in October are more likely to "import" hypoxia.

We conclude: the typical oxygen deficit in late summer is imported along with water from the KB, rather than being produced locally in EB. The following Section 4.3 will elucidate the underlying succession of events by means of a detailed case study.

### 4.3 Hypoxic Event 2017

In fall 2017 a particularly pronounced hypoxic event occurred and led to a mass fish kill incidence (Figure 2). In the following, we analyze this event in the MOMBE *LoMix* simulation.

Figure 16 shows a sequence of snapshots of simulated hypoxia in EB, starting August 20th and ending at peak conditions on September 10th. Over the course of these several weeks, EB loses oxygen and hypoxic waters apparently enter the Bight at the bottom from the east and moves upwards. The notion of "imported" hypoxic conditions is backed by the Hovmoeller Diagrams of simulated age and residence times at the monitoring station *Buoy 2a* in Figure 17: during the buildup of the hypoxic event in EB, the residence time features a local minimum deep inside EB. This suggests the prevalence of water masses "recently-imported" from KB (Figure 17 b). Simultaneously, the age features a maximum (Figure 17 a), indicating that the "recently-imported" hypoxic waters are well-shielded from ventilation by oxygenated surface waters. Further evidence is provided by Figure 18, showing that the oxygen decline in EB is contemporaneous with winds blowing out of the Bight. These winds drive an overturning circulation, shown in Figure 19, with surface waters being pushed out of the Bight and bottom waters, for continuity reasons, being sucked into the Bight at depth. Consequently, we find in Figure 18 that the oxygen decline at the entrance of the Bight (at Station *Boknis Eck*) occurs earlier than the oxygen decline inside the Bight (at Station *Buoy 2a*) - just as expected in a system where water enters the Bight at the bottom.

250

During the relaxation phase, that terminates the 2017 hypoxic event, the processes are reversed: Figure 20 shows that the winds are blowing consistently into the Bight for more than a week - a situation comparably uncommon in these latitudes of prevailing westerlies. Consequently, water is pushed into the Bight at the surface, having nowhere to go. Some of the well-oxygenated surface water is subducted to depth and subsequently leaves EB at depth. Just as expected, the increase in oxygen at the monitoring station *Buoy 2a* inside the Bight occurs earlier than the corresponding oxygen increase at the entrance Station *Boknis Eck*. The oxygen levels at *Boknis Eck* now lag behind *Buoy 2a* by approximately one week.

In summary, we identified a governing mechanism by which EB is - depending on wind direction - either: (1) impacted by imported low oxygenated waters from KB or (2) being flushed by oxygenated surface water, that is subducted to depth in the interior of EB and is exported at depth to KB - whereby EB is effectively ventilating KB.

Open question, however, remain. Of particular interest is the questions why some years are hit especially hard by hypoxia and whether such events are predictable days or weeks in advance. Such predictions may, e.g., allow for netting and landing of doomed fish. The following section applies Artificial Intelligence (AI) to pursue these questions.

#### 4.4 AI-based feature selection and time series prediction

The following section explores the statistical relations between the simulated time series at Station *Buoy 2a* deep in the Bight and *Boknis Eck* at the entrance of the Bight. The major aims are: (1) To gain further mechanistic insight. (2) To develop a surrogate models for the stakeholder that may be implemented on off-the-shelf desktop computers, smart phones or even on very low cost (< 10,- Euros) embedded devices rather than necessitating access to a super-computing facility (as is the case with the full-fledged coupled model). This section is motivated by recent and encouraging success in emulating general circulation models (e.g. Castruccio et al., 2014), ecosystem models (e.g. Fer et al., 2018), the tremendous success in machine learning and data-driven methods in fluid dynamics (as summarized e.g. by Brunton et al., 2020) and the sneaking suspicion that " ... the most pressing scientific and engineering problems of the modern era are not amenable to empirical models or deviations of first principles ..." (Brunton et al., 2020b).

In the following, we describe the application of shallow and deep feed-forward artificial neuronal networks (ANNs) to forecast bottom oxygen concentrations deep inside EB at the monitoring station *Buoy 2a* two weeks in advance from the atmospheric conditions and the regularly sampled monitoring station *Boknis Eck* at the entrance of the Bight. The forecast range is chosen as a compromise between the time needed for mitigation measures (e.g. by netting and landing of doomed fish) and forecast accuracy which typically degrades with forecasting range. During the course of this exercise we will use different combinations of predictors (or input data) and test their impact on the forecast skill - a processes also referred to as capacity estimation and feature selection (e.g., Sbalzarini et al., 2002). Note, however, that a comprehensive analysis of time series forecasting, which must include traditional statistical approaches in addition to machine learning methods (Makridakis et al, 2018), is beyond the scope of this manuscript.

#### 4.4.1 Capacity Estimation and Feature Selection

For training the ANNs, we draw our training (80%) and validation data (20%) randomly from the 2000 to 2016 model hind  
285 cast. We hand-design features (input data) and test their respective capacity to forecast bottom oxygen concentrations at Station  
*Buoy 2a* (target data). Hand-designed features are "... two edged swords" (e.g. Reichstein et al., 2019): they can be seen as an  
advantage because they give us control of the explanatory drivers which may be used to promote system understanding. On the  
other hand, hand-designed features are typically suboptimal. To this end our results here provide a lower bound on the potential  
of ANNs for the task at hand.

290 The ANN is trained using the Levenberg-Marquardt algorithm (Marquardt, 1963) applied to neuronal network training fol-  
lowing (Hagan and Menhaj, 1994) and (Hagan et al., 1996). Each training is repeated 30 times, each of which may yield  
(slightly) differing results because: depending on the (random) initialization of weights, the algorithm may terminate in poten-  
tially differing local optima of the cost function. As cost-function we choose mean-squared errors (calculated from MOMBE  
output and the ANN prediction designed to mimic the MOMBE output). Figure 21 shows respective cost as errors relative to a  
295 naive biweekly persistency forecast based on bottom oxygen concentrations at the monitoring station *Boknis Eck*: apparently  
the ANN's performance converges at 45% relative to the persistency forecast. Defining this as the Pareto Frontier suggests a  
Pareto Optimal of 56% - which corresponds to one or two nodes. The idea of opting for a rather parsimonious two-node model  
that scores 80% of the Pareto Frontier rather than 100% is to reduce the risk of overfitting which may hinder generalization.  
Further, parsimonious models are easier to interpret than their complex counterpart such that their robustness is easier to assess.  
300 This is especially important because we have no straightforward way to extract human semantics from the "rules" the neuronal  
network learned during the optimization process that related our input features to the target bottom oxygen concentrations at  
Station *Buoy 2a*.

We start with a shallow (one input, one hidden and one output layer) ANN utilizing the full vertical profiles of temperature,  
salinity and oxygen along with a biweekly wind forecast totaling at 106 input features (given by the three 1-m resolution  
305 vertical profiles of temperature, salinity and oxygen down to 26 m depth and the 14-daily forecasts of zonal and meridional  
winds each). This setup is based on an optimistic estimate of the number of features available to stakeholders. Specifically, we  
assume to have access to a correct biweekly wind forecast along with one full vertical profile of each temperature, salinity and  
oxygen at the monitoring station *Boknis Eck* located at the entrance of EB (i.e., the 106 features introduced above).

Figure 21 suggests that the Pareto Frontier is at 45% corresponding to a 55% reduction in error relative to the persistence  
310 model. 80% of this yields a Pareto Optimal of 56%. This corresponds to one or two nodes. Additional tests with deeper ANN's  
featuring up to 10 hidden layers with two nodes were unsuccessful in that respective errors were always higher than 50%. We  
conclude that a simple two node shallow ANN features already a reasonable performance and two input features, of the 106  
tested, may suffice to capture the main effects.

Table 3 summarizes our effort to identify the most predictive features by backward elimination (e.g. Dietterich, 2002). Using  
315 combinations of only 15 features comprised of biweekly zonal windspeed and the bottom values of either temperature, salinity  
or oxygen yielded a moderate degrade in performance of only 10% (Table 3 entries 2 to 4). Pushing further we identified a

combination of two features only that are, on the one hand, within this 10% degradation and, on the other hand, especially easy to measure for stakeholders: surface and bottom temperature at Station *Boknis Eck*. Counter to intuition adding wind forecasts does not improve the ANNs fidelity (compare entries 5 and 6 in Table 3). Even so, the ANN fits the training and validation data remarkably well (Figure 22). We conclude that the ANN's biweekly forecast exploits links other than those being direct consequences of the wind driven inflow versus ventilation mechanism identified in Section 4.3. Section 4.4.2 puts this exploitation to the test using independent test (model) data.

#### 4.4.2 ANN Generalization

This section discusses the fidelity of the two-node ANN using bottom and surface temperature identified in Section 4.4.2 as being parsimonious but - even though - yielding reasonable results compared to more complex architectures, such as deeper nets using more nodes and input data. Here, we use independent test data covering the years 2016 to 2018 of our hindcast simulation. This data has neither been used in training nor during validation so far. To rate the forecast it is compared to the "persistence model", which assumes that the oxygen concentrations at station *Boknis Eck* appear two weeks later at station *Buoy 2a* (green line in Figure 23). The first striking impression of the close-ups in Figure 23 is that all years feature a similar seasonal decline in bottom oxygen in autumn and this decline generally closely resembles the oxygen decline in *Boknis Eck* two weeks in advance. Large interannual differences, however, occur in the onset of the trend reversal. This "return-point" in time is not captured well by the persistency model. These results are consistent with our results in Section 4.3 showing that the decline is driven by the import of low-oxygenated waters from KB. Ventilation, however, takes place in the interior of the Bight and its signal reaches Station *Boknis Eck* at the entrance afterwards - such that we indeed expect no predictive power of the persistency model under these circumstances. To this end, our ANN outperforms the persistency model in that it predicts an earlier and more realistic recovery of oxygen values during end of summer / beginning of autumn - despite the ANN also exclusively relying on data at the entrance at Station *Boknis Eck*. The ANN essentially links information regarding season ("derived" from sea surface temperature) and stratification ("derived" from the temperature difference between surface and depth) at the entrance of the Bight with oxygen concentration in the interior of the Bight - without utilizing information on winds. In summary, the ANN features a remarkable (and counter intuitive) performance given that it simply relies on two temperature measurement at the entrance of the Bight.

## 5 Discussion

Oxygen concentrations are controlled by the antagonistic interplay of respiration and ventilation processes. Our model-based analysis suggest that the variability in the occurrence of hypoxic conditions in EB is correlated with the a high variability in wind-driven ventilation rather than with a high variability in local respiration. This result is in agreement with Ærtebjerg et al. (2003), who examined the massive 2002 (one of the worst ever documented) oxygen deficit event that encompassed the Kattegat, the Belt Sea and the Western Baltic Sea. Back then, Ærtebjerg et al. (2003) found no evidence for anomalous respiration patterns i.e. metrics like anthropogenic phosphate loads and the evolution of the phytoplankton spring bloom appeared to

350 have stayed - in contrast to the oxygen concentration - within typical bounds. This, in turn, highlighted the importance of the variability of ventilation in shaping hypoxic events.

In our model frameworks we distinguish between two types of ventilation: for one, vertical mixing driven by isotropic turbulence and composed of a parameterization of constant background mixing complemented by a surface mixed layer model that mimics the effect of convection, shear-instability and wind-induced turbulence (more specifically we use the KPP scheme of Large et al., 1994). Vertical mixing is difficult to constrain in models because direct observations of turbulence are rare and additional complexity arises from numerical subtleties in models (e.g. Burchard et al, 2008). That said, we use the fidelity of simulated temperatures as a proxy for the realism of mixing rates: our simulations *LoMix* and *MedMix* featuring a vertical diffusivity of  $5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$  and  $10^{-4} \text{ m}^2 \text{ s}^{-1}$  both fit the observations inside the Bight reasonably well. The respective correlation coefficients are  $\approx 0.9$  at a simulated standard deviation scoring  $\approx 90\%$  of the observed (Figure 7). This is roughly consistent with an estimate inferred from the rate of spreading of a deliberately released substance from Holtermann et al. (2012) who report a basin-scale Baltic Sea vertical diffusivity of the order of  $10^{-5} \text{ m}^2 \text{ s}^{-1}$  with dramatically increasing values in proximity to the coast.

