19 Keywords: Bloom onset ; Carbon uptake ; Air-sea interaction; Mediterranean sea

20 Abstract

21 Several trigger mechanisms have been proposed for the onset of the phytoplankton spring
22 bloom. Among these, that phytoplankton cells begin to bloom when they experience higher
23 average light levels in shallower mixed layers, a result of the surface net heat fluxes becoming
24 positive and wind strength decreasing. We study the impact of these two forcings in the
25 northwestern Mediterranean Sea. We take advantage of hourly measurements of oceanic and
26 atmospheric parameters collected at two neighboring moorings during the months of March
27 and April in the years 2016 to 2019, combined with glider data in 2016. **We identify the onset**

28 of the surface phytoplankton growth as concomitant with the start of significant biological
29 activity detected by a sudden decrease in dissolved inorganic concentrations derived from
30 measurements in the upper 10 m of the water column. A rapid reduction in wind stress
31 following high-wind events is observed at the same time. A resulting shallow mixing layer
32 favors carbon uptake by phytoplankton lasting a few days. Simultaneously, the air-sea net
33 heat flux switches from negative to positive linked to changes of the latent air-sea heat flux,
34 which is proportional to the wind speed. This results in an increased thermal stratification of
35 the ocean's surface layers. In 2016, glider data show that the mixing layer is significantly
36 shallower than the mixed layer at the onset of the surface phytoplankton bloom. We conclude
37 that decreases in the mixing and mixed layer depths lead to the onset of the phytoplankton
38 growth due to the relaxation of wind speed following storms. We estimate net daily
39 community production in the mixing layer over periods of 3 days between 2016 and 2019 as
40 between 38 mmol C m^{-2} and $191 \text{ mmol C m}^{-2}$. These results have important implications as
41 biological processes play a major role in the seasonal evolution of surface pCO_2 and thereby
42 the rate of reduction of atmospheric CO_2 by exchange at the air-sea interface.

43

44

45

46 Introduction

47 Investigating the physical and biological mechanisms contributing to changes in air-sea
48 carbon dioxide (CO_2) fluxes is essential. It is a critical component of the global carbon cycle
49 and the climate system with the ocean removing about a quarter of the CO_2 emitted into the
50 atmosphere by human activities over the last decade. It depends on the gradient of CO_2 partial
51 pressure, pCO_2 , between the atmosphere and the surface ocean [Takahashi et al., 2009;
52 Rödenbeck et al., 2013; Merlivat et al., 2015]. pCO_2 in the ocean mixed surface layer
53 depends on the relative contribution of dynamic transport, thermodynamics and
54 biogeochemistry. As the biological carbon pump lowers pCO_2 and Dissolved Inorganic
55 Carbon (DIC) at the sea surface, the production of plankton biomass during a bloom can be
56 sufficient to reverse the annual cycle of surface-ocean CO_2 uptake. A decrease in surface DIC,
57 after physical processes have been eliminated, indicates the beginning of phytoplankton
58 spring growth. Conceptual frameworks have been proposed to explain when depth-integrated

59 phytoplankton biomass starts accumulating during blooms [Behrenfeld, 2010; Sverdrup,
60 1953]. The timing of the initiation of the surface spring phytoplankton bloom depends in
61 particular on atmospheric forcing. The physical processes of wind stress, heat flux and
62 vertical mixing control the depth of the mixed/mixing layer and thus the availability of light
63 [Siegel et al, 2002, Chiswell, 2011; Taylor and Ferrari, 2011; Brody and Lozier, 2015;
64 Enriquez and Taylor, 2015, Rumyantseva et al, 2019]. Thus, to better understand which
65 fundamental physical processes control the timing of the onset of the surface bloom, in situ
66 measurements are needed at the appropriate hourly to daily timescale. It is important to draw
67 attention to the atmospheric forcing timescale. In biogeochemical ocean modeling studies,
68 typically built on atmospheric models, reanalysis or satellite data, time resolution of at best a
69 few days are required [Mahadevan et al, 2012].

70

71 Figure 1. The area of the northwestern Mediterranean Sea showing the French and Italian
72 Rivas, the island of Corsica, the main current branches (green arrows) in the Ligurian Sea
73 and the location of the BOUSSOLE buoy (white square) and the AZUR meteorological buoy
74 (yellow square). The black line indicates the glider's path in March-April 2016.

75 In the northwestern Mediterranean Sea, the BOUSSOLE (Bouée pour l'acquisition de Séries
76 Optiques à Long Terme; Antoine et al., 2006, 2008a,b) buoy is located in the central area of
77 the Liguro-Provençal basin (Fig.1), where the dominant ocean currents are generally weak
78 ($<20 \text{ cm s}^{-1}$) [Millot, 1999; Antoine et al., 2008b; Niewiadomska et al., 2008]. The main
79 processes that govern the pCO_2 variations at the sea surface on an annual scale, after removal
80 of the temperature effect, are vertical convective mixing and biological production [Begovic
81 and Copin-Montégut, 2002; Copin-Montégut et al., 2004; Hood and Merlivat, 2001; Merlivat et
82 al., 2018]. Intense convection resulting from repeated high wind events in winter or early
83 spring when atmospheric temperatures are typically low brings nutrients to the surface layer
84 [Andersen and Prieur, 2000; Antoine et al., 2008b; Marty et al., 2002; Pasqueron de
85 Fommervault et al., 2015].

