Abstract. Understanding the dynamics of peatland methane (CH₄) emissions and quantifying sources of uncertainty in estimating peatland CH₄ emissions are critical for mitigating climate change. The relative contributions of CH₄ emission pathways through ebullition, plant-mediated transport, and diffusion together with their different transport rates and vulnerability to oxidation determine the quantity of CH₄ to be oxidized before leaving the soil.

30 Notwithstanding their importance, the relative contributions of the emission pathways are highly uncertain. In particular, the ebullition process is more uncertain and can lead to large uncertainties in modeled CH₄ emissions. To improve model simulations of CH₄ emission and its pathways, we evaluated two model structures: 1) the Ebullition Bubble Growth volume threshold approach (EBG) and 2) the modified Ebullition Concentration Threshold approach (ECT) using CH₄ flux and concentration data collected in a peatland in northern Minnesota, USA. When model
35 parameters were constrained using observed CH₄ fluxes, the CH₄ emissions simulated by the EBG approach (RMSE = 0.53) had a better agreement with observations than the ECT approach (RMSE = 0.61). Further, the EBG approach simulated a smaller contribution from ebullition but more frequent ebullition events than the ECT approach. The EBG approach yielded greatly improved simulations of pore water CH₄ concentrations, especially in the deep soil layers, compared to the ECT approach. When constraining the EBG model with both CH₄ flux and
40 concentration data in model-data fusion, uncertainty of the modeled CH₄ concentration profiles was reduced by 78 to 86 % in comparison to constraints based on CH₄ flux data alone. The improved model capability was attributed to the well-constrained parameters regulating the CH₄ production and emission pathways. Our results suggest that the EBG modeling approach better characterizes CH₄ emission and underlying mechanisms. Moreover, to achieve the best model results both CH₄ flux and concentration data are required to constrain model parameterization.

45

1 Introduction

Methane (CH₄) emissions from wetlands constitute roughly one third of the global CH₄ budget (Denman et al., 2007; Saunio et al., 2020). Methane, following production under anoxic conditions, is stored belowground, oxidized into CO₂ by methanotrophs, or emitted into the atmosphere as CH₄. The emission of CH₄ is a major concern given its sustained-flux global warming potential (SGWP) of 45 (Neubauer and Megonigal, 2015). Methane emissions from wetlands cannot be simply estimated from production rates, as more than 50 % of methane can be oxidized during transport to the atmosphere in various ecosystems (Conrad and Rothfuss, 1991; Teh et al., 2005; Segarra et al., 2015). The global wetland CH₄ oxidation sink has been estimated to be 40–70 % of CH₄ production and it can dominate wetland CH₄ cycling (Megonigal et al., 2004). The oxidation sink depends substantially on the CH₄ emission pathways due to their different oxidation rates (Blodau, 2002).

Methane is produced at depth in the soil and then transported to the atmosphere via three primary pathways: ebullition, plant-mediated transport, and diffusion. Ebullition is the least vulnerable to oxidation, as it allows CH₄ to quickly ascend in a bubble that bypasses the aerobic and anaerobic zones (Epstein and Plesset, 1950). Gases such as CH₄ can be released into the atmosphere by vascular plants (particularly sedges) after being transported through intercellular spaces (molecular diffusion) or aerenchymous tissues. Although plant-transported CH₄ bypasses aerobic zones of the soil, 20–90 % of plant-transported CH₄ can be oxidized in the rhizosphere or within the aerenchymous tissues where gaseous oxygen is present (Schipper and Reddy, 1996; Ström et al., 2005; Laanbroek 2010). Diffusive transport through the peat column is the slowest transport method and therefore, CH₄ is most susceptible to oxidation as it spends the longest time transiting the aerobic and anaerobic zones (Chanton and Dacey, 1991; Megonigal et al., 2004). The relative importance of each pathway determines how much CH₄ is oxidized before it leaves the soil. Uncertainties in the relative contributions of these pathways to CH₄ emission can lead to large errors in the predictions of total CH₄ emissions (Bridgman et al., 2013). Despite their importance, the relative contributions of the CH₄ emission pathways have not been well quantified by either experimental or modeling approaches until recently (Ricciuto et al., 2021; Yuan et al., 2021).

Experimental data on the relative importance of CH₄ emission pathways are limited due to spatiotemporal heterogeneity and the difficulty in directly measuring the different pathways (Klapstein et al., 2014; Iwata et al., 2018). While most state-of-the-art Land Surface Models (LSMs) incorporate CH₄ emission and differentiate the three transport pathways, information on the relative contribution of each pathway from modeling studies is still limited, and none of such studies has estimated the uncertainty or accuracy of the relative contributions of the emission pathways to net CH₄ emission (Bridgman et al., 2013). Comparisons between modeling approaches and empirical CH₄ data suggest that emission pathways may not be well captured by LSMs. For example, plant-mediated CH₄ transport by vascular species measured at northern peatlands accounted for 30–98 % of the total CH₄ emission (Shannon et al., 1996; Waddington et al., 1996), whereas model-estimated proportions in the similar ecosystems were all above 65 % (Tang et al., 2010; Wania et al., 2010). Empirical estimates also suggested that diffusion could range from 9 % to 60 % of the total CH₄ flux (Barber et al., 1988; Shea et al., 2010; Iwata et al., 2018). In contrast, modeled contribution from diffusion were always below 40 % (Tang et al., 2010; Wania et al., 2010; Peltola et al., 2018). More dramatically, modeling approaches estimated that ebullition constituted only 0–

10% of net CH₄ flux in natural vegetated wetlands (Tang et al., 2010; Wania et al., 2010; Peltola et al., 2018), much lower than the 10–64 % that was measured in experimental studies (Glaser et al., 2004; Tokida et al., 2007a; Tokida et al., 2007b). The uncertainties in simulated relative contributions of the pathways to net CH₄ emission in LSMs are
85 mainly due to the lack of in situ information, inadequate representation of CH₄ processes, and unconstrained parameters used to describe emission pathways (Bridgham et al., 2013; Melton et al., 2013).

Since net CH₄ emissions depend on transport mode, all the emission pathways must first be represented correctly in ecosystem models in order to simulate CH₄ emission accurately (Blodau, 2002; Tang et al., 2010).
90 Compared to diffusion and plant-mediated CH₄ transport, ebullition is less certain and could be the main reason for the mismatch between simulated and observed CH₄ concentrations in deep soil layers (Peltola et al., 2018). This is because diffusion is described with Fick's Law and Henry's Law, which have been widely used and well tested, and plant-mediated pathway happens only within the rooting depth, which is typically shallow in wetlands with a high water table level (Iversen et al., 2018). Ebullition makes a significant contribution to the total CH₄ emissions in
95 some wetlands (Christensen et al., 2003; Yu et al., 2014). However, this process has not been well incorporated into most state-of-the-art LSMs. Mechanistically, CH₄ ebullition occurs when the buoyancy force of a bubble exceeds the retention force. During ascent, the bubbles exchange gas with the surrounding pore water and some of the bubbles become trapped, allowing CH₄ to re-dissolve or be oxidized within the confining layer. In modeling studies, ebullition is commonly estimated using the Ebullition Concentration Threshold (ECT) approach. In ECT, when the
100 pore water CH₄ concentration is larger than a defined threshold, the excess CH₄ is directly released into the atmosphere (Walter and Heimann, 2000; Zhuang et al., 2004; Wania et al., 2010; Riley et al., 2011; Xu et al., 2016). However, this approach ignores the possibility of a CH₄ bubble moving into a less saturated layer where it can subsequently dissolve and possibly be oxidized, potentially overestimating ebullition. Other methods for modeling ebullition include the Ebullition Pressure Threshold (EPT) or the Ebullition Bubble Growth volume threshold (EBG)
105 to trigger ebullition (Tang et al., 2010; Zhang et al., 2012). For the EPT method, bubbles form when the CH₄ concentration exceeds a certain threshold. The EBG method describes how temperature, pressure, and gas exchange alter the bubble volume and uses maximum bubble volume as a threshold to trigger ebullition events (Fechner-Levy and Hemond, 1996; Kellner et al., 2006; Zhang et al., 2012). Peltola et al. (2018) compared these modeling approaches and concluded that EBG should be incorporated into LSMs instead of ECT or EPT, given its most
110 realistic representation of the observed temporal variability of CH₄ emissions. However, the ability of the EBG approach to represent the relative importance of CH₄ emission pathways has not been evaluated against observations.