The other type of ventilation that is of relevance in our coupled ocean-circulation biogeochemical model is the explicitly resolved (i.e., not parameterized) wind-driven overturning circulation in EB (Figure 19). A closer look into the seasonal cycle of the years 2016, 2017 and 2018 (Figure 23) revealed that the minimum oxygen concentration is mainly set by the timing of the first overturning event in late summer / beginning of autumn when winds push surface waters into the Bight where it is subducted, overcomes the vertical stratification and replaces deoxygenated bottom waters with recently oxygenated surface waters. This explicitly resolved overturning cycle expands over the whole Bight and apparently exports oxygenated bottom waters thereby ventilating KB. Given the reasonable representation of the seasonal cycles during the 2000 to 2016 period (Figure 8) we conclude that our coupled ocean-circulation biogeochemical model resolves the major processes at play - although at a high computational cost.

Further mechanistic insight resulted from an exploration of the relations between simulated time series at Station *Buoy 2a* in the interior of EB and biweekly lagged series at station *Boknis Eck* at the entrance of the Bight using an ANN: Counter to our intuition, an ANN fed with information on stratification (i.e. bottom and surface temperature whose difference is a measure of stratification) at the entrance of the Bight and season (i.e. surface temperature which is strongly correlated to season) only, performs surprisingly well without access to wind forecasts - even though the major mechanism behind the oxygen variability is wind-driven. This highlights the importance of the preconditioning that has to precede a ventilating overturning event: In EB, deoxygenation continues almost monotonically until destabilizing buoyancy fluxes have eroded the stability of the water column to a point where the next shift to easterly wind can replace the denser bottom waters with lighter surface waters. Because synoptic weather systems and associated wind directions have a lifetime of the order of a week in EB, forecasts based on state of preconditioning are, on average, accurate within a week.

In summary, we made an effort to explore the uncertainties that are associated with poorly constrained processes such as mixing and oxygen consumption: we tested various degrees of mixing (parameterizations) in combination with and without local sources of oxygen consumption. But caveats remain. Among those is the influence of the waste water treating facility

385 Kiel Bülk. Kiel Bülk serves 310.000 citizens and discharges  $19 \times 10^6 \text{ m}^3$  treated sewage per year to the sea close to our  
model boundary. Our model calculations do not account for this because we lack respective data on sewage composition. The  
following back-of-the-envelope calculation based on published data covering an extreme event puts the potential influence of  
Kiel Bülk into perspective: Haustein (2002) documents a discharge corresponding to 24.4 tons of COD (chemical oxygen  
demand) for the extreme heavy rain event of July 18, 2002. This corresponds to  $7.6 \cdot 10^5 \text{ mol O}_2$ . Our model domain covers  
roughly a wet area of  $120 \text{ km}^2$  with an average depth of 11.7 m, corresponding to a volume of  $1.4 \cdot 10^9 \text{ m}^3$ . Hence, assuming  
390 that currents swept the entire discharge of July 18th into EB where it spread out homogeneously yields a reduction of only  
 $1 \text{ mmol O}_2 \text{ m}^{-3}$ . This is negligible - to the extent that the assumption of instantaneous homogeneous distribution over the entire  
Bight holds.

## 6 Conclusions

We set out to dissect the mechanisms driving hypoxic events and associated fish-kills in EB. In order to fill data gaps, both  
395 spatially and temporally, we developed the high-resolution coupled ocean-circulation biogeochemical model MOMBE and  
integrated an ensemble of hind cast simulation covering the years 2000 to 2018. Our analysis based on simulated and observed  
oxygen, temperature and salinity along with artificial model tracers quantifying residence times and local ventilation (*ideal age*)  
revealed the two major and antagonistic processes determining oxygen variability in EB: (1) The oxygen deficit in EB which  
builds up every summer is imported from KB. The prevailing westerlies push surface water out of the Bight. Its replacement  
400 enters the Bight at depth which, in summer, taps into the oxygen depleted deep(er) KB. Local oxygen consumption in EB  
plays a minor role in shaping hypoxic events. (2) Intermittent easterly winds subduct oxygenated surface water at the end of  
the Bight - once the vertical stratification has been sufficiently degraded in late summer / beginning of August. The subducted  
water ventilates the entire EB and, as it is exported to KB, contributes to ventilating KB.

Further, we explored the predictability of hypoxia in the interior of EB (at Station *Buoy 2a*) based on data from the entrance  
405 (at Station *Boknis Eck*). The rationale was to identify main controlling mechanisms and to develop a computationally cheap  
forecasting tool for stakeholder. Successful experiments with an Artificial Neuronal Network, trained with data from the cou-  
pled MOMBE model revealed in a backward elimination exercise that surface and bottom temperature on their own (taken at  
a monitoring station at the entrance of EB) provide enough information for a reasonable biweekly forecast of bottom oxygen  
concentrations deep in EB. This finding traces the severity of hypoxia in late summer as being a consequence of a wind-induced  
410 subduction of surface water that is delayed (or advanced) by the state of stratification.

*Code and data availability.* The circulation model code MOM4p1 is distributed by NOAA's Geophysical Fluid Dynamics Laboratory (<http://www.gfdl.noaa.gov/fms>). We use the original code without applying any changes to it. Meridional sections and bottom values of simu-  
lated oxygen concentrations, temperature, salinity, residence time and age have been visualized for the hind cast period 2000-2018 for the  
stakeholder. They are archived under <https://doi.org/10.5281/zenodo.4271941> and accessible via <https://doi.org/10.5281/zenodo.4271941>.

415 The Boknis Eck Time-Series Station is run by the Chemical Oceanography Research Unit of the GEOMAR Helmholtz Centre for Ocean Research Kiel. The data from Boknis Eck are available from [www.bokniseck.de/database-access](http://www.bokniseck.de/database-access).

*Author contributions.* H. Dietze and U. Löptien have been equally involved in setting up and running the model configurations. Both authors contributed to the interpretation of model results, to outlining and writing of the paper in equal shares.

*Competing interests.* The authors declare that they have no conflict of interest.

420 *Acknowledgements.* We acknowledge support by Birgit Schneider. This work is part of an collaborative effort between the Christian-Albrechts-Universität zu Kiel and the Landesamt für Landwirtschaft, Umwelt und ländliche Räume titled *Frühwarnsystem Upwelling (FRAM)*, *Vergabenummer 0608.451812*. We are grateful to the MOM community for sharing code and expertise. Haustein (2002)	Average (dry days) oxygen consumption equivalent of Kiel Bülk sewage effluent, distributed evenly over Eckernförde Bight		0.04	
Haustein (2002)	Episodic, extreme discharge event during 18th and 19th July 2002 of the Kiel Bülk sewage plant, converted into oxygen consumption equivalent distributed evenly over Eckernförde Bight		0.36	
Nausch et al. (2011)	Average Kiel Bülk sewage phosphorous effluent, converted into oxygen consumption assuming that it fuels organic matter production that is remineralized in Eckernförde Bight		0.03	
Nausch et al. (2011)	Phosphorous loads of rivulet Schwentine that drains into Kiel Bight, converted into oxygen consumption assuming that it fuels organic matter production that is entirely remineralized at depth in Eckernförde Bight		0.18	

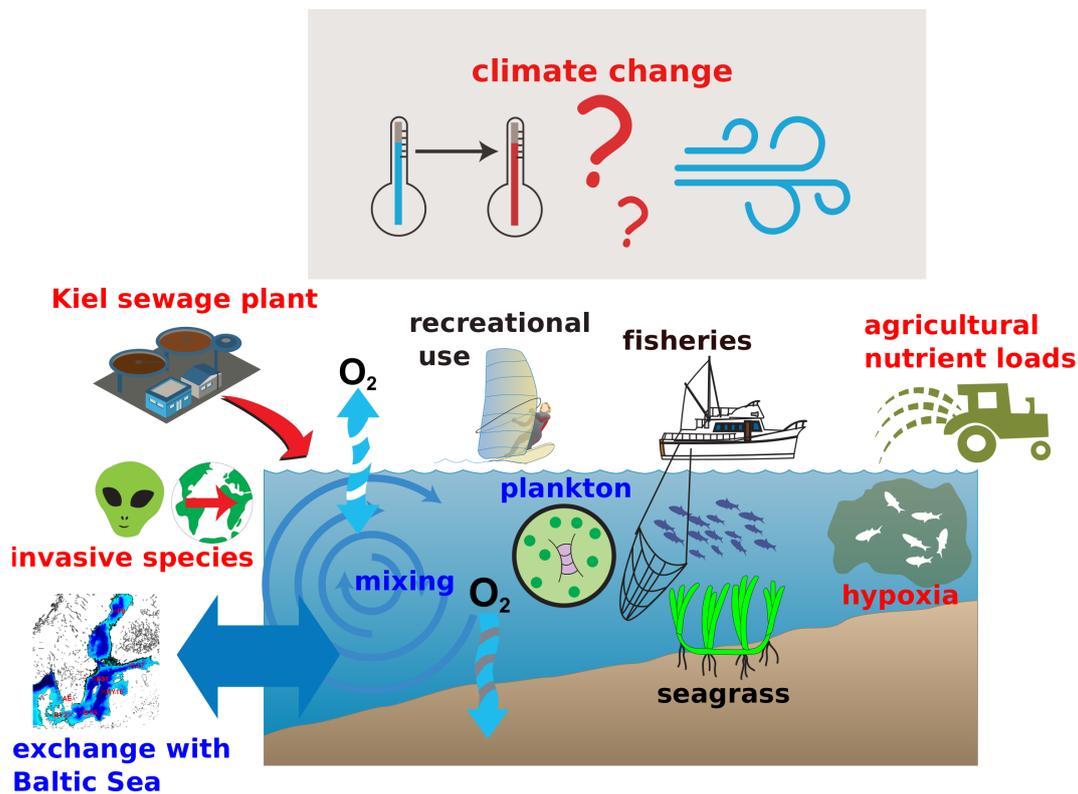

**Table 2.** List of model parameter settings for the EckO<sub>2</sub>-module and diffusive background mixing in MOMBE.  $\kappa_v$  refers to vertical background mixing (diffusivity). *opro*, *orewa* and *orese* refer to monthly (one value per month starting with the January value) oxygen production, water column oxygen respiration and oxygen consumption by the sediment, respectively (cf. Figure 6). Values for *orewa* and *orese* are derived from the published estimates listed in Table 1. *opro* is calculated as residual assuming instant equilibration of sedimentary fluxes.

tag	description	$\kappa_v$ $m^2 s^{-1}$	<i>opro</i> [mmol O <sub>2</sub> m <sup>-2</sup> day <sup>-1</sup> ]	<i>orewa</i> [mmol O <sub>2</sub> m <sup>-3</sup> day <sup>-3</sup> ]	<i>orese</i> [mmol <sub>2</sub> m <sup>-2</sup> day <sup>-1</sup> ]
<i>LoMix</i>	Low vertical background mixing of momentum and tracers. Local oxygen consumption/production rates at the upper limit of published estimates.	$5 \times 10^{-5}$	48 47 47 46 46 45 48 50 50 49 48 48	3.8 3.8 3.8 3.8 3.8 3.8 3.8 3.8	4 3.5 3 2.5 2.1 1.6 3.95 6.3 5.8 5.4 4.9 4.4
<i>LoMixRem</i>	Low vertical background mixing of momentum and tracers. No local oxygen consumption/production.	$5 \times 10^{-5}$	0 0 0 0 0 0 0 0 0 0	0 0 0 0 0 0 0 0 0 0	0 0 0 0 0 0 0 0 0 0 0
<i>MedMix</i>	Medium vertical background mixing of momentum and tracers. Local oxygen consumption/production rates at the upper limit of published estimates.	$1 \times 10^{-4}$	48 47 47 46 46 45 48 50 50 49 48 48	3.8 3.8 3.8 3.8 3.8 3.8 3.8 3.8	4 3.5 3 2.5 2.1 1.6 3.95 6.3 5.8 5.4 4.9 4.4

**Table 3.** Capacity estimation of input features. This table relates the fidelity of biweekly walk-forward ANN forecast of bottom oxygen concentrations at the monitoring station *Buoy 2a* with data from Station *Boknis Eck* fed to the ANN. The average of windspeed squared refers to respective biweekly forecast of zonal winds. The error is the RMS deviation between the (computationally cheap) ANN projection and simulated (computationally expensive; full-fledged coupled biogeochemical ocean circulation model) bottom oxygen concentrations at Buoy 2a relative to the respective RMS of the persistence model (which naively assumes that *Boknis Eck* bottom oxygen concentrations will persist for 14 days at Buoy 2a).