86 The objective of this study is to examine the impact of atmospheric forcing on surface
87 phytoplankton bloom initiation in the northwestern Mediterranean Sea. To this aim we use
88 concurrent hourly data of seawater carbon chemistry measured at depths less or equal to 10 m
89 at the BOUSSOLE mooring [Merlivat et al., 2018] and atmospheric flux measurements at the
90 Azur meteorological buoy 3.1 nm (5.8 km) away from BOUSSOLE in March and April 2016
91 to 2019. Additional measurements of phytoplankton chlorophyll-a (Chla), temperature and
92 density were provided by an underwater glider deployed in March-April 2016. The initiation
93 of biological carbon uptake is revealed by the sudden decrease in DIC measured at the
94 BOUSSOLE buoy.

95 In the Material and Methods section, we provide the description of data processing,
96 theoretical framework, and calculations used to evaluate mixing regimes in the water column
97 and net community production. The results section presents measured atmospheric and
98 biogeochemical parameters observed in March-April, and NCP estimates from 2016 to 2019.
99 The Discussion section relates our results to previous findings and presents our conclusions
100 regarding the drivers of phytoplankton bloom initiation.

101

102 2 Material and methods

103 2.1- Data from the BOUSSOLE mooring

104 CARIOCA sensors [Merlivat and Brault, 1995] installed on the BOUSSOLE buoy ($43^{\circ}22'N$,
105 $7^{\circ}54'E$; Fig.1) monitored hourly partial pressure, pCO_2 , at both 3 and 10 m alongside salinity

106 and temperature (SEABIRD Scientific SBE 37 MicroCAT CTDs). Protocols for calibration of
107 in situ measurements are described in [Merlivat et al, 2018]. CARIOCA measurements of
108 pCO₂ and temperature are combined with total alkalinity (Alk) derived from salinity
109 [Merlivat et al., 2018] to calculate DIC. The dissociation constants of Mehrbach et al., (1973)
110 refitted by Dickson and Millero (1987) are used, as recommended by Alvarez et al. (2014) for
111 the Mediterranean Sea. For the March-April months mean salinity is 38.3, corresponding with
112 mean Alk equal to 2571.4 μmol kg⁻¹ [Copin et al, 2004]. The expected precision of the
113 CARIOCA pCO₂, and DIC is 5 μatm, and 3 μmol kg⁻¹, respectively [Merlivat et al, 2018].

114 2.2- Glider observations

115 An iRobot Seaglider model 1KA (SG537) with an ogive fairing operated by the University of
116 East Anglia (UEA) [see Hemming et al., 2017] was deployed during the BOUSSOLE
117 monthly cruise (#169) [Golbol et al 2000] and recovered 1 month later with a ship of
118 opportunity. Diving to 1000 m, 147 dives were completed between March 7 and April 5 2016
119 repeatedly-sampling a square-shaped path surrounding the BOUSSOLE buoy (Fig. 1) with
120 corners pointing to cardinal directions. Out of 147 dives, a number of them contain data that
121 are within 10 km of the BOUSSOLE mooring, i.e. when it was sampling in the eastern corner
122 of the diamond path. The glider was equipped with a non-pumped SEABIRD Scientific SBE
123 9 CTD instrument package providing temperature and salinity, and a WET Labs Eco Puck
124 sensor providing relative phytoplankton Chla fluorescence, factory calibrated into Chla
125 concentration units (mg m⁻³) **locally adjusted with top 10 m HPLC chlorophyll from CTD**
126 **and mooring samples.**

127

128 2.3- Azur meteorological buoy

129 The Azur meteorological buoy has been deployed since 1999 by the French weather forecast
130 Agency (Meteo-France) at 43°23'N, 7°50'E (Fig. 1). It provides hourly measurements of
131 surface wind speed extrapolated to 10 m height, U₁₀ (m s⁻¹), net incoming and emitted long-
132 wave radiation, incoming short-wave radiation, and the sensible and latent heat fluxes. These
133 are needed to estimate the net air-sea heat budget at the sea surface (<http://mistrals.sedoo.fr>).
134 U₁₀ is used to calculate wind stress, τ, as follows: $\tau = \rho_a C_d U_{10}^2$, where ρ_a is air density (1.2
135 kg m⁻³), and C_d is the drag coefficient (1.4 x 10⁻³). Photosynthetically Active Radiation (PAR,
136 mol photons m⁻² d⁻¹) is related to solar irradiance (i.e. short-wave flux), SW, following PAR =
137 0.473 SW [Papaioannou et al., 1993].