A more realistic projection of the emission pathways requires not only an improved model structure, but also more appropriate parameter values (Wania et al., 2010; Riley et al., 2011; Shi et al., 2018). Data-model fusion
115 directly informs process-based models by synthesizing multisource data streams and thus can help determine parameter values that lie within biophysically realistic ranges and reduce model uncertainty (Williams et al., 2009; Keenan et al., 2013; Shi et al., 2015a; Liang et al., 2018). Previous studies have found that sporadic measurements of net CH₄ emissions were only useful to constrain a few model parameters and data assimilation with only CH₄ emission (flux-based) data did not help reduce the uncertainties in emission pathways (Bridgham et al., 2013; Ma et

120 al., 2017). In our previous study, we found that monthly CH₄ emission data could only constrain CH₄ production-
related parameters such as temperature sensitivity (Q₁₀) and basal production rate of CH₄ production (Ma et al.,
2017). While direct measures of CH₄ emission pathways are rare, depth-specific pore water CH₄ concentration
profiles can help elucidate the relative importance of CH₄ emission pathways. Indeed, measured CH₄ concentration
125 profiles are critical for constraining the responsive parameters associated with CH₄ emission pathways because in
process-based CH₄ models, all the three emission pathways are calculated based on the CH₄ concentration in each
soil layer.

To date, few modeling studies have considered CH₄ concentration data for structural improvement or parameter
optimization (Zhuang et al., 2004; Wania et al., 2010; Riley et al., 2011; Zhu et al., 2014). In those studies that
130 compared simulation results to observed pore water CH₄ concentrations, the simulated concentration profiles did not
agree well with observations, despite good agreements between simulated and observed CH₄ emission data (Walter
and Heimann, 2000; Tang et al., 2010). Thus, when CH₄ emission pathway parameters are calibrated using only net
CH₄ flux data, models may not realistically represent CH₄ production, oxidation, and emission pathways. The
exclusion of concentration profile data results in poorly constrained model parameters due to equifinality, in which
135 multiple combinations of parameters result in similar flux predictions. This can cause misunderstanding of the
mechanisms of CH₄ processes. It will be problematic to use these not-yet-well-calibrated parameter sets for climate
change predictions or extrapolating CH₄ fluxes from the site level to larger spatial and temporal scales as these
intermediate processes may have different responses to perturbations in climate.

To address these uncertainties, we evaluated the performance of two state-of-the-art methods for modeling
ebullition, EBG and ECT, against the observed net CH₄ fluxes and pore water CH₄ concentration profiles in a
140 northern Minnesota peatland. We also compared the strength of the flux-based data and pool-based data in
constraining the parameters using data-model fusion. We hypothesized that: (1) the EBG approach can reproduce
the observed pore water CH₄ profiles better than the ECT approach, given its more mechanical representations of
bubble formation, gas exchange, and release; and (2) pore-water CH₄ concentration data offer more information for
model parameters to reduce the uncertainties in simulated CH₄ emission and its pathways.

145 **2 Methods**

2.1 Site and measurements

The data we used to calibrate our model were collected from the Spruce and Peatland Responses Under Climatic and
Environmental Change Experiment (SPRUCE), which is conducted in the 8.1-ha S1 bog in northern Minnesota in
the USDA Forest Service Marcell Experimental Forest (N 47° 30.476', W 93° 27.162') to study the responses of
150 northern peatlands to climate warming and elevated atmospheric CO₂ concentration (Hanson et al., 2017a). The
mean annual peat temperature from 1961 to 2009 at the SPRUCE site was 3.4 °C, and the mean annual precipitation was
780mm (Sebestyen et al., 2011). The mean peat depth is 2–3 m (Parsekian et al., 2012). The dominant plant species
include *Picea mariana*, *Larix laricina*, a variety of ericaceous shrubs, and *Sphagnum* sp. moss. The graminoids
Carex trisperma and *Eriophorum vaginatum*, as well as the forb *Maianthemum trifolium*, have seasonal dieback of

155 their aboveground tissues in this peatland. Whole-ecosystem warming levels of +0, +2.25, +4.5, +6.75 and +9°C are paired with two CO₂ treatments (ambient or ~400 ppm, and 900 ppm) in open-top infrastructures (12 m × 8 m). Deep peat warming began in June 2014, aboveground warming began in August 2015, and elevated CO₂ treatments began in June 2016. In this study, however, all observed data we used were only from ambient plots (no infrastructures and no warming treatment) for our research goals and we did not explore the warming effects on CH₄ processes. Modeling CH₄ emissions in response to warming and elevated CO₂ at this experiment site can be found in Yuan et al. (2021). A complete list of data streams used in this study is included in Table 1.

Table 1. The SPRUCE site data used in this study.

Purpose	Data name	Year	Period	Time step	References
Environmental variables (input) to drive the TECO model	Soil temperature at 0, 5, 10, 20, 30, 40, 50, 100, 200 cm depth	2011–2016	Whole year	Hourly	Hanson et al., 2015a; Hanson et al., 2015b; Hanson et al., 2016b
	Air temperature at 2m				
	Relative Humidity at 2m				
	Wind speed at 10m				
	Precipitation				
	Photosynthetically Active Radiation (PAR) at 2 m				
Water-heat balance and carbon cycle data to calibrate the model	Soil moisture at 0, 20 cm	2011–2016	Whole year	Hourly	Same as above
	Water table depth	2011–2016	Whole year	Hourly	Same as above
	Leaf, wood, root biomass	2011–2016	End of growing season	Once a year	Hanson et al., 2018a; Hanson et al., 2018b; Norby et al., 2018
	Soil C content	2012	August 13–15	Yearly	Iversen et al., 2014
	NEE, GPP, ER fluxes	2011–2016	All year around except mid-winter*	1–2 times a month	Hanson et al., 2014; Hanson et al., 2016a
Data streams used in data-model fusion	Total CH ₄ emission	2011–2016	All year around except mid-winter*	1–2 times a month	Hanson et al., 2014; Hanson et al., 2016a; Hanson et al., 2017b
	Pore water CH ₄ concentration at 25, 50, 75, 100, 150, 200 cm depth	2014–2016	Growing season	Once a month	Wilson et al., 2016
Generate vertical profile of heterotrophic respiration and used in calculating plant-mediated CH ₄ transport	Fine root biomass vertical distribution	2011–2012	Growing season	Estimated from minirhizotron images collected weekly	Iversen et al., 2018; Malhotra et al., 2020;

* Total CH₄ emission were measured in August, September, and October 2011, May through November 2012, July, September, and October 2013, June through December 2014, April through November 2015, March through
165 December 2016.

Environmental variables, including soil temperature, air temperature, relative humidity, wind speed, precipitation, and photosynthetically active radiation plots were used as model input data. Measurements of environmental variables in ambient plots started in 2011. Soil temperature and moisture in different layers, water table depth (Hanson et al., 2015a; Hanson et al., 2015b; Hanson et al., 2016b), carbon pools (leaf, wood, root, and
170 peat soil, Hanson et al., 2018a; Hanson et al., 2018b; Norby et al., 2018), and community-scale fluxes, including gross primary production (GPP), net ecosystem exchange (NEE), ecosystem respiration (ER), and CH₄ flux data (Hanson et al., 2014; Hanson et al., 2016a; Hanson et al., 2017b) were used to calibrate the modeled water-heat balance and carbon cycle similarly as in our earlier studies (Huang et al., 2017; Ma et al., 2017; Jiang et al., 2018).

CH₄ fluxes and pore water CH₄ concentrations were used for data assimilation. We averaged the data from all
175 ambient plots measured on the same dates to represent the site-level CH₄ emissions and concentration profiles and variations among different ambient plots were not considered in this study. In total, 45 daily CH₄ emission measurements were obtained from ambient plots from 2011–2016. In situ pore water CH₄ concentrations were measured monthly during the growing seasons in 2014–2016 (11 profiles in total) with the pore water samples collected from a series of piezometers permanently installed in the plots at 25, 50, 75, 100, 150, and 200 cm depths,
180 respectively (Wilson et al., 2016). Piezometers consisted of a <1 cm diameter pipe that limited diffusion. Twenty-four hours prior to sampling, piezometers were pumped dry and allowed to recharge naturally so that the sampled water would not have been in prolonged contact with the atmosphere prior to collection. A perforated stainless-steel tube was inserted into the peat to collect samples within 0–25cm depth. Samples were immediately filtered in the field through 0.7 μM Whatman glass-fiber filters and stored in pre-evacuated, septum-sealed glass vials. Phosphoric acid (1 mL, 20 %) was added to preserve each sample during shipment to Florida State University for analyzing CH₄
185 concentrations.

2.2 Model description

2.2.1 Overview of TECO_SPRUCE

For this study, we used the process-based biogeochemistry model, TECO_SPRUCE (Terrestrial ECOsystem model
190 at the SPRUCE site). The model was built with six major modules running at an hourly time step: canopy photosynthesis, soil water dynamics, plant growth, soil thermal dynamics, soil carbon/nitrogen (N) transfer, and soil CH₄ dynamics. A detailed description of these modules can be found in Weng and Luo (2008), Shi et al. (2015b), Huang et al. (2017), and Ma et al. (2017). Here we give a brief description of these modules but describe in detail how we calculated CH₄ ebullition with the EBG and ECT approaches.