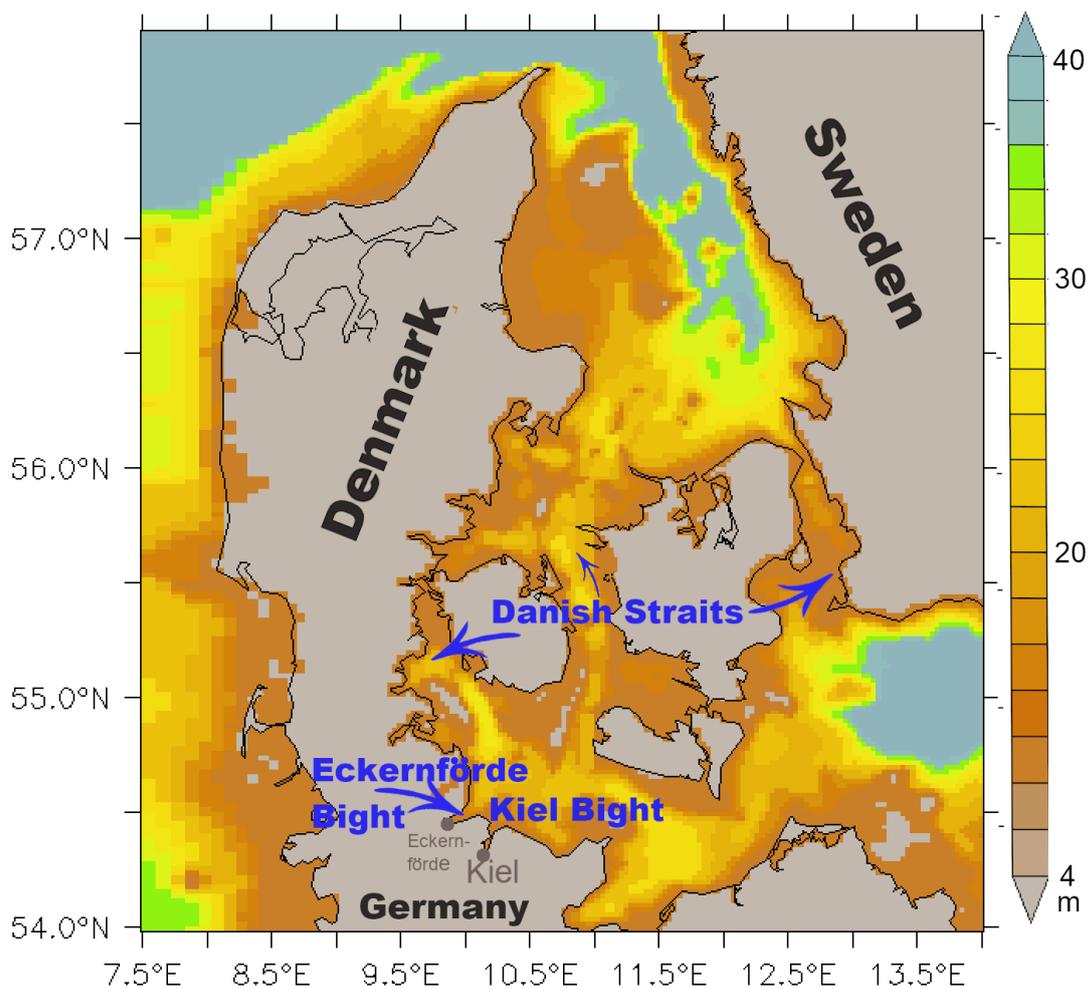

Input Features	Error [%]
average of zonal and meridional windspeed squared, full vertical profiles (26 depth levels) of O <sub>2</sub> , temperature and salinity	54
average of zonal windspeed squared, bottom O <sub>2</sub>	64
average of zonal windspeed squared, bottom salinity	65
average of zonal windspeed squared, bottom temperature	62
average of zonal windspeed squared, surface and bottom temperature	58
surface and bottom temperature	58

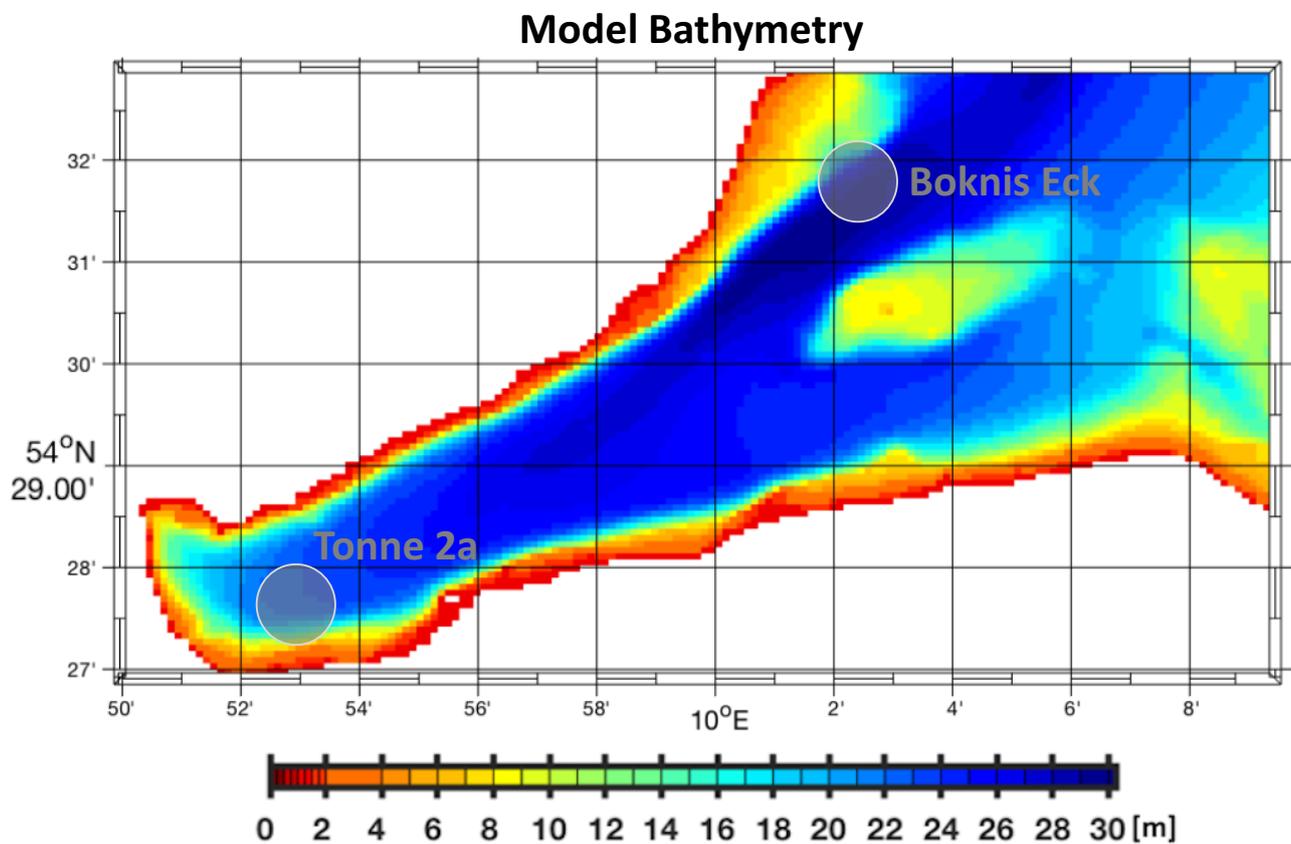

**Figure 1.** Schematic of the processes in Eckernförde Bight exemplarily for many coastal regions in the anthropocene. Assets such as fisheries, recreational use, and seagrass - which stands as a proxy for biodiversity and blue carbon - are printed in black. Potential stressors putting these assets at risk (such as climate change) are printed in red. Processes that call for a comprehensive and quantitative understanding in order to facilitate cost-efficient mitigation and adaptation strategies are printed in blue.

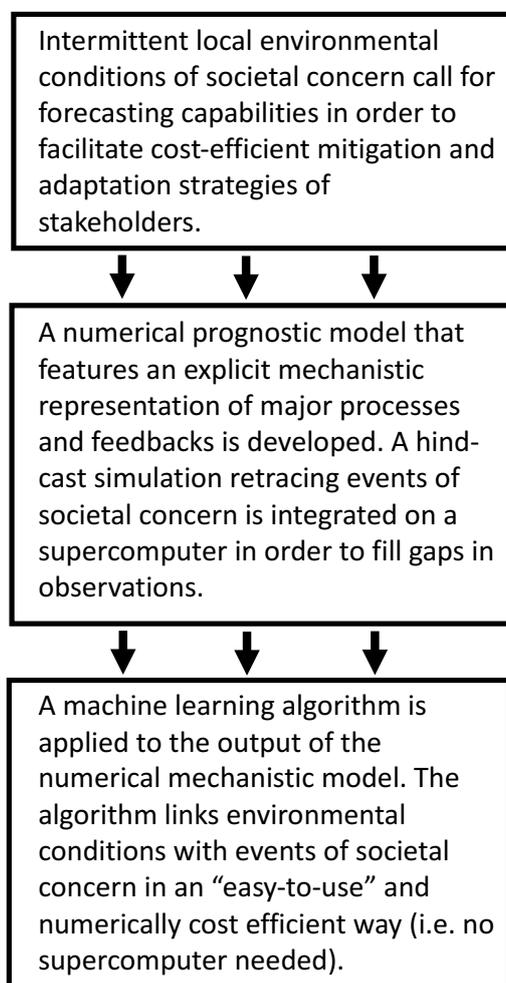

**Figure 2.** Fish kill incident in the inner Eckernförde Bight. Dead fish washed up on the southern shore in September 2017.