138 2.4- Estimation of mixed and mixing layer depths

139 The mixing layer depth, Z_{mx} , is the upper part of a mixed layer of uniform density where
140 active turbulence occurs [Brainerd and Gregg 1995]. Several recent studies have highlighted
141 the significance of this layer to understand the phytoplankton phenology of phytoplankton
142 blooms [Brody and Lozier, 2015; Taylor and Ferrari, 2011]. Autonomous profiling floats
143 equipped with bio-optical sensors have also highlighted the importance of mixing rather than
144 mixed layers to characterize the onset and the development of a phytoplankton bloom. Wind-
145 driven and buoyancy-driven regimes control the characteristics and depth of active mixing
146 [Brody and Lozier, 2014, 2015, Ramuyantseva et al, 2015, Lacour et al, 2019, Pellichero et al,
147 2020]. Wind-driven mixing dominates in the presence of weak buoyancy forcing when heat
148 fluxes are small. In that case, the dominant mixing length scale is equal to the Ekman length
149 layer depth scale.

150 The daily mean mixed layer depth, Z_{ml} is derived for 2016 from glider vertical profiles of
151 temperature and salinity using the algorithm provided by Holte and Talley, (2009) estimated
152 using the potential density algorithm.

153 To estimate Z_{mx} , τ is used to calculate the Ekman layer depth, Z_{ek} , $Z_{ek}=\gamma u_*/f$, where γ is an
154 empirical constant (0.5), f is the Coriolis parameter ($10^{-4} s^{-1}$) over the BOUSSOLE area, and
155 u_* is the turbulent friction velocity, $u_* = \sqrt{\frac{\tau}{\rho_w}}$ ($m s^{-1}$), with ρ_w the density of the surface sea
156 water [Lacour et al, 2019]. When heat fluxes are large and positive, Enrikez and Taylor
157 (2015) proposed to express the mixing depth Z_{mx} in terms of the surface forcing, i.e. the
158 surface stress and a stabilizing surface buoyancy flux B_0 , as follows:

$$159 \quad \frac{1}{Z_{mx}^2} = \frac{f^2}{(C_3 u_*)^2} + \frac{f B_0}{(C_4 u_*^2)^2} \quad (1)$$

160 With $C_3=1$, $C_4=0.57$, $B_0 = Q \lambda g / c_p \rho_0$, where Q is the net surface heat flux, λ the thermal
161 expansion coefficient ($1.65 \cdot 10^{-4} \text{ } ^\circ\text{C}^{-1}$), g the gravitational acceleration (9.81 m s^{-2}), c_p the
162 specific heat of water ($4 \cdot 10^3 \text{ J kg}^{-1} \text{ } ^\circ\text{C}^{-1}$) and ρ_0 the pure water density (1000 kg m^{-3}).

163 2.5-Estimation of euphotic zone depth

164 The euphotic depth, Z_{eu} , is generally derived as the depth where PAR is 1% of its surface
165 value. Z_{eu} can be estimated from Chla at the surface using the method described by Lee et al.
166 (2007) based on the equation of Morel and Berthon (1989):

167
$$Z_{eu} = 34 (\text{Chla})^{-0.39} \quad (2)$$

168 For the period between 2017 and 2019, GlobColour merged Chla products were used, which
169 are based on satellite observations with a resolution of 25 km, and a binning period of 8 days
170 (<http://www.oceancolour.org>). For 2016, glider surface Chla was used to derive Z_{eu} instead
171 of satellite measurements. We excluded glider Chla between 05:00 and 20:00 UTC affected
172 by sunlight-induced fluorescence quenching, and we applied a depth-constant offset to glider
173 measurements using Chla water samples available on March 7.

174 2.6-Estimation of average mixing layer irradiance

175 We calculate the average mixing layer irradiance, I , function of the incident surface
176 irradiance, PAR, mixing layer depth, h , and the diffuse attenuation coefficient, K_d , estimated
177 from surface chlorophyll-a concentrations (Venables and Moore, 2010).

$$K_d = 0.05 + 0.057 \text{ Chla}^{0.58}$$

178
$$I = \frac{\text{PAR}}{K_d h} (1 - e^{-K_d h}) \quad (3)$$

179

180 2.7 – Estimation of net community production

181 Biological Net Community Production rates, NCP ($\text{mmol m}^{-2} \text{ day}^{-1}$), are calculated for
182 separate 3-day periods in March-April, 2016 to 2019 from DIC concentrations derived from
183 CARIOCA measurements, assuming that measurements in the top 10 m of the water column
184 are representative of an homogeneous mixing layer [Boutin and Merlivat, 2009; Merlivat et al,
185 2015; Pelichero et al, 2020]. In the study area, current velocities are expected to be small
186 [Millot, 1999; Antoine et al., 2008; Niewiadomska et al., 2008], hence to estimate NCP, we
187 **assume** that the contribution of horizontal advection was negligible. Vertical mixing events
188 are identified by an increase in DIC resulting from upward movement of high DIC Levantine
189 Intermediate Water (LIW) at approximately 200 m depth [Copin-Montégut and Bégovic,
190 2002]. We isolated time periods when local physical processes were largely one-dimensional
191 in order to study changes in biological and chemical parameters that occurred during rapid
192 transitions from deep mixing to intermittent stratification. In 2016, over a four-day period,
193 March 18-21, the diurnal cycle of DIC values characterized by a maximum in the morning
194 followed by a minimum at the end of the day indicates the onset of organic matter formation.
195 The eddy diffusion term is negligible as the DIC gradient at the base of the mixing layer is

196 very weak, entrainment is not expected as changes in DIC are observed during periods of
197 stratification. For the identified periods, biological production and air-sea exchange are the
198 dominant processes responsible for daily changes in DIC.