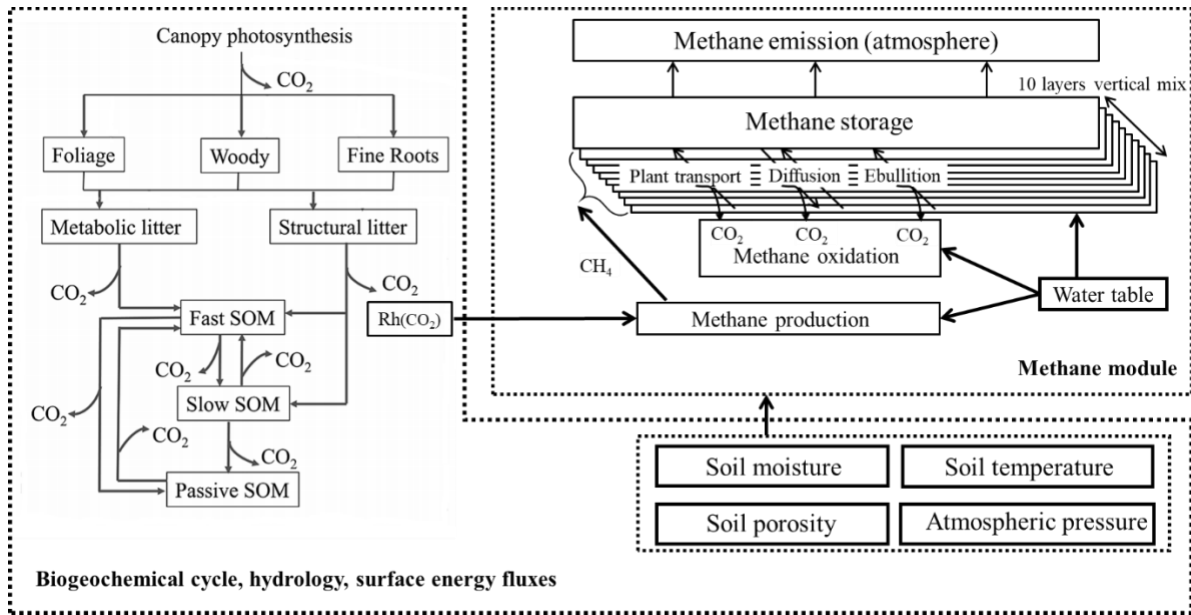

195 The canopy photosynthesis module was mainly derived from a two-leaf model. It couples surface energy, water, and carbon fluxes. Leaf photosynthesis is estimated based on the Farquhar photosynthesis model (Farquhar et

al., 1980) and the Ball and Berry stomatal conductance model (Ball et al., 1987). The soil water dynamic module has 10 soil layers and simulates water table level and soil moisture dynamics using rainfall, snowmelt, evapotranspiration, and runoff. Evaporative losses of water and associated latent heat are regulated by soil moisture in the first layer and atmospheric demand. Transpiration is determined by stomatal conductance and soil water content of the layers with roots present. When precipitation exceeds water recharge to soil water holding capacity, runoff occurs. The water table level is estimated using a simple bucket model as described by Granberg et al. (1999). The plant growth module calculates the allocation of photosynthesis carbon to individual plant pools (foliage, stem and root), plant growth, plant respiration, phenology, and carbon transfer to the litter and soil carbon pools. Leaf onset is regulated by growing degree days (GDD) and leaf senescence is determined by low temperature and/or dry soil conditions. Phenology is represented by the seasonal variations of leaf area index (LAI) with LAI < 0.1 indicating the end of the growing season. The soil thermal dynamics module simulates snow cover, freezing depth, and soil temperature in 10 layers. The soil C/N transfer module simulates the movement of C and N from plants to two litter pools and three soil pools through litterfall, litter decomposition, and soil organic matter mineralization. Carbon fluxes from the litter and soil carbon pools are based on residence time and pool size of each C pool (Luo and Reynolds, 1999).

The CH₄ module simulates the transient, vertical dynamics of CH₄ production, oxidation, and belowground transport (via ebullition, plant-mediated transport, and diffusion), and CH₄ emissions at the soil surface-atmosphere interface (Fig. 1). The soil column is divided into 10 layers with each of the first five layers being 10 cm thick whereas each of the rest layers being 20 cm thick. Within each soil layer, CH₄ concentration dynamics are calculated by a transient reaction equation with CH₄ production, CH₄ oxidation, released bubbles, plant-mediated transport, and the diffusion of CH₄ into/out of this soil layer from the lower/upper soil layer or the atmosphere for the first layer. Similar to CLM4Me (Riley et al., 2011), LPJ-WHyMe (Spahni et al., 2011; Wania et al., 2010), and TRIPLEX-GHG (Zhu et al., 2014) models, we assume that CH₄ production (P_{ro}) within the catotelm is directly related to heterotrophic respiration from soil and litter (R_h , g C m⁻² h⁻¹) via the following equation:

$$P_{ro}(z, t) = R_h(z, t) f_{CH_4} f_{stp}(z, t) f_{pH} f_{red}, \quad (1)$$

where f_{CH_4} is an ecosystem-specific conversion scaler describing the fraction of anaerobically mineralized C atoms becoming CH₄. The parameters f_{stp} , f_{pH} , and f_{red} are environmental scalars, representing the effects of soil temperature, pH and redox potential, respectively on CH₄ production. Total emission of CH₄ from the soil to the atmosphere is calculated as the sum of CH₄ ebullition from saturated soil layers, plant-mediated CH₄ emissions from all the soil layers, and the diffused flux from the first soil layer into the atmosphere. A sensitivity test was done to decide which parameters need to be optimized by data-model fusion (Ma et al. 2017), and more detailed descriptions on the CH₄ module can be found in Ma et al. (2017).

230

Figure 1. Conceptual structure of the CH₄ emission module in TECO_SPRUCE

The original method used in TECO_SPRUCE for the ebullition process was the constant concentration threshold method (Walter and Heimann 2000, Ma et al. 2017). However, a number of factors such as atmospheric pressure, water table level, and temperature have been shown to affect ebullition (Beckmann et al., 2004; Kellner et al., 2006; Tokida et al., 2007a). Here, we used two new methods, i.e., the modified Concentration Threshold method (ECT) and the Bubble Growth volume threshold method (EBG), to describe CH₄ ebullition. In both methods, direct ebullition into the atmosphere can take place only when the water table level is at or above the soil surface; otherwise, CH₄ in bubbles is added to the soil layer just above the water table and then continues to diffuse through the soil layers to the atmosphere. Below we describe these two methods in detail.

235

240

2.2.2 Ebullition approach based on the Concentration Threshold (TECO_SPRUCE_ECT)

245

With the concentration threshold approach, we assume that bubbles form when the CH₄ concentration exceeds a certain threshold based on the equilibrium concentration defined by Henry's Law. Instead of using a constant value for the threshold, in this study, we allowed the threshold to fluctuate with atmospheric pressure, water column pressure, and soil temperature, following the method proposed by Wania et al. (2010). The maximum solubility of CH₄ at a given temperature was calculated using a statistical model used by Yamamoto et al. (1976) based on the empirical data:

$$V = 0.05708 - 0.001545T + 0.00002069T^2, \quad (2)$$

250

where V is the Bunsen solubility coefficient, defined as the volume of gas dissolved per volume of water at atmospheric pressure and a given temperature. The volume of CH₄ dissolved per volume of water was converted into grams using the ideal gas law:

$$[CH_4]_{thre} = PV * C/RT, \quad (3)$$

where $[\text{CH}_4]_{\text{thre}}$ is the maximum concentration threshold (g C m^{-3}), P is the sum of the atmospheric and hydrostatic pressures (Pa), V is the Bunsen solubility coefficient as in Eq. (2), the constant C is the atomic weight of carbon (12 g mol^{-1}), the gas constant R is $8.3145 \text{ m}^3 \text{ Pa K}^{-1} \text{ mol}^{-1}$, and T is the temperature (K). Then the CH_4 ebullition flux can be calculated using the following equation:

$$E_{\text{bu}}(z, t) = \begin{cases} K_{\text{ebu}}([\text{CH}_4](z, t) - [\text{CH}_4]_{\text{thre}}) & \text{if } [\text{CH}_4] > [\text{CH}_4]_{\text{thre}} \\ 0.0 & \text{if } [\text{CH}_4] \leq [\text{CH}_4]_{\text{thre}} \end{cases}, \quad (4)$$

where $E_{\text{bu}}(z, t)$ is the ebullition flux of CH_4 (g C h^{-1}) to the lowest air layer, K_{ebu} is a rate constant of 1.0 h^{-1} (Walter and Heimann 2000, Zhuang et al. 2004, Zhuang et al. 2006), and $[\text{CH}_4](z, t)$ is the pore water CH_4 concentration in soil depth z at model time step t .