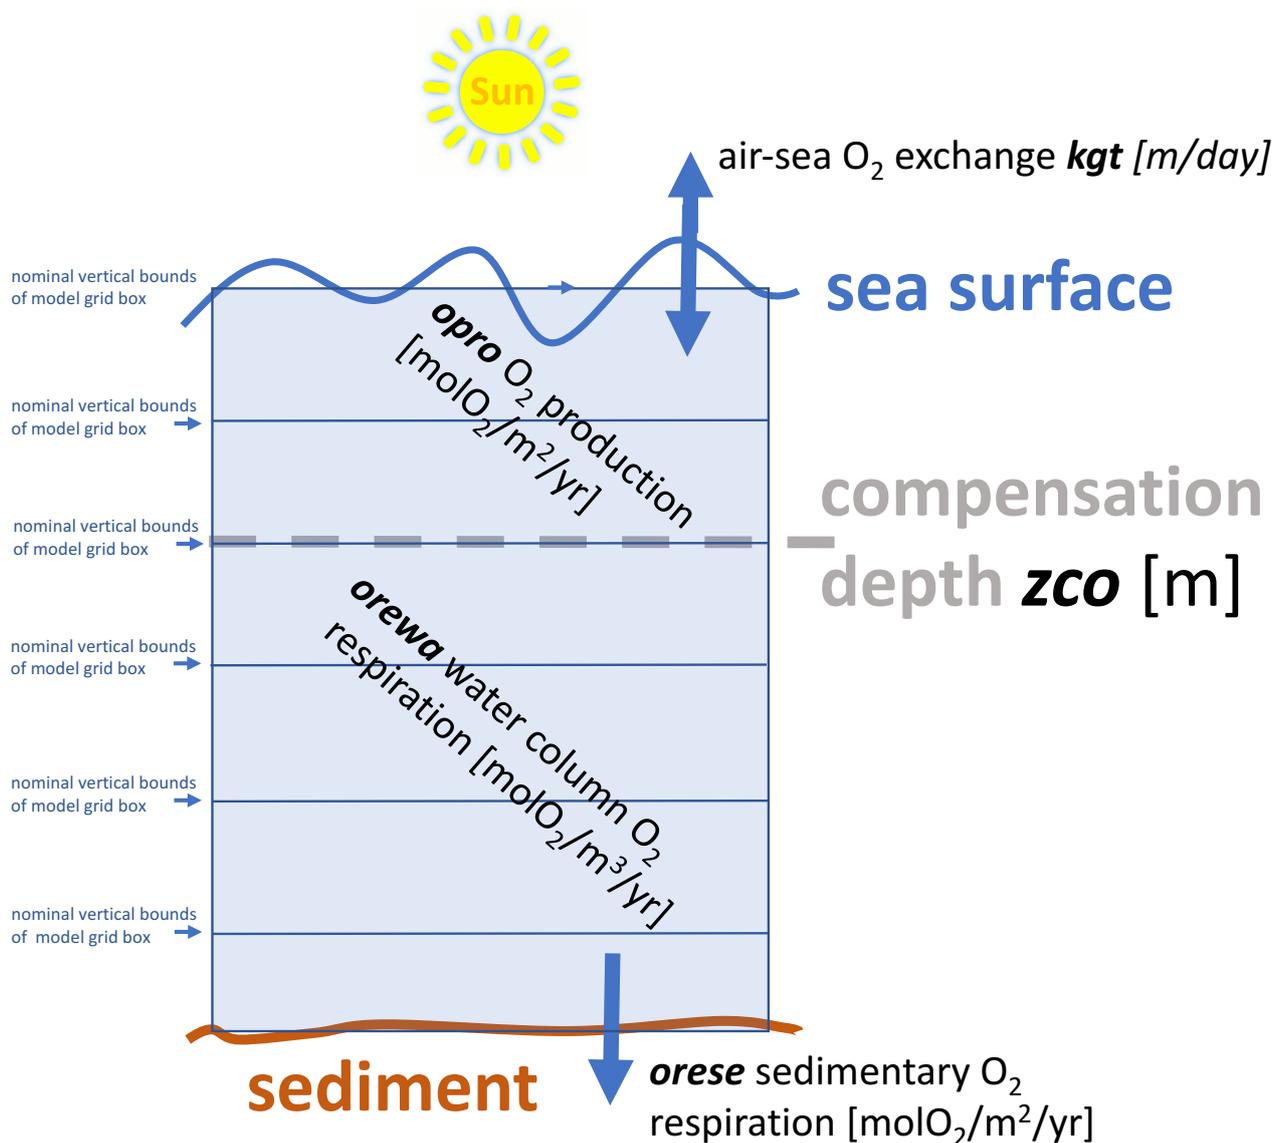

**Figure 3.** Overview map. The colors indicate water depth in m.

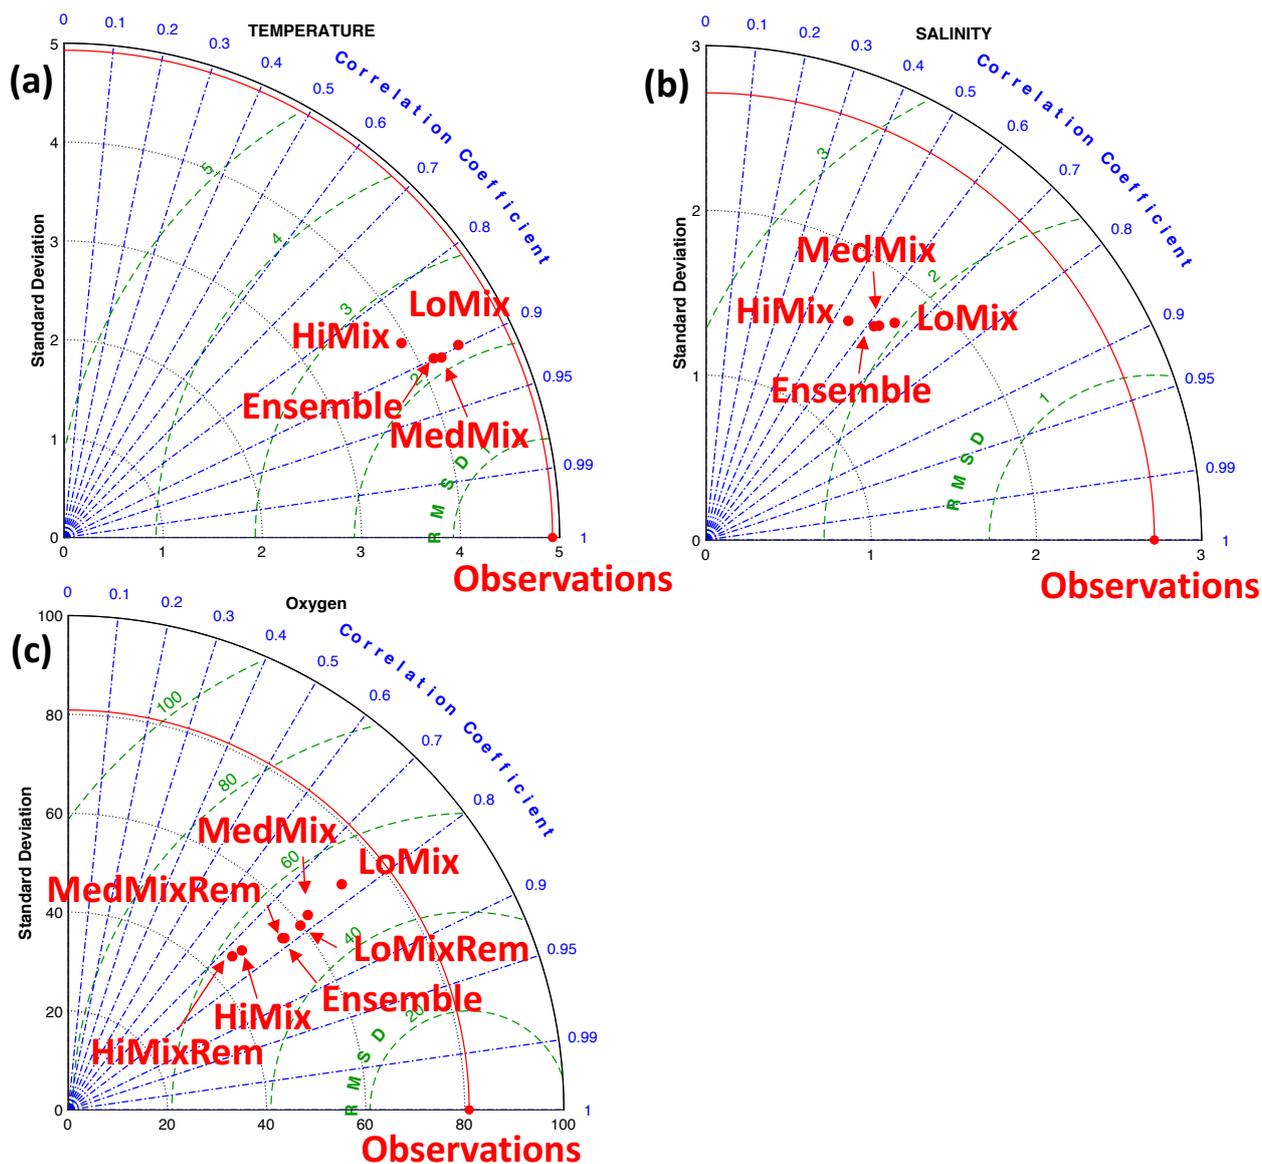

**Figure 4.** Model bathymetry. The horizontal and vertical resolution are 100 m and 1 m, respectively. The northern and eastern boundaries are closed (rigid walls). Sea surface height, temperatures and salinities around the closed boundaries are restored to prescribed values. Grey circles depict the locations of the observational sites at the entrance and deep inside EB.