199 NCP is thus estimated from temporal variation of the DIC integrated over Z_{mx} (DIC_{int}), and
200 corrected for the air-sea CO_2 flux contribution [Pelichero et al, 2020]:

$$201 \quad \text{NCP} = \left(\frac{\Delta \text{DIC}_{\text{int}}}{\Delta t} \right)_{\text{bio}} = \left(\frac{\Delta \text{DIC}_{\text{int}}}{\Delta t} \right)_{\text{meas}} - k \times s \times (\text{pCO}_{2\text{atm}} - \text{pCO}_{2\text{sw}}) \quad (4)$$

202 The first term in equation 4, $\left(\frac{\Delta \text{DIC}_{\text{int}}}{\Delta t} \right)_{\text{meas}}$, is the daily variation of DIC_{int} calculated over 3
203 days from the date identified as the start of phytoplankton **growth** (t_0), whilst the remaining
204 part corresponds to DIC variability due to air-sea CO_2 exchange, where k is the gas transfer
205 velocity [Wanninkhof, 2014], s is the solubility of CO_2 in seawater [Weiss, 1974], and
206 $\text{pCO}_{2\text{sw}}$ and $\text{pCO}_{2\text{atm}}$ are respectively the partial pressures of CO_2 , in μatm , in sea water and in
207 air [Merlivat et al, 2018].

208 3 Results

209 3.1- Description of the 2016 time-series

210

211 Figure 2. 2016 (a) Hourly DIC (green) and SST(purple) at the BOUSSOLE site, (b) hourly
 212 wind stress (blue) and net heat flux (pink) at the Azur buoy site. The pink dotted line indicates
 213 the change of sign of the net heat flux from negative to positive values, (c) daily depths of the
 214 mixed layer (black), mixing layer (dotted black), Ekman layer (cyan) and euphotic layer
 215 (orange) at the BOUSSOLE site. The black dotted line on panels (a), (b), (c) (d) and (e)
 216 indicates the beginning of DIC decrease on March 18. (d) PAR (orange) and I, average
 217 mixing layer irradiance (blue), (e) Glider-derived depths of the mixed layer (black curve,
 218 same as in (c)), euphotic layer (orange), and nighttime 2-day binned chlorophyll concentration
 219 (green coloring) retrieved between March 7 and April 5.

220 Physical and biogeochemical parameters have been measured between March 7 and April 5
221 2016 (Fig. 2). We observe an initial increase in DIC until March 18 (Fig. 2a), resulting from
222 the vertical mixing of surface waters with the DIC-enriched underlying LIW [Copin-
223 Montégut and Bégovic, 2002], followed by a decrease in DIC that corresponds to an increase
224 of surface Chla (Fig 2e). Temperature increases intermittently over the same time period (Fig.
225 2a), with a sharp increase on March 18 and 25. Before March 18 frequent atmospheric fronts
226 associated with wind forcing between 0.2 and 0.5 N m⁻² were observed (Fig. 2b). $Q_{0,net}$ was
227 negative most of the time leading up to March 18, but mostly positive afterwards (Fig. 2b). A
228 clear anticorrelation was observed between τ and $Q_{0,net}$ (Fig. 2b). The mixed-layer depth
229 derived from the glider measurements (< 20 km away from the Boussole site) deepened to >
230 70 m at times between March 8 and March 18, consistent with the passage of frequent
231 atmospheric fronts. From March 18 to April 5, Z_{ml} shoaled from ~ 45 m to ~10 m, excluding
232 two short periods around March 24 and April 2 when atmospheric fronts were passing (Fig.
233 2c). From March 18 to 31, Z_{mx} was for a considerable time either shallower than, or at similar
234 depth to Z_{ml} and Z_{eu} (Fig. 2c). The start of the increase in PAR from March 15 precedes the
235 increase in irradiance by 3 days as a result of the decrease of the mixing layer depth observed
236 only after March 18 (Fig. 2d).