2.2.3. Ebullition approach based on the Bubble Growth volume threshold (TECO_SPRUCE_EBG)

In contrast to the concentration threshold approach, the EBG approach uses bubble volume as a threshold to trigger ebullition events (Fechner-Levy and Hemond 1996) and it has been applied to model CH_4 ebullition (Kellner et al., 2006; Zhang et al., 2012; Peltola et al., 2018). The total bubble volume in each soil layer is calculated and updated continuously based on the ideal gas law and Henry's law. In detail, if CH_4 concentration exceeds the limit that the water can withhold based on Henry's law, then excess CH_4 is converted to a gaseous volume calculated using the predefined bubble CH_4 mixing ratio (f). This gaseous volume is divided evenly into a certain number of bubbles (N_{bub}). N_{bub} is a unitless tuning parameter ranging between 5–500 in each 10 cm thick soil layer and 10–1000 in each 20 cm thick soil layer, which essentially controls the mass exchange rate between the gas volume and the pore water. The CH_4 exchange between the stationary bubbles and the pore water (Q_{ebu}) is calculated using the equation proposed by Epstein and Plesset (1950):

$$Q_{\text{ebu}} = \frac{4\pi r D_w N_{\text{bub}}}{V_w} \left(c_w - \frac{H^{\text{cc}} f P}{RT} \right), \quad (5)$$

where r is the radius of a bubble (m), D_w is the CH_4 diffusion coefficient in water ($\text{m}^2 \text{ s}^{-1}$) calculated using the quadratic curve of observed diffusivities against temperatures (Broecker and Peng, 1974), V_w is the amount of water in this layer (m^3), c_w is dissolved CH_4 concentration in the pore water, and H^{cc} is the dimensionless Henry solubility of CH_4 calculated following Sander (1999). P , R , and T are same as in Eq. (3). A negative value of Q_{ebu} indicates CH_4 transfer from the bubbles back to the pore water. This reverse gas exchange mechanism has not been included in other ebullition methods but has been revealed as an important process in empirical studies (McGinnis et al., 2006; Rosenberry et al., 2006). The ebullition flux $E_{\text{bu}}(z, t)$ is then calculated when the bubble volume at a certain depth (z) exceeds the volume threshold (V_{max}) within the time step t :

$$V_{\text{max}} = V_{\text{maxfraction}} * V_w, \quad (6)$$

$$E_{\text{bu}}(z, t) = \begin{cases} c_b * (V_B + \Delta V_B - V_{\text{max}}), & \text{if } V + \Delta V > V_{\text{max}} \\ 0.0 & \text{if } V + \Delta V < V_{\text{max}} \end{cases}, \quad (7)$$

where $V_{\text{maxfraction}}$ is the free-phase gas-filled fraction of the pore space in the soil layer above which ebullition occurs, c_b is the CH_4 concentration in a bubble (mol m^{-3}), V_B is the total volume of all bubbles, and ΔV_B is the change in the total volume due to the diffusive gas exchange in Eq. (5). The amount of CH_4 in all bubbles after each time step is:

$$n_b = \frac{f P V_B'}{RT}, \quad (8)$$

where f is the predefined bubble CH_4 mixing ratio as mentioned earlier, and V'_B is the updated total bubble volume after each time step. Excess bubbles will be released into the lowest air layer within one time step unless they are trapped in the soil profile. To determine if a bubble will be trapped, we adopted an approach similar to Peltola et al. (2018), assuming that the probability for a bubble to be trapped within a certain soil layer is a predefined constant number (bubprob), thus the bubbles formed in deeper layers would have a larger probability of being trapped during ascent. In contrast, all other ebullition modeling methods assume that no bubbles will get trapped.

The values of bubprob, f , and $V_{\text{maxfraction}}$ are dependent on the soil texture, porosity, water content, etc. and have been found to significantly affect the modeled CH_4 fluxes, the layers where bubbles were formed, and the number of ebullition events (Zhang et al., 2012; Peltola et al., 2018). The tuning parameter, N_{bub} , however, has a minimal effect on modeled ebullition (Peltola et al., 2018). In this study, we used the empirical values measured from other sites or the values used in other models as the prior ranges of bubprob, f , and $V_{\text{maxfraction}}$ in our models (Table 2). Then we constrained these parameter values via data-model techniques so that the model estimation of ebullition process was more accurate.

300

Table 2. Parameters used for data-model fusion

Process	Symbol	Range	Units	Definition	References
CH ₄ production	f_{CH_4}	[0.0, 0.7]	-	Fraction of anaerobically mineralized C atoms becoming CH ₄	Zhuang et al., 2004; Segers, 1998; Zhu et al., 2014
	$Q_{10\text{pro}}$	[0.0, 10]	-	Q_{10} for CH ₄ production	Walter and Heimann, 2000
CH ₄ oxidation	O_{max}	[3.0, 45.0]	$\mu\text{mol L}^{-1} \text{h}^{-1}$	Maximum oxidation rate	Zhuang et al., 2004
CH ₄ ebullition	f	[0.01, 0.5]	mol mol^{-1}	CH ₄ mixing ratio in bubbles	Tang et al., 2010; Peltola et al., 2018
	bubprob	[0.01, 0.5]	-	Probability that a bubble will get trapped at one layer	Tang et al., 2010; Peltola et al., 2018
	$V_{\text{maxfraction}}$	[0.01, 0.2]	-	Maximum fraction of volume occupied by bubbles	Peltola et al., 2018
Plant-mediated transportation	T_{veg}	[0.01, 15.0]	-	Capability of conducting CH ₄ gas at plant community level	Walter and Heimann, 2000; Zhuang et al., 2004

2.3 Data-model fusion

We used the Markov Chain Monte Carlo (MCMC) method based on the Metropolis-Hasting algorithm (Metropolis et al. 1953) to optimize the posterior distribution of parameters and explore model uncertainty. Both the observed data and simulated results were rescaled to a daily emission unit for comparison. The prior range for each parameter was assumed to be uniformly distributed, which indicates that all values within the range have equal likelihood. We also assumed that errors between observations and model simulations independently follow a normal distribution

305

with a zero mean. The cost function weights the mismatch between observations and the modeled corresponding variables, represented by:

$$p(Z|\theta) \propto \exp \left\{ - \sum_{i=1}^2 \sum_{t \in Z_i} \frac{[Z_i(t) - X(t)]^2}{2\sigma_i^2(t)} \right\}, \quad (9)$$

where $Z_i(t)$ is the i th observation stream at time t , $X(t)$ is the model simulated value, and $\sigma_i(t)$ is the standard deviation of observation error estimates.

The parameter space was explored for 50,000 iterations during the optimization process. The new parameter value at the current step was based on the accepted parameter in the previous step by a proposed distribution. The current value was accepted if the observation-model difference was reduced or otherwise passed with a random probability. We ran five chains of 50,000 simulations and used the Gelman-Rubin statistic (Gelman and Rubin, 1992) to check the convergence of sampling chains. The first half of the accepted parameters were discarded as the burn-in period, and the second half were used for posterior analysis. More details on sampling and the cost function can be found in Xu et al. (2006).

Parameters directly regulating CH_4 emission pathway and belowground dynamics and their prior ranges used for data assimilation are listed in Table 2. Specifically, we selected four parameters (i.e., f_{CH_4} , $Q_{10\text{pro}}$, O_{max} and T_{veg}) from the TECO_SPRUCE_ECT and seven parameters (all the seven parameters in Table 2) from the TECO_SPRUCE_EBG during data assimilation. The prior ranges were determined by combining information from empirical measurements or modeling studies from peatland ecosystems. The in situ CH_4 emission and pore water CH_4 concentration data from ambient plots (Table 1) were used as observations to constrain model parameters. In order to evaluate how a proper model structure and constrained parameter values help improve model-simulated CH_4 emission pathways, we conducted four data assimilation runs with the TECO_SRUCE model, as shown in Table 3.

330

Table 3. Details for data assimilation runs.

Data assimilation runs	Ebullition approaches embedded with TECO	Observation data streams used for constraining the parameters
ECT_F	ECT	CH_4 fluxes
ECT_FC	ECT	CH_4 fluxes + pore water CH_4 concentration profiles
EBG_F	EBG	CH_4 fluxes
EBG_FC	EBG	CH_4 fluxes + pore water CH_4 concentration profiles

We illustrate the improvement from model structure by comparing ECT_F and EBG_F, which were calibrated using the observed CH_4 flux data. Then we compare results from EBG_F and EBG_FC to show the ability of pore water CH_4 concentration data to help constrain the parameters related to the CH_4 emission pathways. Model performance was evaluated against the observed data using Root Mean Square Error (RMSE). Model uncertainties in pore water CH_4 concentrations were quantified as the standard deviation across all soil layers in each of model runs listed in Table 3.