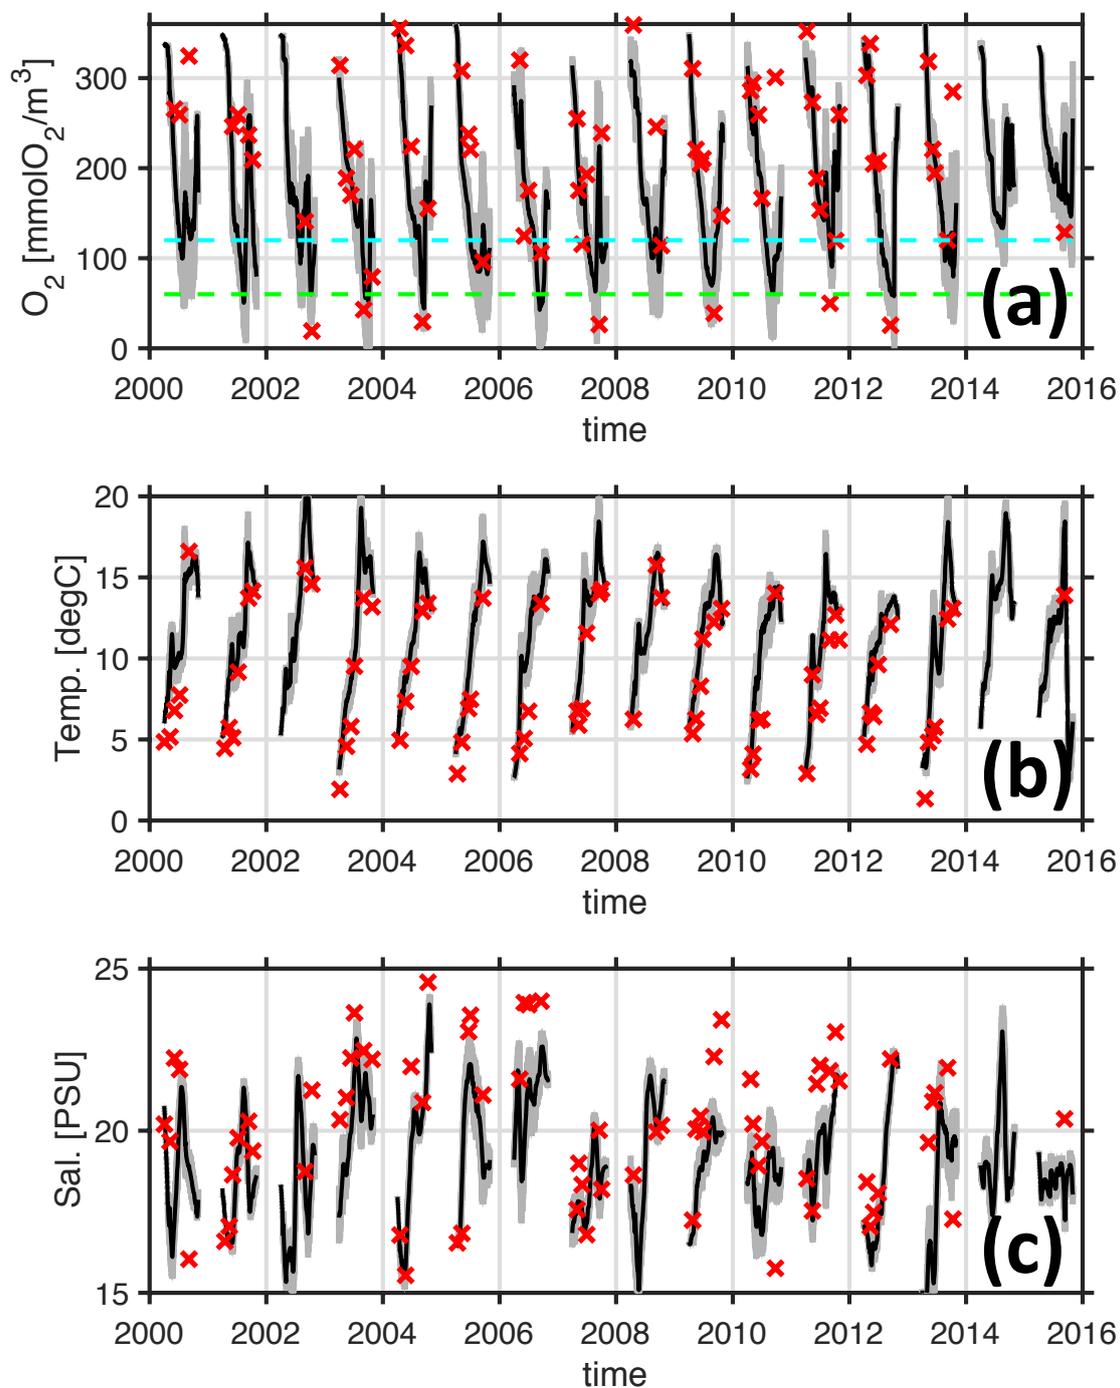

**Figure 5.** Schematic of workflow.

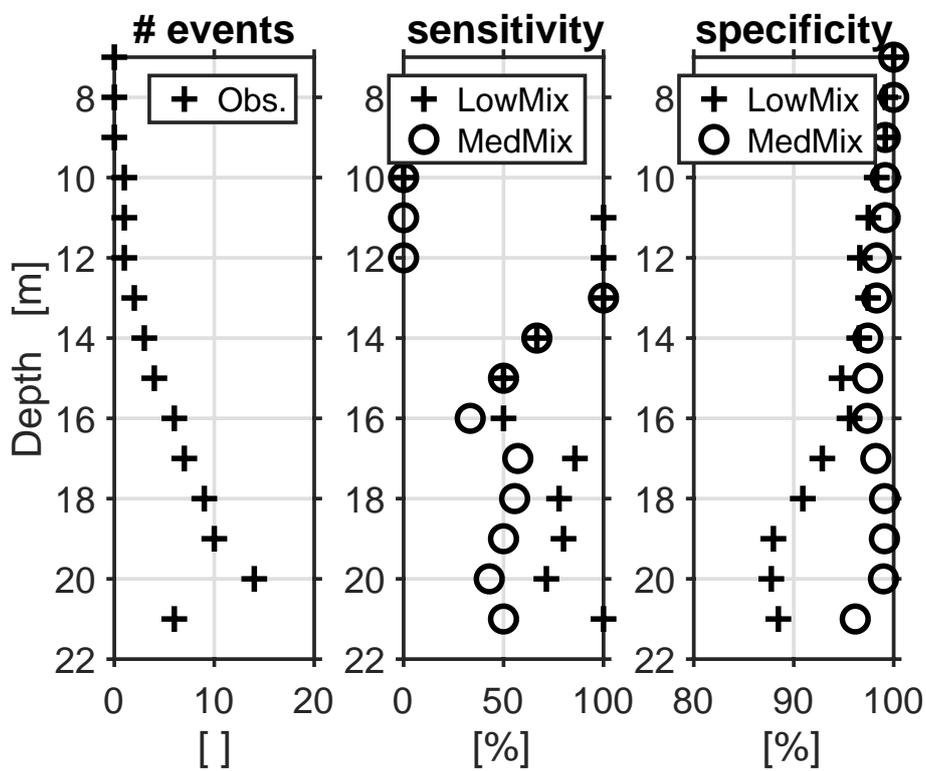

**Figure 6.** Schematic of dissolved oxygen module *EckO<sub>2</sub>*. *EckO<sub>2</sub>* calculates sinks and sources of oxygen throughout the water column for every grid box. These terms are then passed to the 3-dimensional general ocean circulation that handles the effect of advection and diffusion. The velocity of the air-sea gas exchange is determined by the piston velocity *kgt*. Above the compensation depth *zco*, primary production produces oxygen at a rate prescribed by the model parameter *opro*. Below the compensation depth *zco*, respiration of organic matter consumes dissolved oxygen at a rate prescribed by *orewa*. At the bottom, prescribed oxygen fluxes *orese* mimic the oxygen consumption of the sediment that is fuelled by the transfer across the water-sediment boundary. Table 2 summarizes respective parameter settings.

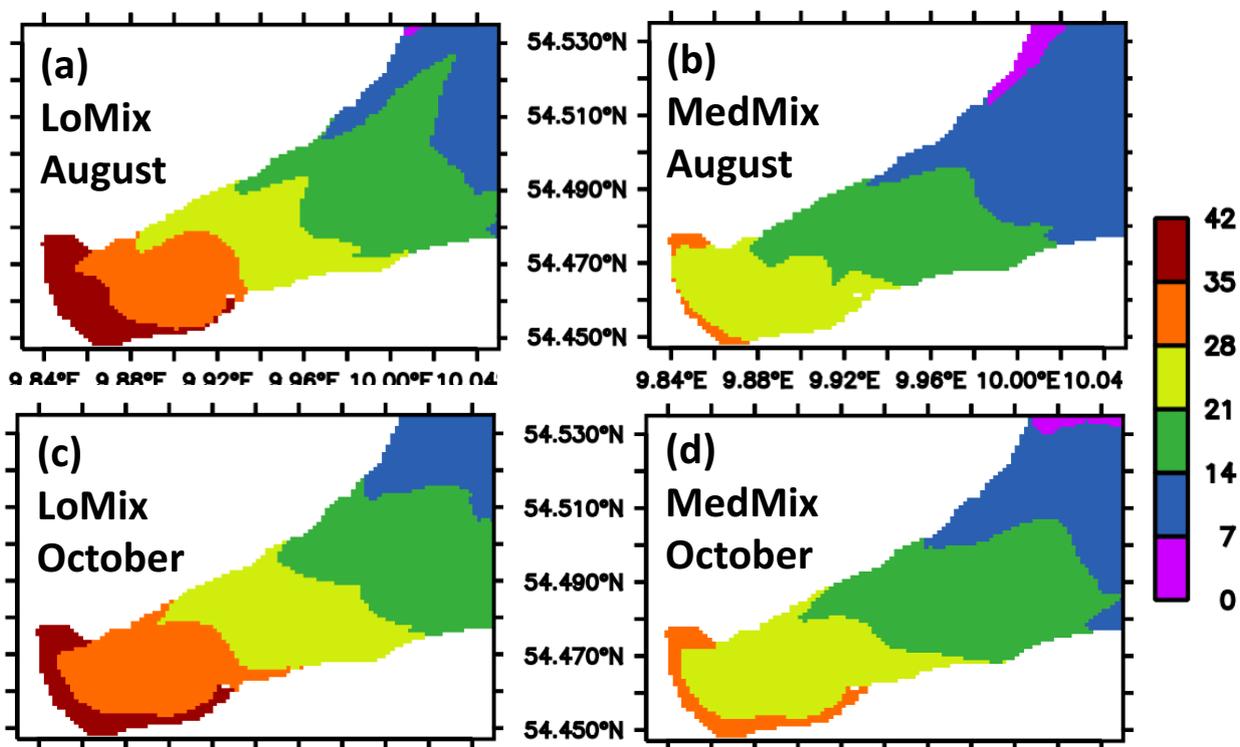

**Figure 7.** Model assessment (Taylor Plots) at Station *Buoy 2a* in the interior of EB (Figure 4). Observational data and model output refer to the 2000 to 2015 period. The simulation tags are defined in Table 2: *LoMix*, *MedMix* and *HiMix* denote the levels of diffusive background mixing. *Rem* indicates remote effects of biogeochemical sources and sinks of oxygen only (i.e. no local oxygen consumption in EB).

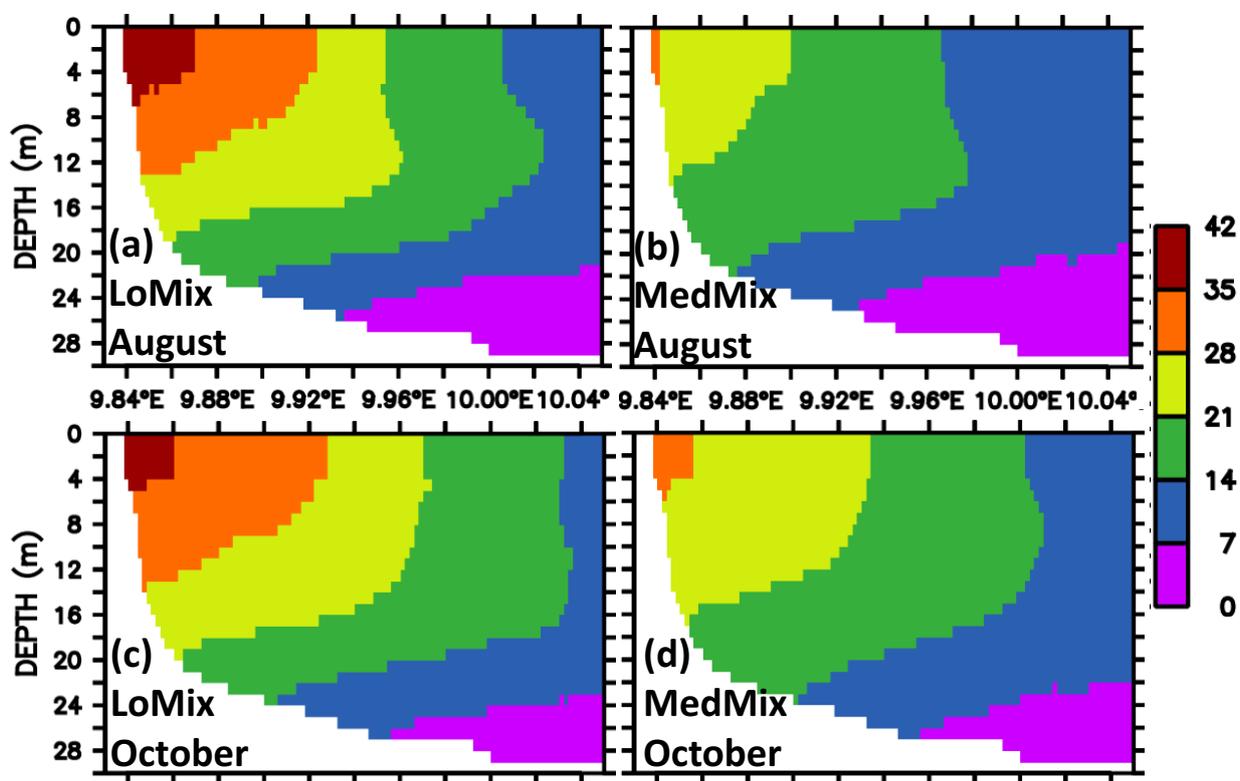

**Figure 8.** Simulated and observed oxygen concentrations at the bottom (20 m depth) of the monitoring station *Buoy 2a*. Panel a, b and c refer to oxygen concentrations, temperature and salinity, respectively. Red crosses denote observations. The black line denotes the ensemble mean of the simulations *MedMix* and *LowMix*. The grey line envelopes the ensembles' extremes at any given time. The horizontal dashed cyan and green lines in panel a show 120 and 60 mmol O<sub>2</sub> m<sup>-3</sup> hypoxia thresholds, respectively.

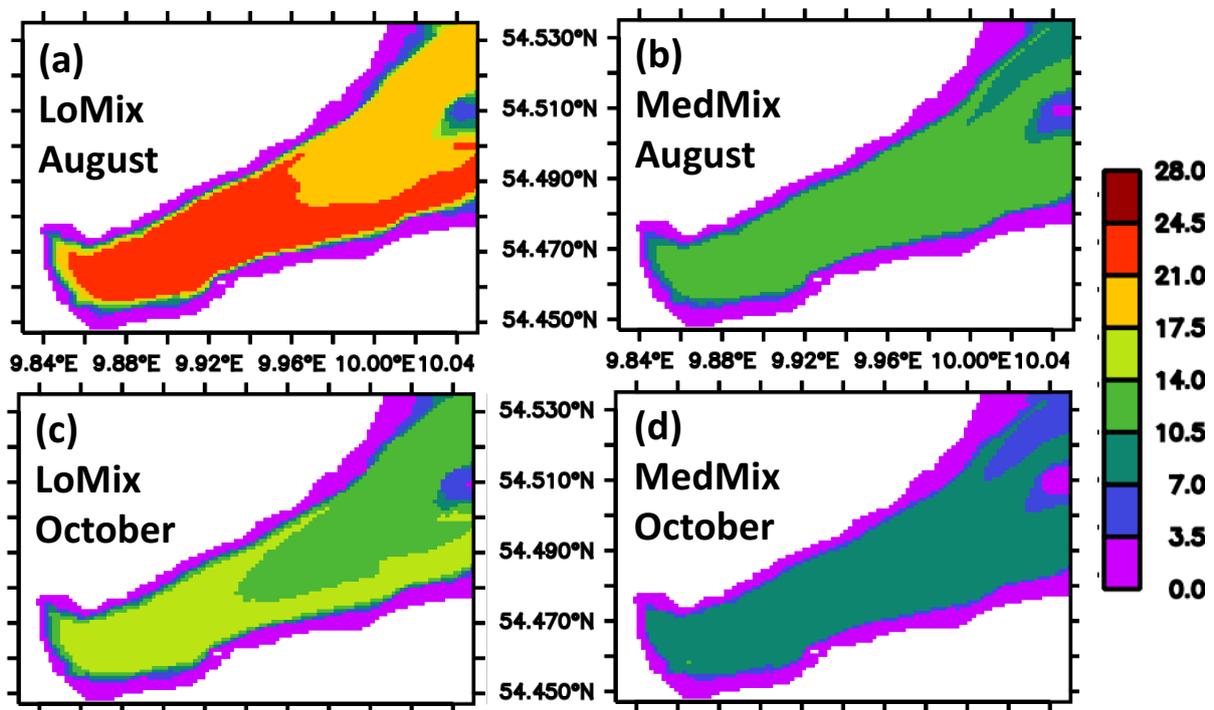

**Figure 9.** Fidelity of hindcasted hypoxic events (oxygen threshold of  $120 \text{ mmol O}_2 \text{ m}^{-3}$ ) at Station *Buoy 2a*.