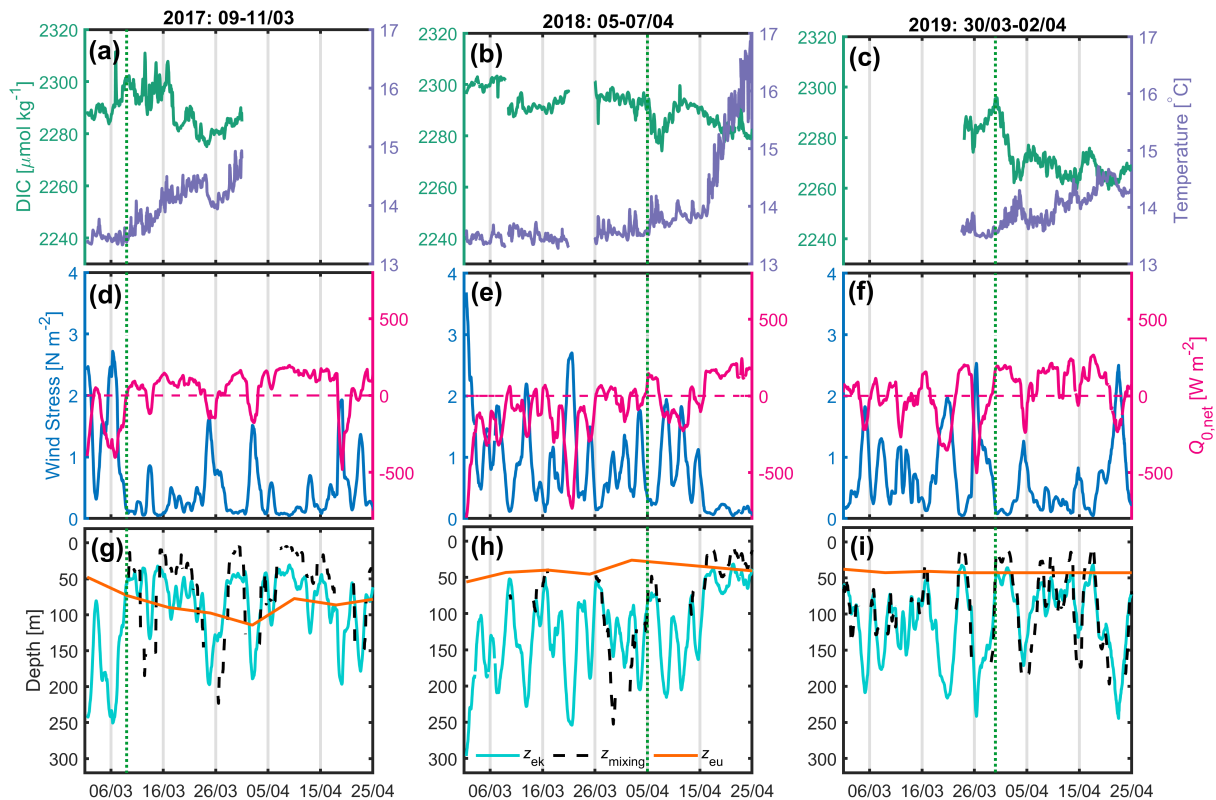

237 During periods of a few days, from March 7 to April 5, increases in glider Chla were
238 observed as the result of a series of net accumulation/mixing events. Following the initial
239 growth of surface phytoplankton identified by the DIC decrease on March 18, biomass
240 accumulation was observed a few days later (Fig. 2e). The same was observed in the Southern
241 Ocean [Pelicherro et al, 2019].

242 3.2- Description of the 2017-2018-2019 time-series

243 Only measurements at the BOUSSOLE and Azur buoys were available between 2017 and
244 2019. Here we focus on the periods between March 1 and April 25. In 2017, from March 9,
245 after the passage of a very active atmospheric front (τ up to 2.7 N m⁻²), a decrease in DIC
246 accompanied by an increase in temperature was observed for a period of 14 days despite a
247 few short bursts of vertical mixing, typically lasting less than 1 day (Fig.3a, d, g). At the same
248 time, the net surface heat flux switched from negative to positive most of the time. Over this
249 14-day period, Z_{mx} was predominantly shallower than the Z_{eu} at times when DIC was
250 decreasing.

251 In 2018 (Fig. 3b, e, h) and 2019 (Fig. 3c, f, i), the weather records throughout the month of
 252 March are very similar, showing a succession of very strong wind events at the start of the
 253 investigated time periods, with τ values of up to 3.7 N m^{-2} and Z_{ek} values as deep as 300 m.
 254 On April 5, 2018, following a period of high wind stress resulting in the formation of a deep
 255 mixing layer ($\sim 250 \text{ m}$), a decrease in DIC and an increase in SST were observed over 3 days.
 256 At the same time, the net heat flux oscillated around zero. In 2019, CARIOCA data were only
 257 available after March 24. On March 30, 3 days after high winds, a decrease in DIC and an
 258 increase in temperature lasted 3 days, while simultaneously the net heat flux reversed from
 259 negative to positive.

260

261

262 Figure 3. (a, b, c) 2017, 2018 and 2019 DIC (green) and SST (purple) at the BOUSSOLE site,
 263 (d, e, f) wind stress (blue) and net heat flux (red) at the Azur buoy site. (d, e, f) The red dotted
 264 line indicates the change of sign of the net heat flux from negative to positive values, (g, h, i)
 265 depths of the mixing layer (dotted black), Ekman layer (cyan) and euphotic layer (orange) at
 266 the BOUSSOLE site. The vertical dotted green line indicates the onset of the decrease of DIC.

267 For the period between 2017 and 2019, only satellite chlorophyll-a concentrations with a
 268 binning period of 8 days were available, which is too large to calculate the average mixing
 269 irradiance as it is highly variable on a daily scale (Fig 2.d).