335

3 Results

3.1 Parameter optimization using CH₄ flux data with different model structures

The CH₄ production-related parameters, f_{CH_4} (fraction of anaerobically mineralized C atoms becoming CH₄) and $Q_{10\text{pro}}$ (temperature sensitivity of CH₄ production), were constrained using the CH₄ emission flux data for both TECO_SPRUCE_ECT and TECO_SPRUCE_EBG (Table 4, Fig. 2a, b). However, the maximum likelihood estimates (MLEs) for parameters varied between the two models (Table 4), with f_{CH_4} slightly increased from 0.16 to 0.17 and $Q_{10\text{pro}}$ decreased from 3.0 to 2.69 in the EBG approach compared to the ECT approach. In contrast, O_{max} and T_{veg} were not constrained in either model with large uncertainties in model-estimated CH₄ oxidation and plant transport parameters (Table 4, Fig. 2c, d).

Table 4. Parameter values for the posterior distribution of parameters.

Parameter	Ebullition method	Observation data	Posterior distribution Mean \pm sd	MLE*	Parameter class
f_{CH_4}	ECT	Flux	0.16 ± 0.016	0.16	bell-shaped
	EBG	Flux	0.17 ± 0.023	0.17	bell-shaped
	EBG	Flux + Concentration	0.15 ± 0.021	0.15	bell-shaped
$Q_{10\text{pro}}$	ECT	Flux	3.0 ± 0.85	3.0	bell-shaped
	EBG	Flux	2.69 ± 0.82	2.69	bell-shaped
	EBG	Flux + Concentration	3.21 ± 1.07	3.21	bell-shaped
O_{max}	ECT	Flux	22.8 ± 12.1	-	flat
	EBG	Flux	22.5 ± 12.1	-	flat
	EBG	Flux + Concentration	22.4 ± 12.0	-	flat
T_{veg}	ECT	Flux	7.7 ± 4.0	-	flat
	EBG	Flux	5.8 ± 4.0	-	flat
	EBG	Flux + Concentration	1.43 ± 0.46	1.43	bell-shaped
f	EBG	Flux	0.11 ± 4.0	0.11	edge-hitting
	EBG	Flux + Concentration	0.29 ± 0.46	0.29	bell-shaped edge-hitting; big variance;
bubprob	EBG	Flux	0.22 ± 0.87	0.19	bell-shaped
	EBG	Flux + Concentration	0.25 ± 0.015	0.23	bell-shaped
$V_{\text{maxfraction}}$	EBG	Flux	0.1 ± 0.13	0.08	bell-shaped
	EBG	Flux + Concentration	0.11 ± 0.12	0.1	bell-shaped

*MLE: Maximum Likelihood Estimation.

Of the three ebullition-related parameters used only in the EBG approach, when assimilating only the CH₄ emission flux data, $V_{\text{maxfraction}}$ (maximum fraction of volume occupied by bubbles) was constrained with a unimodal shaped posterior distribution (Fig. 2g), f (CH₄ mixing ratio in bubbles) was edge hitting with a marginal distribution downward (Fig. 2e), and bubprob (probability that a bubble will get trapped at a certain soil layer) was constrained with a wide, slightly domed distribution (Fig. 2f).

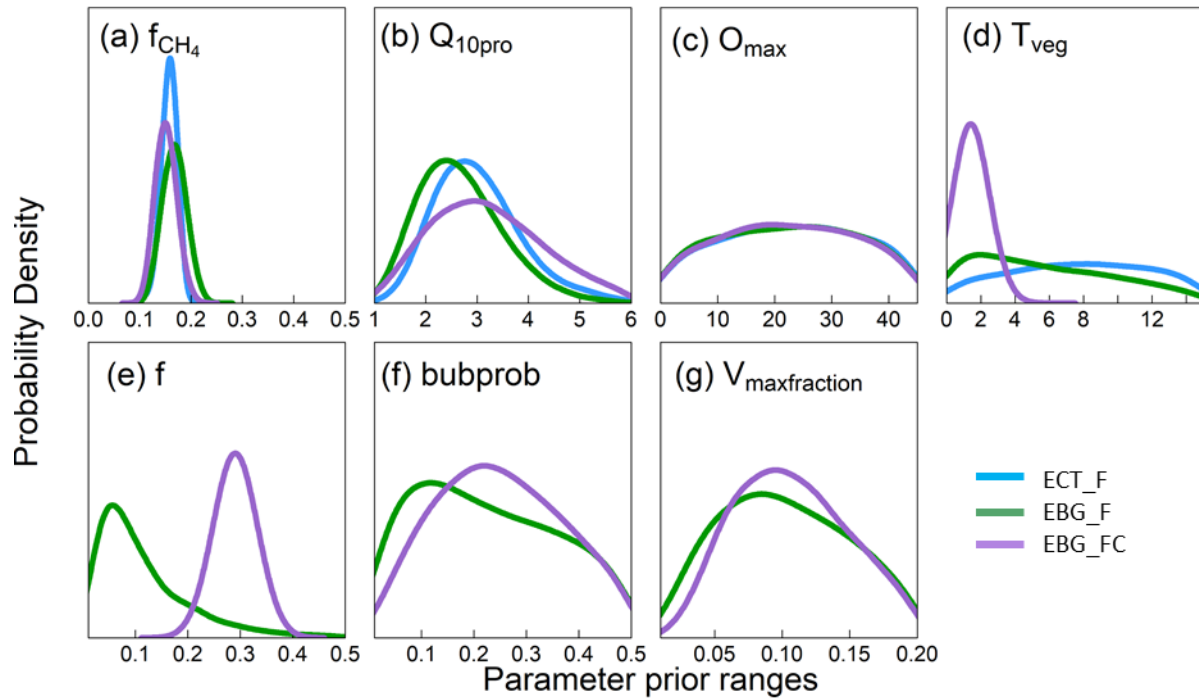

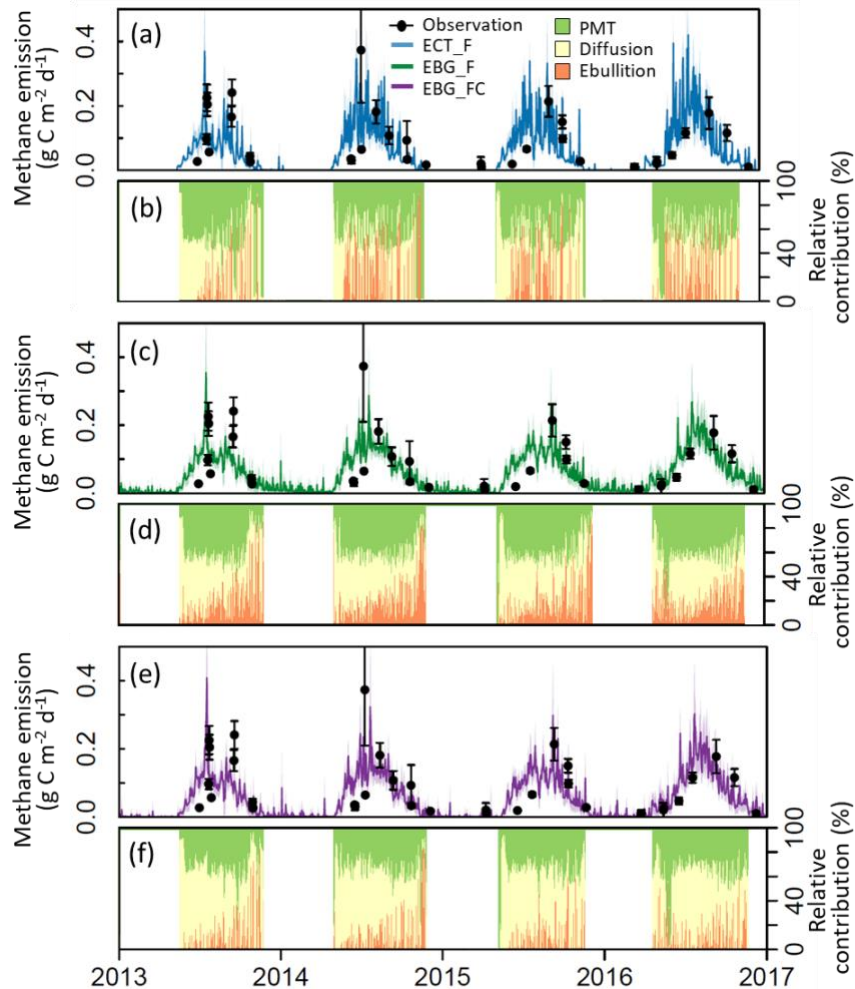

Figure 2. Posterior distribution of parameters that govern methane emission processes from data-model fusion. Parameters are defined in Table 2. (a) and (b) are parameters related to methane production, (c) is a parameter related to methane oxidation, (d) is a parameter related to plant transport, and (e)–(g) are parameters related to ebullition. X axes indicate the prior ranges of parameters used for data-model fusion. The blue lines are the parameter posterior distributions (PPDs) from the ECT model structure trained with CH_4 emission data (ECT_F). The green lines are the PPDs from the EBG model structure trained with CH_4 emission data (EBG_F). The purple lines are the PPDs from EBG trained with both CH_4 emission and CH_4 concentration data (EBG_FC). Well-constrained parameters have a unimodal distribution whereas poorly constrained parameter distributions tend to be flat.