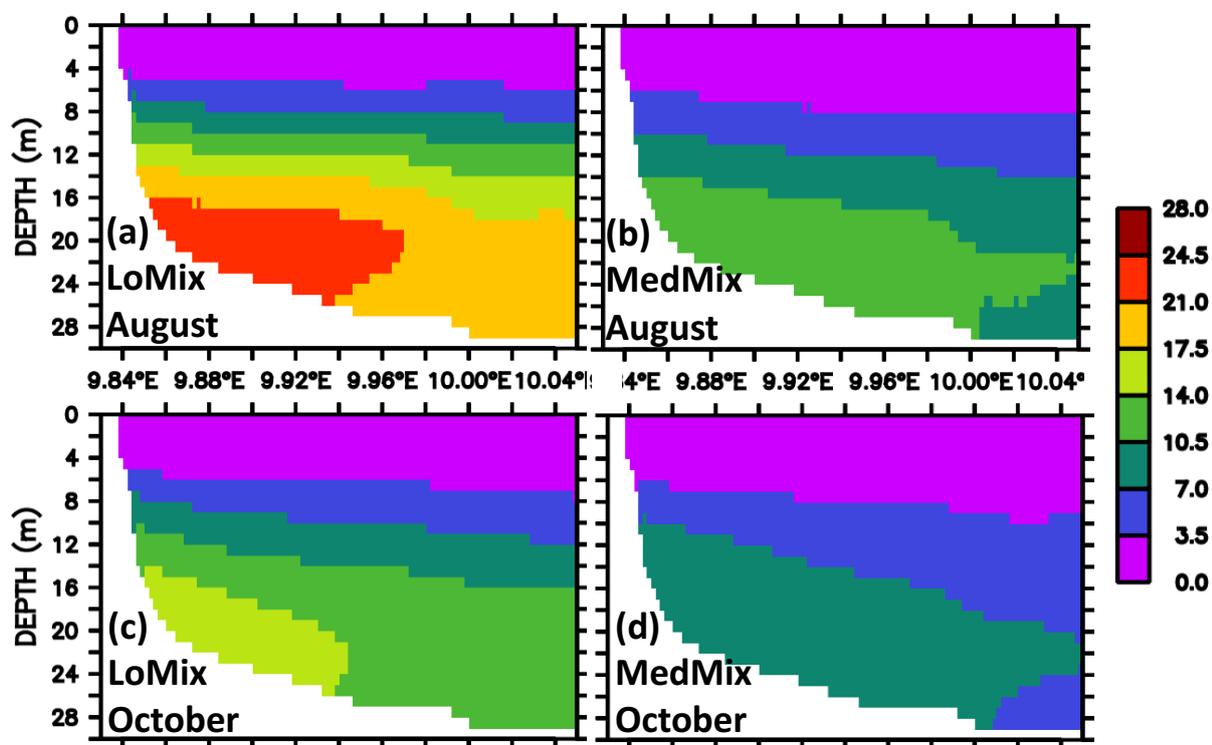

**Figure 10.** Simulated climatological estimate of the residence time of water parcels in EB. The units are days elapsed since the water flushed into the Bight. The estimate refers to the longest residence time found in local water columns. Panels (a) and (b) refer to August calculated by the simulations *LowMix* and *HiMix*, respectively. Panels (c) and (d) refer to October calculated by the simulations *LowMix* and *HiMix*, respectively.

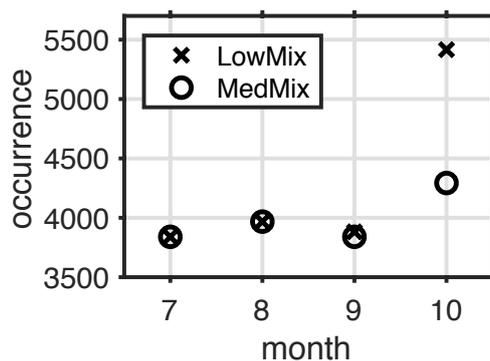

**Figure 11.** Simulated climatological estimate of the residence times of water parcels in EB. The units are days elapsed since the water flushed into the Bight. Shown are sections along EB. Panels (a) and (b) refer to August calculated by the simulations *LowMix* and *HiMix*, respectively. Panels (c) and (d) refer to October calculated by the simulations *LowMix* and *HiMix*, respectively.

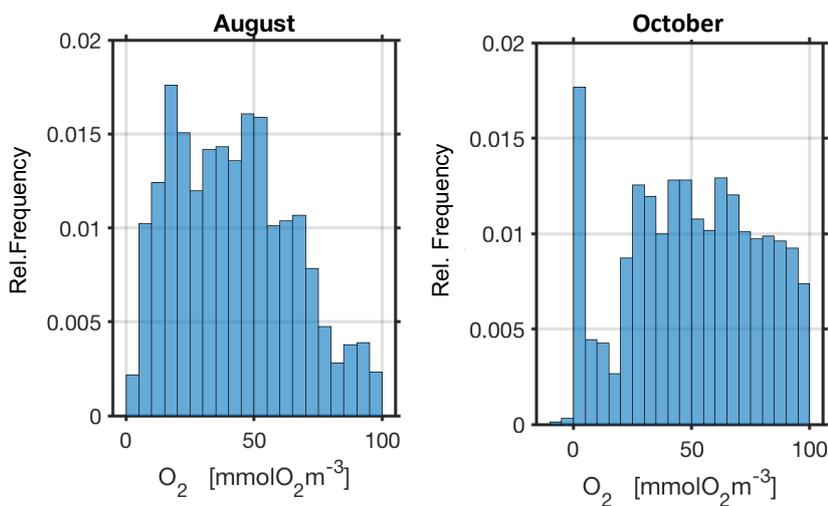

**Figure 12.** Simulated climatological estimate of local ventilation. The color shading denotes the time elapsed (age) since bottom water has been in contact with the atmosphere in units days. Panels (a) and (b) refer to August calculated by the simulations *LowMix* and *HiMix*, respectively. Panels (c) and (d) refer to October calculated by the simulations *LowMix* and *HiMix*, respectively.

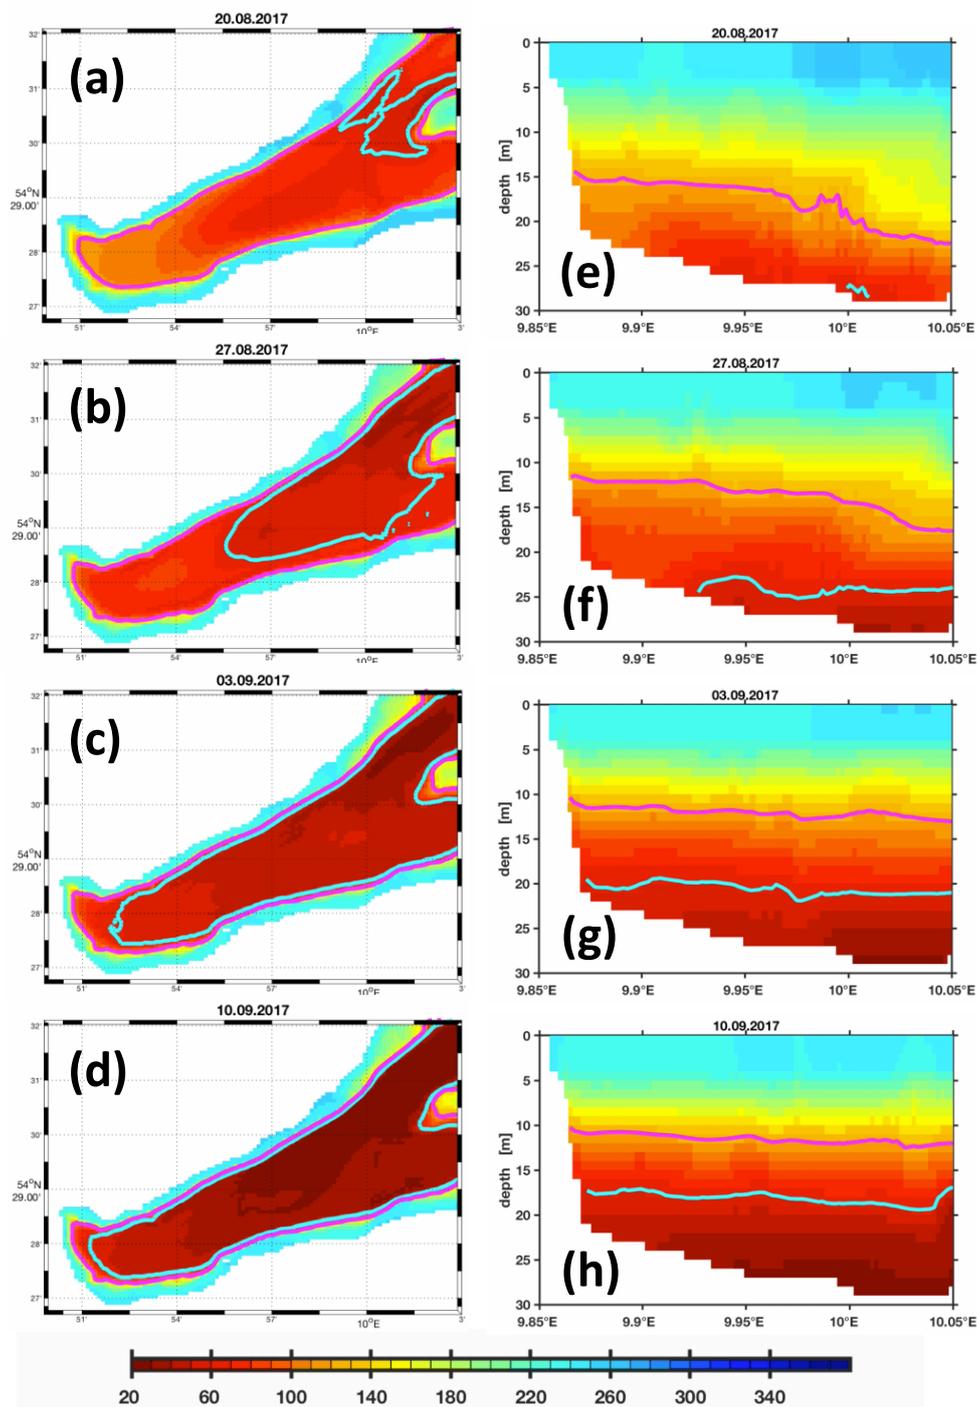

**Figure 13.** Simulated climatological estimate of local ventilation. The color shading denotes the time elapsed (age) since water parcels have been in contact with the atmosphere in units days. Shown are sections along EB. Panels (a) and (b) refer to August calculated by the simulations *LowMix* and *HiMix*, respectively. Panels (c) and (d) refer to October calculated by the simulations *LowMix* and *HiMix*, respectively.