270 3.3- NCP

271 NCP was estimated (Eq. 3) for 3-day periods over the four time-series between 2016 and
 272 2019 (Table 1). Because we compute NCP only during periods when Z_{ml} and Z_{mx} shoal and
 273 the air-sea CO_2 flux is very small, the measured total daily changes of DIC, $dDIC/dt$
 274 (correlation coefficient, $r^{*2} > 0.70$), is expected to represent the biological consumption of
 275 DIC. In 2016, 2017, and 2019, daily biological carbon uptake fluxes are between 38 and 191
 276 $mmol\ m^{-2}\ d^{-1}$. PAR and I vary respectively from 30 to 53 and 13 to 25 $mol\ photons\ m^{-2}\ d^{-1}$ for
 277 the four considered periods (Table 2).

	T_0	$dDIC/dt^a$	$r^{*2\ b}$	$\Delta DIC / \Delta t^c$	$r^{*2\ d}$	air-sea flux CO_2^e	NCP ^f
		$\mu mol\ kg^{-1}d^{-1}$		$mmol\ m^{-2}d^{-1}$		$mmol\ m^{-2}d^{-1}$	$mmol\ m^{-2}\ d^{-1}$
2016	March 18	-3.0	0.80	-37	0.68	1	38
10m							
2017	March 9	-4.5	0.84	-188	0.86	3	191
3m							
2018	April 5	-6.5	0.70			17	
3m							
2019	March 30	-8.3	0.93	-163	0.63	4	167
10m

 284 the manuscript.

285

286 4 Discussion

287 4.1 Analysis of the physical drivers of the bloom initiation over the 4 years, 2016-2019

288 4.1.1 In 2016, the consumption of carbon indicated by the decrease in DIC from March 18
289 attests the initiation of the formation of phytoplankton biomass (Fig. 2.). Between 2
290 successive days, March 17 and 18, a rapid decrease in daily wind stress from 0.24 to 0.04 N
291 m^{-2} results in a change of sign of the net heat flux from -68 to +56 W m^{-2} (Fig.4a) and a
292 shoaling Z_{mx} , which is for the most part shallower than Z_{eu} (Fig.4b) after March 18.

293

294 Figure 4. Changes of physical parameters (hourly values) at the onset of the 2016 bloom
295 during 2 consecutive periods of 4 days, March 14-17 (blue) and March 18-21 (red) as a
296 function of wind stress (a) net surface heat flux (b) depths of the Ekman, mixing and euphotic
297 layer. Grey circles and grey squares indicate mean values respectively on March 17 and
298 March 18. For comparison, the orange line shows the euphotic layer depth (March 14-21).

299 This illustrates the very fast change in heat flux and mixing layer thickness resulting from the
300 decrease in wind stress. The main drivers to explain the initiation of near surface spring
301 phytoplankton blooms proposed by [Taylor and Ferrari, 2011, Brody-Lozier, 2014, 2015] are
302 a decrease in wind strength, a positive surface heat flux, and a decrease in the dominant

303 mixing length scale. Our results indicate that a decrease in τ is a common component for these
304 last two mechanisms (Fig.4). The variability of $Q_{0,\text{net}}$ is strongly controlled by the variability
305 of the latent heat flux proportional to the wind speed. From March 17 to 18, the latent heat
306 flux changed by 84 W m^{-2} representing nearly 2 thirds of the total change of Q_0 , with the
307 remainder originating from an increased short-wave flux. Hence, $Q_{0,\text{net}}$ increased as τ
308 decreased. In the same way Z_{mx} , which is related to τ and $Q_{0,\text{net}}$, decreased. This highlights the
309 major contribution of wind stress relaxation in controlling the net surface heat flux, and
310 subsequent stratification leading to shallower Z_{mx}

311 4.1.2 Over the 4 years, 2016-2019, during the months of March and April, at the very
312 beginning of spring, the conditions required for initiating the spring bloom are very similar
313 although the range of wind stress values is smaller in 2016 (Fig. 2, Fig. 3). The wind stress
314 values are low following storm events. For all years except 2018, Z_{mx} is smaller than Z_{eu} . The
315 average atmospheric and oceanographic conditions during the onset of the bloom are shown
316 in Table 2. The decrease of wind-driven mixing is then a dominant physical mechanism,
317 namely mixed layer shoaling which best predicts the timing of the spring bloom [Brody
318 Lozier, 2014, 2015]. Likewise, in the Southern Ocean, Pelicherro et al (2020) showed that a
319 bloom is initiated only when the wind-driven mixed layer decreases, even if the net heat flux
320 has been positive for some months.

321 4.2 DIC, Chla, Irradiance at the ocean surface in 2016

322 Between March 18 and 21, a diurnal cycle in DIC is observed (Figure 5a) characterized by a
323 maximum in the morning followed by a minimum at the end of the day, indicating the onset
324 of organic matter formation. The decrease in DIC is accompanied by an increase of glider
325 surface Chla on March 18 and a simultaneous increase in the average mixing layer irradiance
326 (Fig. 5 b). It is worth noting that the Chla maximum does not occur until 31 March, 13 days
327 after the first decrease in DIC. This maximum is the one identified in most cases by the Chla
328 satellite measurements with a binning period of 8 days. It follows that satellite data cannot
329 accurately characterize the conditions that prevail for the **onset of the phytoplankton**
330 **growth**, as these are dictated by a great temporal variability of atmospheric forcings.
331 Due to the seasonal increase of surface irradiance, as well as the availability of nutrients
332 following vertical mixing with intermediate nutrient-enriched waters [Begovic and Copin-
333 Montégut, 2002], the conditions for the onset of a bloom are met.