3.2 Evaluations of model structures against the observed data

Using CH_4 emission data to constrain the parameters, EBG-simulated CH_4 emissions (RMSE = 0.53, Fig. 3c) had a better agreement with observations than ECT (RMSE = 0.61, Fig. 3a). In addition, EBG simulated a smaller seasonal variability in CH_4 emissions (Fig. 3c) than ECT (Fig. 3a). The simulated contributions from plant-mediated transport, diffusion, and ebullition were $40.7 \pm 8.0 \%$, $35.7 \pm 8.7 \%$, and $23.5 \pm 9.4 \%$, respectively in ECT_F (Fig. 3b) and $38.4 \pm 13.9 \%$, $38.7 \pm 9.9 \%$, and $22.7 \pm 9.4 \%$, respectively in EBG_F (Fig. 3d). Compared to ECT (Fig. 3b), EBG simulated a smaller contribution from ebullition, but more frequent ebullition events (Fig. 3d).

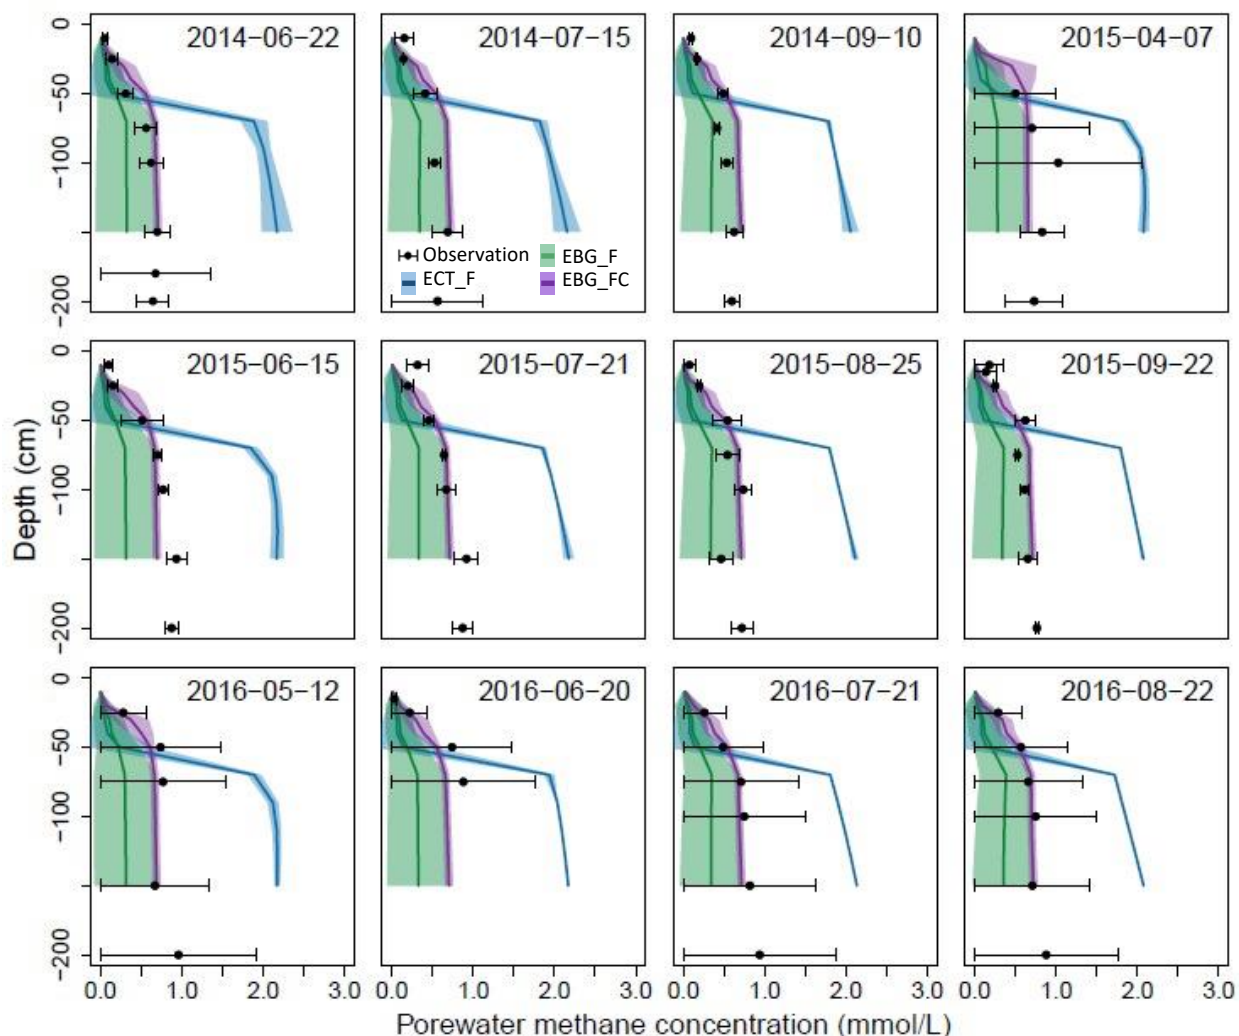

375 **Figure 3.** Observed versus modeled methane emissions (a, c, e) and simulated relative contributions (%) of plant-
 mediated transportation (PMT), diffusion, and ebullition under ambient conditions (b, d, f). Black dots are observed
 CH₄ emissions from static chamber measurements. Error bars are the standard errors. Blue lines are ECT model
 simulated CH₄ emissions based on the parameter probability distributions (PPDs) constrained by CH₄ flux data
 (ECT_F, RMSE = 0.61). Green lines are EBG model simulated CH₄ emissions based on the PPDs constrained by
 380 CH₄ flux data (EBG_F, RMSE = 0.53). Purple lines are EBG model simulated emissions based on the PPDs
 constrained by both CH₄ flux and concentration data (EBG_FC, RMSE = 0.52). The midlines and shaded areas
 correspond to the means and standard deviations, respectively from 500 model simulations with parameters
 randomly drawn from the posterior distributions. Relative contributions (%) are the daily mean values calculated
 from the simulations.

385

The ECT model constrained by CH₄ flux data could not reproduce well the patterns of the observed pore water
 CH₄ concentrations, especially in the deep peat layers (RMSE = 0.77, Fig. 4, ECT_F). When calibrated by CH₄ flux
 data alone, the EBG approach for ebullition captured deep layer CH₄ concentrations much better than the ECT
 approach (RMSE = 0.33, Fig. 4, EBG_F). The observed concentration profiles lay within the 95 % probability

390 intervals and the means were comparable to observed patterns. However, the EBG model structure simulated a relatively large range of CH₄ concentration profiles, especially in the deep peat layers, mainly due to the unconstrained T_{veg} and bubprob controlling the plant transport and ebullition pathways, respectively (Fig. 2, EBG_F).

395

400 **Figure 4.** Observed versus simulated pore water CH₄ concentration profiles. Black dots are observed concentrations measured from piezometer samples. Blue lines are the ECT model simulated concentrations based on the parameter probability distributions (PPDs) constrained by CH₄ flux data (ECT_F). Green lines are the EBG model simulated concentrations based on the PPDs constrained by CH₄ flux data (EBG_F). Purple lines are the EBG model simulated concentrations based on the PPDs constrained by both CH₄ flux and concentration data (EBG_FC). All midlines and shaded areas correspond to the means and standard deviations, respectively from 500 model simulations with parameters randomly drawn from the posterior distributions.

405 3.3 Comparison of the flux- and pool-based data in constraining the parameters for simulating CH₄ processes

For the ECT approach, as described earlier, assimilating the observed CH₄ flux could constrain parameters such as f_{CH_4} and $Q_{10\text{pro}}$. However, when using both observed CH₄ flux and concentration data to constrain the parameters of TECO_SPRUCE_ECT (i.e., the ECT_FC run), no parameter set was accepted within the observational uncertainty range, indicating that the ECT model structure failed to simultaneously simulate the dynamics of CH₄ emissions and
410 pore water CH₄ concentrations.