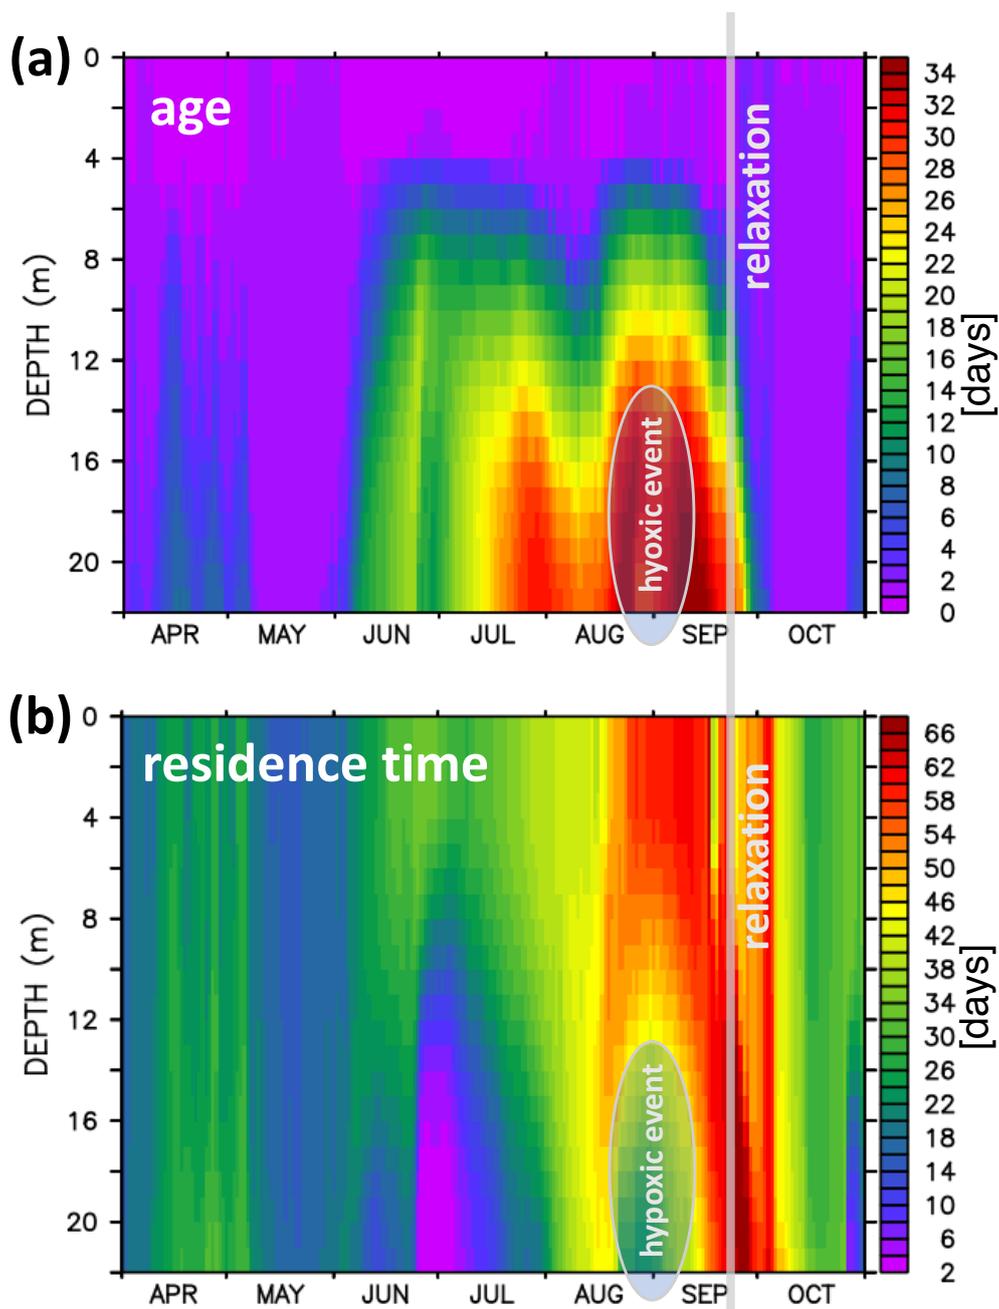

**Figure 14.** Simulated climatological (2000 - 2015) occurrence of hypoxia at the monitoring station *Buoy 2a*. Occurrence refers to the sum of suboxic (i.e.,  $<120 \text{ mmol O}_2 \text{ m}^{-3}$ ) model grid boxes, identified in climatological daily model output. From November to June no suboxic conditions were absent.

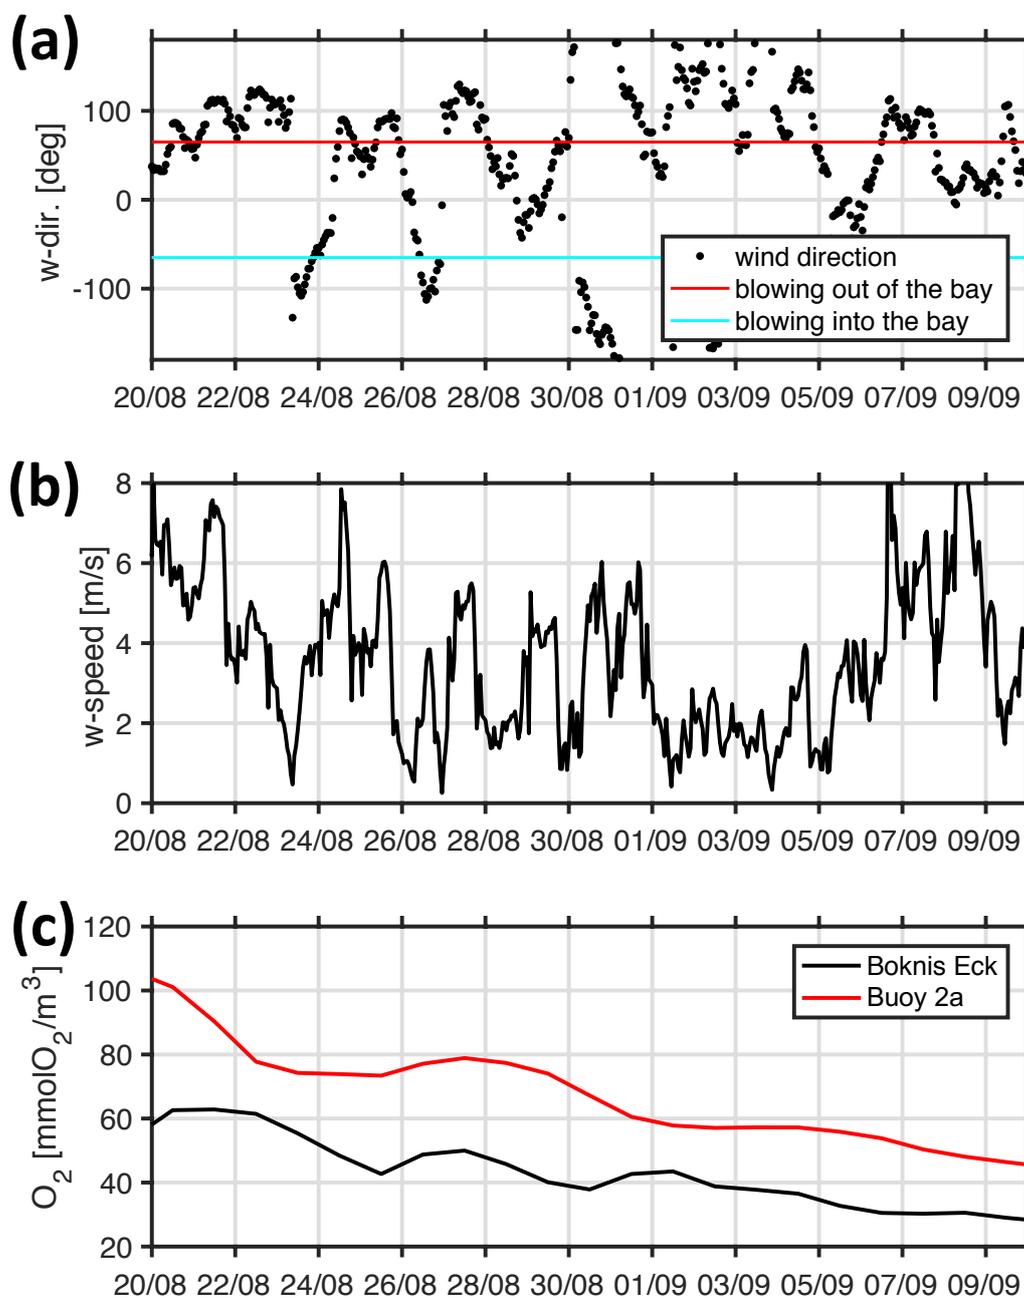

**Figure 15.** Histogram of observed climatological bottom oxygen concentrations at Boknis Eck (capped at  $100 \text{ mmol O}_2 \text{ m}^{-3}$ ).

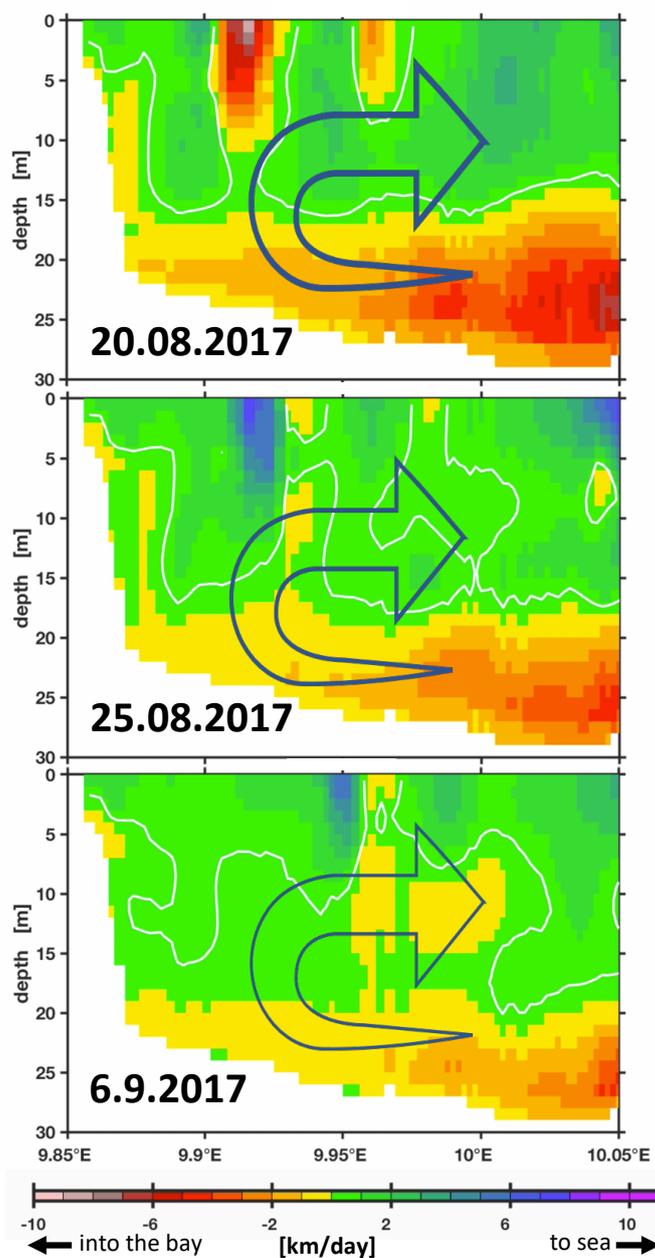

**Figure 16.** Simulation (*LoMix*) of the 2017 hypoxic event. The colors refer to oxygen concentrations in  $\text{mmol O}_2 \text{ m}^{-3}$ . The contours in cyan and magenta show the 60 and 120  $\text{mmol O}_2 \text{ m}^{-3}$  isolines. The left column (Figures a to d) show oxygen concentrations on the sea floor. The right column (Figure e to h) shows a section through the Bight with the city of Eckernförde to the left and the entrance to the Bight to the right. (Corresponding animations featuring daily resolution named *LowMix\_O2\_Bottom\_2015.m4v* and *LowMix\_O2\_zonal\_2017.m4v* are archived at <https://doi.org/10.5281/zenodo.4271940>.)