334

336

337 Figure 5. From March 7 to April 5, (a) DIC and Chla. The purple line and the squares
 338 (blue, morning; grey, evening) indicate the 3 days biological diurnal DIC changes during the
 339 period considered to compute NCP. The blue and orange lines indicate the surface Chla when
 340 the glider was at a distance of less than 5 km (blue) and less than 20 km (orange) respectively
 341 from the Boussole buoy. (b) PAR and I average mixing layer irradiance. The vertical dotted
 342 black line indicates the onset of the bloom on March 18.

343 4.3- Biological carbon uptake

344 In 2016, 2017, and 2019, at the onset of the bloom Z_{mx} is shallower than Z_{eu} (Table 2). Two
 345 factors account for the observed large range of NCP variability at the time of triggering the
 346 bloom: $dDIC/dt$ and Z_{ml} . In 2016 and 2017, DIC decreased over a period of 14 days, whereas
 347 it lasted for 3 days in 2018 and 2019, as a result of short-lived high wind events ($\tau > 1 \text{ N m}^{-2}$).
 348 On April 2, 2018, a high surface phytoplankton Chla, 1.9 mg m^{-3} , was measured by satellite
 349 (Globcolour data) suggesting a strong biological signal. However, as Z_{eu} is significantly
 350 shallower than Z_{mx} (26 m vs. 65m; Fig. 3h), it would be incorrect to estimate NCP integrated

351 over Z_{mx} using the DIC gradient measured at 3 m depth and likewise to compute the average
 352 mixing layer irradiance.

353 At the nearby DyFAMed site (Dynamique des Flux Atmospheriques en Mediterranee), using
 354 a 20-year O_2 time series, Coppola et al. (2018) estimated an annual net community carbon
 355 production equal to $7.1 \text{ mol m}^{-2} \text{ yr}^{-1}$, or $19.4 \text{ mmol m}^{-2} \text{ d}^{-1}$. Additionally, using
 356 determinations of primary production from ^{14}C in-situ incubations and of carbon export fluxes
 357 from sediment traps at DyFAMed, Marty and Chiaverini (2002) calculated average daily
 358 primary productions between 19.6 and $53 \text{ mmol m}^{-2} \text{ d}^{-1}$. These estimates may have
 359 underestimated the annual NCP values as they were calculated from monthly observations
 360 while phytoplankton production varies on a daily timescale. Our DIC measurements highlight
 361 the large short-term variability of carbon consumption over a few days in March-April when
 362 bloom-triggering atmospheric conditions are met, such as a seasonal light increase and the
 363 availability of nutrients.

	T_0	Wind stress N m^{-2}	Net heat flux W m^{-2}	PAR $\text{mol photons m}^{-2}\text{d}^{-1}$	Z_{mixing} m	Z_{Euphotic} m	Irradiance $\text{mol photons m}^{-2}\text{d}^{-1}$
2016	March 18	0.04 +/-0.02	56+/-36	37+/-3	20+/-9	47	18
2017	March 9	0.12+/-0.02	45+/-21	30+/-3	28+/-12	71	13
2018	April 5	0.30+/-0.24	127+/-12	42+/-6	62+/-9	29	
2019	March 30	0.10+/-0.02	183+/-9	53+/-2	20+/-5	43	25

 366 standard deviation on the day of the start of the bloom, T_0 .

367

368 5- Concluding remarks

369 Around March and April in the northwestern Mediterranean Sea, the seasonal change in
 370 lighting conditions and atmospheric forcing are the essential parameters that control the
 371 triggering of near-surface phytoplankton blooms. These mechanisms have been highlighted
 372 through the coupling of high-frequency physical and biogeochemical in situ observations. For
 373 years 2016 to 2019, a bloom started in March or early April identified by a decrease in surface

374 DIC, following a period of intense mixing. The rapid decrease in surface wind speed entailed
375 a switch from negative to positive air-sea net heat fluxes, essentially due to changes in the
376 latent air-sea heat flux proportional to wind speed. These analysis support the hypothesis that
377 decreases in the depth of active mixing, a result of the transition from buoyancy-driven to
378 wind-driven mixing, control the timing of the surface spring bloom.

379 We have shown that the onset of surface phytoplankton growth, identified in 2016 by a
380 simultaneous initial decrease in DIC and an increase in surface Chla, precedes by a few days
381 the surface chlorophyll maximum **when** detected by satellite measurements with a binning
382 period of 8 days. This time span does not allow to identify precisely the contribution of
383 atmospheric drivers to trigger the onset of the growth of phytoplankton as it occurs on a daily
384 basis.

385

386

387 Data availability

388 BOUSSOLE data (2016-2019) are available in the SEANOE data base (Merlivat Liliane,
389 Boutin Jacqueline (2020). Mediterranean Sea surface CO₂ partial pressure and temperature
390 data. SEANOE. <https://doi.org/10.17882/56709>

391 Azur Meteorological buoy: <http://mistrals.sedoo.fr>

392 SChl, 8-day, 4 km x4 km resolution, level 3 mapped ocean color product distributed by the
393 European Space Agency, available at <http://www.ocean colour/org>

394 All glider data is archived at the British Oceanographic Data Centre
395 (BODC, https://www.bodc.ac.uk/data/bodc_database/gliders/).