In contrast to the ECT approach, incorporation of porewater CH₄ concentration data in the EBG approach greatly improved parameter estimations. While T_{veg} and bubprob were not constrained by flux-based observation data alone (Table 4, Fig. 2, EBG_F), they were well constrained to a unimodal distribution when both CH₄ flux and pore water CH₄ concentration data streams were used in the data-model fusion (Table 4, Fig. 2, EBG_FC).

415 Compared to EBG_F, the parameter T_{veg} was well constrained to a very small range of 1.43 ± 0.46 , and the parameter bubprob was also well constrained to a range of 0.25 ± 0.015 with less uncertainty under EBG_FC (Table 4, Fig. 2). The parameter f_{CH_4} decreased from 0.17 in EBG_F to 0.15 in EBG_FC whereas $Q_{10\text{pro}}$ increased from 2.69 in EBG_F to 3.21 in EBG_FC (Table 4, Fig. 2). Moreover, the formerly constrained range of parameter f under EBG_F shifted from 0.11 ± 4.0 to 0.29 ± 0.46 when the pore water CH₄ concentration information was added into
420 data assimilation. All the emission pathway-related parameters (T_{veg} , bubprob , f , and $V_{\text{maxfraction}}$) were well constrained once the pore water CH₄ concentration profile information was added to data-model fusion. However, incorporation of the porewater CH₄ concentration data in data assimilation with the TECO_SPRUCE_EBG did not improve the constraint of O_{max} .

In terms of model's performance fitting observed CH₄ emission patterns, the two parameterization methods for
425 the EBG approach were comparable, with RMSE of 0.53 under EBG_F and RMSE of 0.52 under EBG_FC (Fig. 3c, e). However, the simulated contributions from plant-mediated transport, diffusion, and ebullition by EBG_FC, which were 31.8 ± 4.9 %, 58.1 ± 5.1 %, and 9.9 ± 6.1 %, respectively (Fig. 3f), varied greatly from those simulated by EBG_F (Fig. 3d). The contribution from ebullition under EBG_FC was much less than that under EBG_F (Fig. 3d). CH₄ flux and concentration data together reduced the uncertainty of the modeled CH₄ concentration profiles by
430 78–86 % compared to the flux data alone for data-model fusion, with RMSE reducing from 0.33 in EBG_F to 0.12 in EBG_FC (Fig. 4). The uncertainty in modeled CH₄ concentration profiles was decreased mainly due to the well-constrained parameters regulating the CH₄ production and emission pathways (Fig. 2a, b, d–g).

4 Discussion

In this study, we evaluated two alternative model structures with two data streams, i.e., CH₄ emission and pore water
435 CH₄ concentration data, in simulating peatland CH₄ emission and its pathways.

4.1 Better representing CH₄ emission and pore water CH₄ concentrations by the Ebullition Bubble Growth (EBG) model

Previous studies suggested that the EBG method of modeling ebullition agreed better with the observed temporal variability in CH₄ emissions ($R^2 = 0.63$) when compared with the ECT ($R^2 = 0.56$) and EPT ($R^2 = 0.35$) methods (Peltola et al. 2018). We also found that the EBG-simulated CH₄ emissions (RMSE = 0.53) had a better agreement with observations than the ECT method (RMSE = 0.61). Ebullition events simulated by EBG had a higher frequency but a smaller magnitude than those obtained from ECT, which is consistent with onsite minirhizotron observations of small bubbles around fine roots (Fig. S1). Although the ECT method was able to simulate a similar seasonal pattern of CH₄ emissions as EBG, the mean annual CH₄ emission was 17.8 % lower compared with the EBG method. Peltola et al. (2018) reported that the different ebullition modeling approaches simulated significantly different amount of CH₄ stored belowground and distinctly different distributions of CH₄ along the soil profiles. In line with their results, we found that the ECT method produced much higher pore water CH₄ concentrations than the EBG method, especially in the deep layers (Fig. 4).

Of the few modeling studies that compared results with observed belowground CH₄ concentration, Walter et al. (2000) simulated CH₄ concentration with an early-generation ECT method. This method used a constant concentration threshold that was tuned to match the observed concentration data, but they also found discrepancies with observed data (only CH₄ concentrations within the first 50 cm soil were compared). Tang et al. (2010) compared the EPT method with the early-generation ECT method and found that EPT had an improved CH₄ concentration profile, although a mismatch in the concentration profile remained, especially from the model that best reproduced observed CH₄ emissions. The recently developed Land Surface Model (LSM) with a new microbial-functional group-based CH₄ module incorporated, i.e., the ELM_SRUCE model, used the modified ECT method for ebullition process, but incorporated the acetoclastic and hydrogenotrophic pathways for methanogenesis as well as anaerobic and aerobic oxidations (Ricciuto et al., 2021). This model could accurately predict the seasonal cycle of CH₄ production and net fluxes, but CH₄ concentrations in soil layers deeper than 1m were still not well simulated (Ricciuto et al., 2021) and led to different estimates of emission pathways (23.5 % for PMT, 15.0 % for diffusion, and 61.5 % for ebullition) with our study (31.8 ± 4.9 % for PMT, 58.1 ± 5.1 % for diffusion, and 9.9 ± 6.1 % for ebullition). In our study, when training the modified ECT model with both CH₄ emission and pore water concentration data, no parameter set was accepted, which suggested that the ECT method was not able to simultaneously reproduce both the magnitude of observed CH₄ fluxes and the patterns of pore water CH₄ concentrations, no matter the combinations of parameters used. In contrast, the EBG method could capture observed CH₄ emissions and the patterns of pore water CH₄ concentration profiles simultaneously (Figs. 3 and 4).

Moreover, we found that although both the ECT and EBG methods were able to represent the general patterns of observed CH₄ emissions, the flux-constrained parameter distributions varied between the two methods. For example, f_{CH_4} increased but Q_{10pro} decreased in EBG compared to ECT (Table 4, Fig. 2), which might be attributed to the confounding effects of missing/inappropriate model structures on parameter estimation because different combinations of model parameter values or structures can give similar model outputs (Williams et al., 2009). More studies are needed to further explore model structures and parameter optimization methods to best simulate CH₄ production and emission processes and the underlying mechanisms.

4.2 Pool-based CH₄ concentration data reduced the uncertainty of the emission pathways

475 Our study suggests that even using a more reasonable model structure, i.e., EBG, parameter sets that resulted in
good simulations of CH₄ emissions did not necessarily reproduce a realistic pore water concentration profile (Figs. 3
and 4). By comparing the parameter posterior distributions trained by observed CH₄ emissions with and without
observed pore water concentration profiles using the same model structure, TECO_SPRUCE_EBG, we revealed that
480 CH₄ emission data could constrain the CH₄ production-related parameters f_{CH_4} and $Q_{10\text{pro}}$ and ebullition-related
parameter $V_{\text{maxfraction}}$ very well. The ebullition-related parameter f was edge hitting, but parameter bubprob and plant
transport-related parameter T_{veg} remained unconstrained, causing large uncertainty in simulated ebullition and plant-
mediated transport (Table 4). However, by training the model with both CH₄ emission and pore water CH₄
concentration data, the parameters regulating CH₄ production, plant transport, and ebullition were all well
485 constrained (Fig. 2). This is because the vertical concentration profile of CH₄ is a balance between the dynamic CH₄
production, oxidation and three emission pathways. The constrained parameters contributed to a more accurate
estimation of porewater CH₄ concentration (RMSE = 0.12) and better constrained emission pathways (Table 4, Fig.
4).

Previous studies have emphasized the importance of combining carbon-pool data with carbon-flux data to
improve estimated ecosystem carbon exchange. For example, Richardson et al. (2010) reported the initial leaf pool
490 size could not be constrained until biomass information was combined with flux data. Du et al. (2015) also found
that carbon flux data could constrain parameters reflecting instant responses to environmental changes such as
temperature sensitivity, while pool-based data mainly contained information that could help constrain transfer
coefficients. GPP/ER data could effectively constrain parameters that were directly related to flux data, such as the
temperature sensitivity of heterotrophic respiration, the carbon allocation to leaves, and leaf turnover rate (Fox et al.,
495 2009). In our study, the CH₄ emission data mainly constrained parameters that represented instant responses to
temperature change ($Q_{10\text{pro}}$) and input rate from the source pool (f_{CH_4}). The pore water CH₄ concentration data
contributed to constraining the allocation rates of CH₄ to the different emission pathways. Due to the different
information contained between CH₄ flux and concentration data, we highly recommend that both types of
measurements should be made when possible, and that both data streams should be used when constraining CH₄
500 models.