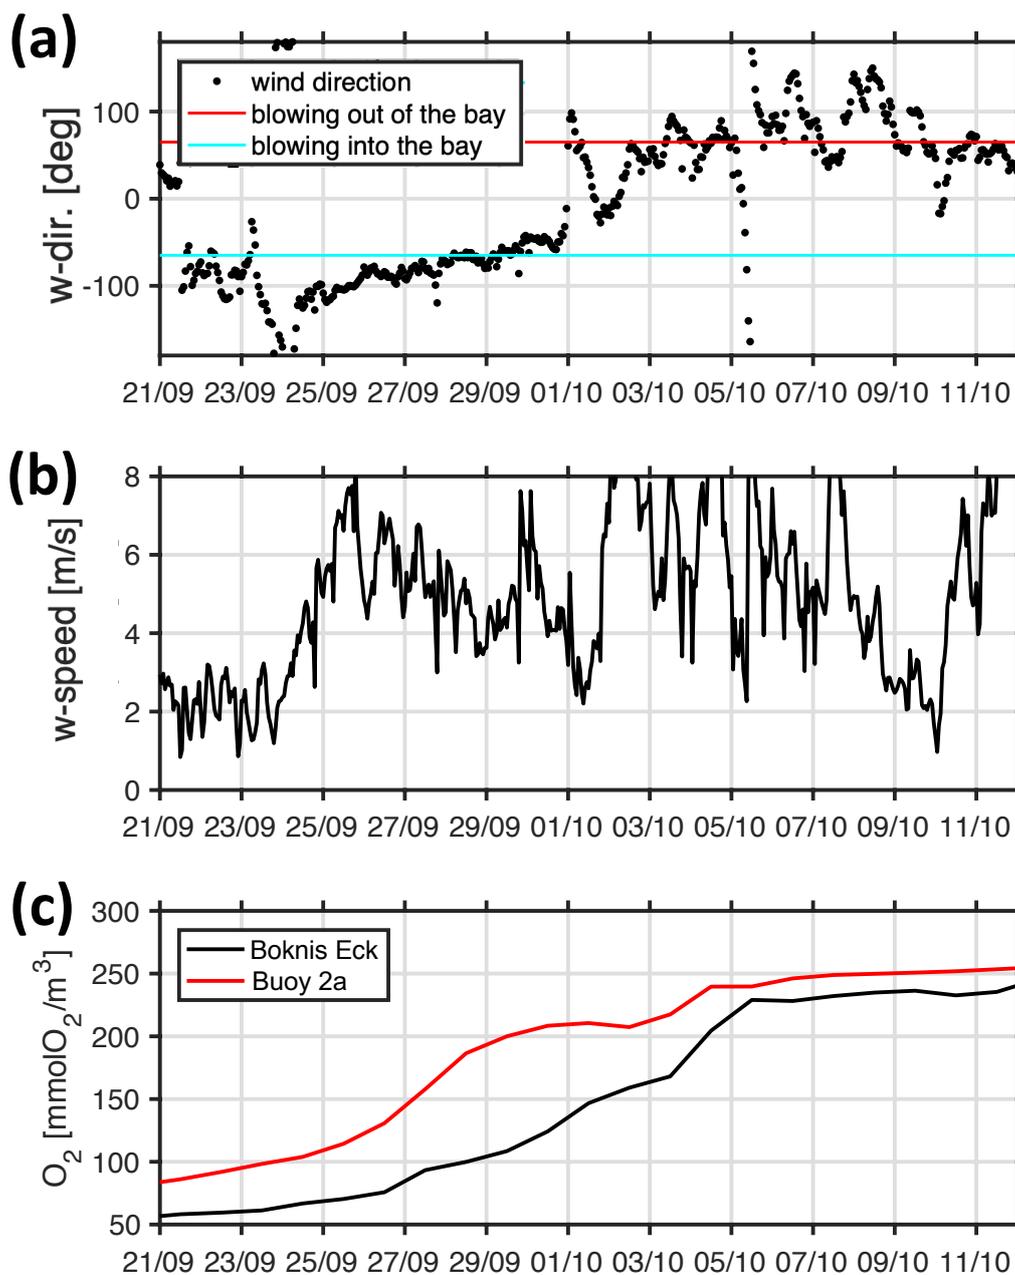

**Figure 17.** Hovmoeller Diagrams of simulated water age and residence time at the monitoring station *Buoy 2a* (panel a and b, respectively). The oval marking in August - September highlights the 2017 hypoxic event. The vertical gray line marks the start of the relaxation phase, ending the hypoxic event.

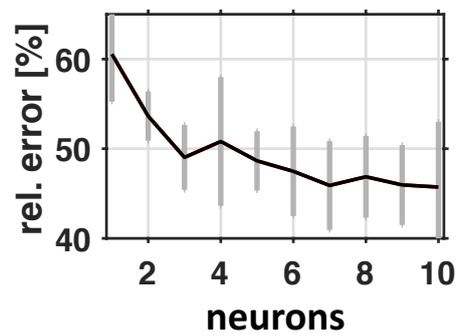

**Figure 18.** Simulated temporal evolution of wind direction, wind speed and bottom oxygen concentrations during the buildup of the 2017 hypoxic event. Panel a, b and c show wind direction, wind speed and bottom oxygen concentrations at the entrance (Station *Boknis Eck*) and deep inside EB (Station *Buoy 2a*).

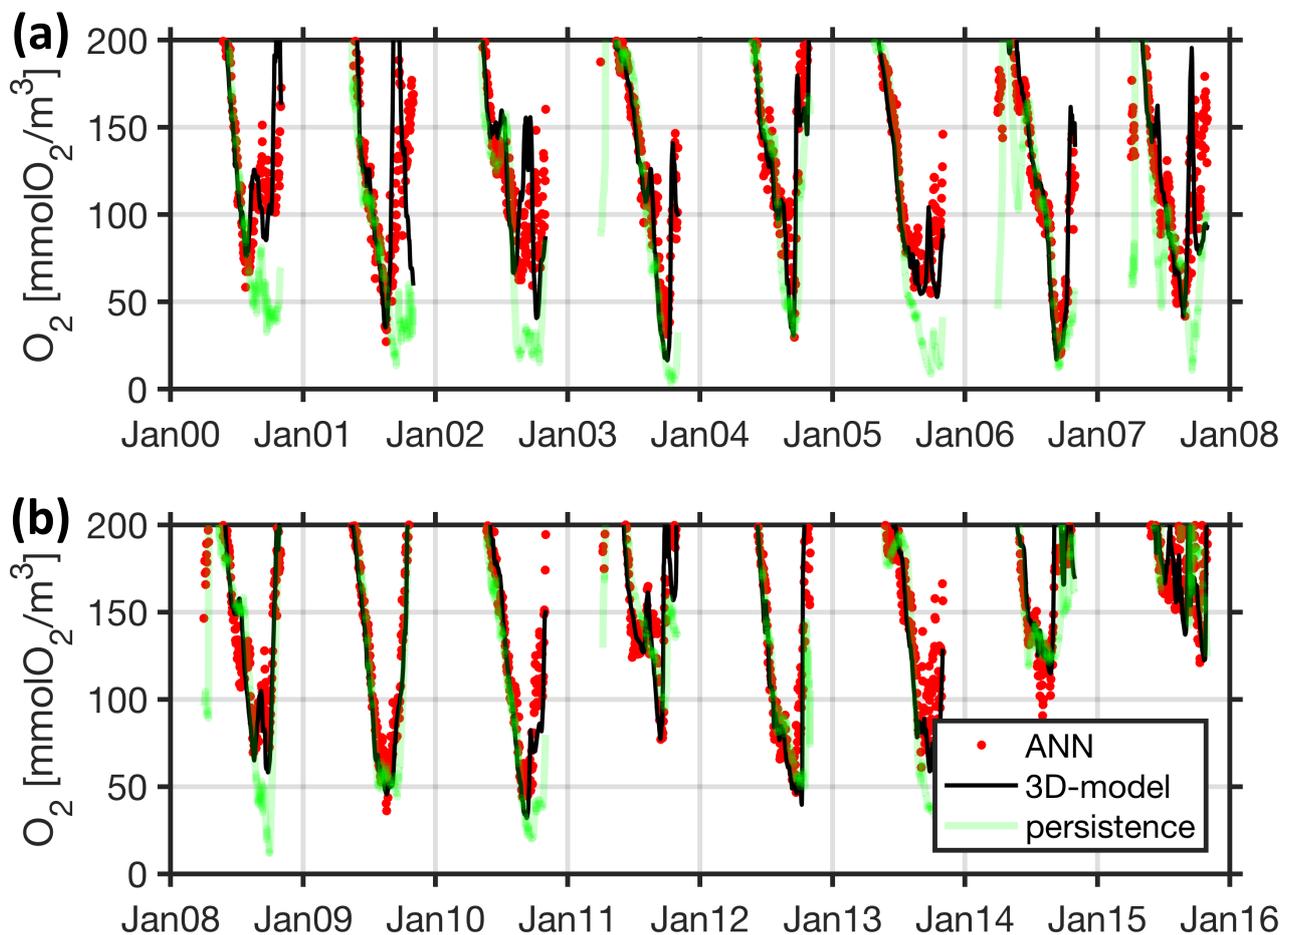

**Figure 19.** Simulated, daily mean zonal currents during the buildup of the 2017 hypoxic event shown in Figures 16, 17, and 18. Green to blue colors characterize flows to the east (towards the KB). Yellow to red colors indicate flows to the west (into EB). The unit is km per day. The depicted section has an extension of  $\approx 13$  km.

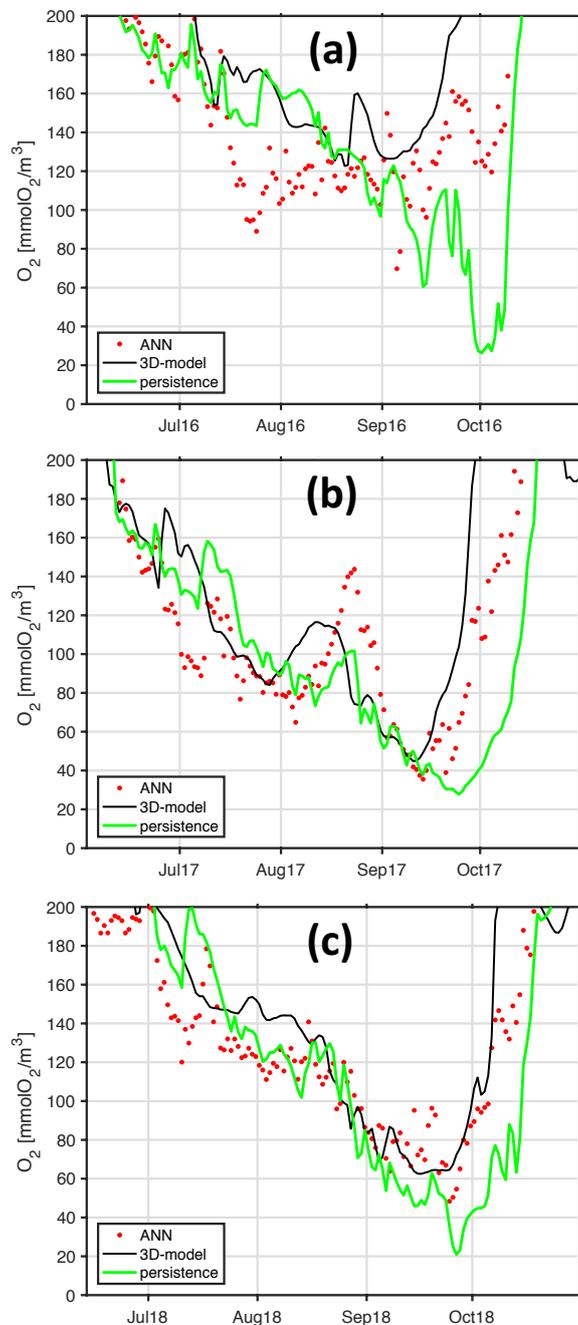

**Figure 20.** Simulated temporal evolution of wind direction, wind speed and bottom oxygen concentrations during the relaxation phase that terminates the 2017 hypoxic event. Panel a, b and c show wind direction, wind speed and bottom oxygen concentrations at the entrance (Station *Boknis Eck*) and deep inside EB (Station *Buoy 2a*).

**Figure 21.** ANN error relative to naive persistency forecast versus the number of neurons in the hidden layer. The black line features the best ANN parameter setting found within an ensemble of 30 optimizations for each of the number of neurons tested. The grey bars denote the ensemble's standard deviations.

**Figure 22.** Walk-forward performance of ANN based on training and testing data (corresponding to 80% and 20% of the data shown here). The black line shows bottom oxygen concentrations at Station *Buoy 2a* as simulated with the full-fledged and computationally expensive 3-D coupled ocean-circulation biogeochemical model. Each of the red dots denotes a respective biweekly walk-forward (computationally cheap) ANN forecast utilizing surface and bottom temperatures at Station *Boknis Eck* only. For comparison, the green line features a naive biweekly persistency forecast based on bottom oxygen concentrations at Station *Boknis Eck*.

**Figure 23.** Walk-forward validation (generalization) of ANN. The panels a, b, and c refer to year 2016, 2017, 2018. The black line shows bottom oxygen concentrations at the monitoring station *Buoy 2a* as simulated with the full-fledged and computationally expensive 3-D coupled ocean-circulation biogeochemical model. Each of the red dots denotes a respective biweekly walk-forward (computationally cheap) ANN forecast utilizing surface and bottom temperatures at Station *Boknis Eck* only. The green line features a naive biweekly persistency forecast based on bottom oxygen concentrations Station *Boknis Eck* for comparison.