396 Author contributions: VV and MG were respectively in charge of the BOUSSOLE mooring
397 buoy maintenance and monthly water sampling. LB was responsible for the laboratory
398 preparation and calibration of the CARIOCA sensors. GAL led the UEA glider mission in
399 March-April 2016. DA and VV provided data and funding through the BOUSSOLE project
400 and contributed to writing and editing of the manuscript.

401 The authors declare that they have no conflict of interest.

402 Acknowledgments: Michael Hemming was a PhD student at the University of East Anglia
403 and Sorbonne University under the supervision of Prof. Jan Kaiser, Prof. Karen J. Heywood,
404 Dr Dorothee Bakker and Dr Jacqueline Boutin, funded by the Defence, Science and
405 Technology Laboratory (Contract no. DSTLX1000092277) with cooperation with Direction
406 Générale de l'Armement (DGA)-. The assistance of the UEA Glider Group in keeping the
407 glider flying is also gratefully acknowledged. The BOUSSOLE time series project is funded
408 by the Centre National d'Etudes Spatiales (CNES) and the European Space Agency
409 (ESA/ESRIN contract 4000119096/17/I-BG). The authors acknowledge Météo-France for
410 supplying the data from the Azur buoy and the HyMeX database teams (ESPRI/IPSL and
411 SEDOO/Observatoire Midi-Pyrénées) for their help in accessing their data. Crew and
412 Captains of R/V Tethys II are warmly thanked for assistance with operations at sea.

413 **We thank two reviewers for their careful and conscientious reviews.**

549 Figure 1. The area of the northwestern Mediterranean Sea showing the French and Italian
550 Rivièras, the island of Corsica, the main current branches (green arrows) in the Ligurian Sea
551 and the location of the BOUSSOLE buoy (white square) and the AZUR meteorological buoy
552 (yellow square). The black line indicates the glider's path in March-April 2016.

553 Figure 2. 2016 (a) Hourly DIC (green) and SST (purple) at the BOUSSOLE site, (b) hourly
554 wind stress (blue) and net heat flux (pink) at the Azur buoy site. The pink dotted line indicates
555 the change of sign of the net heat flux from negative to positive values, (c) daily depths of the
556 mixed layer (black), mixing layer (dotted black), Ekman layer (cyan) and euphotic layer
557 (orange) at the BOUSSOLE site. The black dotted line on panels (a), (b), (c) (d) and (e)
558 indicates the onset time of the bloom (18 March). (d) PAR (orange) and average mixing layer
559 irradiance (blue), (e) Glider-derived depths of the mixed layer (black curve, same as in (c)),
560 euphotic layer (orange), and nighttime 2-day binned chlorophyll concentration (green
561 coloring) retrieved between March 7 and April 5.

562 Figure 3. (a, b, c) 2017, 2018 and 2019 DIC (green) and SST (purple) at the BOUSSOLE site,
563 (d, e, f) wind stress (blue) and net heat flux (red) at the Azur buoy site. The red dotted line
564 indicates the change of sign of the net heat flux from negative to positive values, (g, h, i)
565 depths of the mixing layer (dotted black), Ekman layer (cyan) and euphotic layer (orange) at
566 the BOUSSOLE site. The vertical dotted green line indicates the onset of the bloom.

567 Figure 4. Changes of physical parameters (hourly values) at the onset of the 2016 bloom
568 during 2 consecutive periods of 4 days, March 14-17 (blue) and March 18-21 (red) as a
569 function of wind stress (a) net surface heat flux (b) depths of the Ekman, mixing and euphotic
570 layer. Grey circles and grey squares indicate mean values respectively on March 17 and
571 March 18. For comparison, the orange line shows the euphotic layer depth (March 14-21).

572 Figure 5. From March 7 to April 5, (a) DIC and Chla. The purple line and the squares
573 (blue, morning; grey, evening) indicate the 3 days biological diurnal DIC changes during the

574 period considered to compute NCP The blue and orange lines indicate the surface Chla when
575 the glider was at a distance of less than 5 km (blue) and less than 20 km (orange) respectively
576 from the BOUSSOLE buoy. (b) PAR and I average mixing layer irradiance. The vertical
577 dotted black line indicates the onset of the bloom on March 18.

578 Table 1. Net community production computed in the mixing layer over 3 days (NCP) after the
579 bloom onset (T_0). (a, b) variation of DIC at the measurement depth and linked correlation
580 coefficient; (c, d) change of integrated DIC over Z_{mx} and linked correlation coefficient ;(e)
581 CO_2 flux from the atmosphere to the ocean; (f), absolute value of calculated NCP is
582 considered in order to provide positive values throughout the presentation and discussion in
583 the manuscript.

584 Table 2. 2016-2019. Atmospheric drivers of the onset of the bloom: average values and
585 standard deviation on the day of the start of the bloom, T_0 .