It needs to be noted that there is a large disagreement in simulated relative contribution by ebullition between
CH₄ flux data constrained models (i.e., 0.13 % by the ECT approach with a constant concentration threshold (Ma et
al., 2017), 23.5 % by the modified ECT approach with varied concentration thresholds in our study, and 22.7 % by
the EBG approach in our study, and the EBG approach constrained with both CH₄ flux and concentration data
505 (9.9 %) (Figure 3). This suggests the urgent need of observed data for separating these relative contributions in field
experiments, possibly through: 1) having continuous total emission flux measurement (Susiluoto et al., 2018),
despite being hard to deploy and calibrate in the field; 2) separately measuring diffusive/plant-mediated-
transport/ebullition fluxes, despite being technically challenging; and 3) measuring belowground CH₄ concentration
profile as suggested in our study. At the SPRUCE experiment site, starting in the summer of 2022, two auto-
510 chambers with footprint of 0.2m² will be deployed in each plot to measure CO₂ and CH₄ fluxes. Along with the

continued CH₄ profile measurement, these whole set of observations will provide the opportunity to further evaluate these discussed approaches for improving model simulations.

4.3 Broader impacts and implications

515 Large uncertainties exist in understanding future wetland CH₄ emissions in response to projected climate change, which result from inappropriate model structure and insufficient parameterizations even after the uncertainties in wetland areas are considered (Melton et al., 2013; Luo and Schuur, 2020). Decades of modeling research on CH₄ has evolved to a stage that the emission pathways are explicitly calculated with various complexities, but determining the accuracy and uncertainty of individual pathways still requires more research (Xu et al., 2016).
520 Currently, models fail to reproduce diffusive fluxes by more than 40 %, mainly due to the lack of validations by the pore water CH₄ concentrations (Tang et al., 2010; Riley et al., 2011). In LSMs, plant transport exclusively dominates CH₄ emission in all wetland types tested (Tang et al., 2010; Wania et al., 2010; Peltola et al., 2018). However, according to the experimental studies, each of the three emission pathways can dominate, depending on the wetland type, vascular plant coverage, and the height of the water table (Whiting and Chanton, 1992, Shannon et al. 1996).
525 By assimilating empirical data of both CH₄ flux and pore water CH₄ concentration data, our data-model fusion study proposes a more reasonable model structure and more robust parameter estimates with greatly reduced uncertainties.

Our results also implicate barriers of current CH₄ modeling studies and suggest future directions for both modeling and experimental efforts, namely: 1) the under-described CH₄ processes in models and 2) the lack of observational data to constrain key CH₄ processes in the models. More explicit CH₄ processes are needed in modeling CH₄ emission and its pathways. For example, in this study, the maximum aerobic oxidation rate (O_{max})
530 was always poorly constrained with wide, slightly domed distributions (Fig. 2c) regardless of what observation data was being assimilated into the models. This poor constraint might partly result from the missing anaerobic oxidation process in the models. In current process-based models, much of the descriptions of CH₄ dynamics in wetland soils are based on the premise that the oxidation of CH₄ occurs only in aerobic environments (Wania et al., 2010; Riley et al., 2011; Bridgham et al., 2013). However, the anaerobic oxidation of CH₄ may be an important sink for CH₄,
535 sometimes reducing emissions by over 50 % in experimental studies (Smemo and Yavitt, 2011; Gupta et al., 2013; Segarra et al., 2015). Recently, a microbial-functional-group-based CH₄ model was developed accounting for both aerobic and anaerobic CH₄ oxidations and this model has been validated against the concentration of CH₄ and CO₂ from incubation data (Xu et al., 2015). In Xu et al. model, 7 out of total 33 key CH₄ process parameters controls CH₄ oxidation and their values varies widely across different ecosystems and environmental conditions. Incorporation of
540 anaerobic CH₄ oxidation into LSMs may help improve the calculations of CH₄ oxidation, if the uncertainties from these CH₄-oxidation-related parameters can be reduced.

While more comprehensive and process-based models for simulating all the processes or mechanisms involved in CH₄ emissions are laudable, observations on such specific processes are critical to constrain parameters and reduce model uncertainty. Without sufficient data to evaluate such processes or to calibrate models, developing such
545 complex models to explicitly simulate these processes could also introduce large uncertainties. Increased model complexity only contributes to the improved forecasting if parameters can be calibrated adequately by observed data

(Famiglietti et al., 2021). If there were not enough observational data for model calibrations, increased complexity can lead to even worse forecast skills than the intermediate-complexity models (Shi et al., 2018; Famiglietti et al., 2021). Currently, similar to our model, many process-based biogeochemistry models (e.g., CLM, LPJ, TRPLEX, 550 JULES, TEM) also use a parameter that varies with soil conditions to describe the potential ratio of CO₂ becoming CH₄ (f_{CH_4}), which is due partly to the limitation of data availability. Another example of observational data hindering model development is the unconstrained parameters to calculate plant-mediated transport. Although new algorithms and parameters to calculate plant aerenchyma transport have been added to LSMs to represent this mechanism more realistically, the parameters such as tiller radius, number of tillers, cross section area of tillers, and 555 the tiller porosity are highly idealized and poorly constrained (Wania et al., 2010; Riley et al., 2011). In the TECO_SPRUCE model used in this study, the parameter T_{veg} was used as a proxy of the ability of the whole plant community (e.g., biomass and abundance) to emit CH₄. Root growth was simulated by a phenological process using LAI and temperature and in situ fine root profile measurements were used as a proxy for vertical rooting distributions (Iversen et al., 2018). T_{veg} was well constrained by the observed CH₄ emission and concentration data 560 at a range of 1.43 ± 0.46 , which indicated that the ability of the plant community to emit CH₄ at this site was low (compared to its prior knowledge of 0.01-15, Table 2). Empirical measurements of plant-mediated CH₄ transport at the same study site supported our model results (Scott Bridgman, personal communications). This finding can also be explained given that the diversity and abundance of aerenchymous plants at our study site were low, similar to many other northern ombrotrophic bogs.

565 **5 Conclusions**

Understanding relative contributions of CH₄ emission pathways is critical to mechanistically modeling future CH₄ dynamics. Acknowledging that pore water CH₄ concentration is the driving force for each emission pathway, we evaluated the ability of two ebullition modeling approaches to reproduce observed CH₄ emissions and pore water concentration profiles at a large-scale manipulated experimental site in a northern Minnesota, USA peatland. The 570 Ebullition Bubble Growth volume threshold approach (EBG) fits the observed CH₄ emissions and CH₄ concentration profiles much better than the modified Ebullition Concentration Threshold approach (ECT), especially for CH₄ concentrations in the deeper soil layers. By assimilating the net CH₄ emission and belowground CH₄ concentration data into the models, we substantially reduced the uncertainties of modeled CH₄ emissions from the involving emission pathways. While net CH₄ efflux data are often the only data stream for CH₄ model validations, 575 we recommend that more attention be given to in situ measurements of the porewater CH₄ concentrations and assimilations of the concentration data for model parameterization. Since the relative ratio of the emission pathways (ebullition, plant-mediated transport and diffusion) determines how much CH₄ is oxidized before leaving the soil, due to their different transport rate and vulnerability to oxidation, we also suggest that the EBG approach should be incorporated into Land Surface Models (LSMs) so that the projections of both CH₄ emission and its transport 580 processes are more realistic in response to climate change scenarios. Future studies should also include anaerobic CH₄ oxidation into LSMs and constrain its parameters to better predict wetland CH₄ emissions.

Data availability. All data sets from this study are publicly available at project websites. Relevant measurements were obtained from the SPRUCE webpage (<http://mnspruce.ornl.gov/>), the archival ftp site (585 <ftp://sprucedata.ornl.gov>), or from the USDA Forest Service.

Author contributions. SM and YQL designed the project. SM, JJ, YYH, and XJL carried out modeling study. RMW, JPC, CMI, AM, PJH and SB provided experimental data for model evaluations and parameter optimization. SM, LFJ and YQL prepared the manuscript. All authors contributed to analyzing and interpreting the modeling results, (590 and improving the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. Part of this research was carried out at the Jet Propulsion Laboratory, California Institute of (595 Technology, under a contract with the National Aeronautics and Space Administration. We thank Dr. Zhenggang Du's help with discussing the data-model fusion techniques.

Financial support. This work was primarily funded by subcontract 4000158404 from Oak Ridge National Laboratory to Northern Arizona University. Oak Ridge National Laboratory is managed by UT-Battelle, LLC, for (600 the U.S. Department of Energy under contract DE-AC05-00OR22725. The SPRUCE (Spruce and Peatland Responses Under Changing Environments) project is supported by the Biological and Environmental Research program in the U.S. Department of Energy's Office of Science.
