Abstract: Tropical mangrove forests are important carbon sinks, the soil being the main carbon reservoir. Understanding the variability and the key factors that control fluxes is critical to accounting for greenhouse gas (GHG) emissions, particularly in the current scenario of global climate change. This study is the first to quantify carbon dioxide (CO₂) and methane (CH₄) emissions using a dynamic chamber in a natural mangrove soil of the Amazon. The plots for the trace gases study were allocated at contrasting topographic heights. The results showed that the mangrove soil of the Amazon estuary is a source of CO₂ (6.66 g CO₂ m⁻² d⁻¹) and CH₄ (0.13 g CH₄ m⁻² d⁻¹) to the atmosphere. The CO₂ flux was higher in the high topography (7.86 g CO₂ m⁻² d⁻¹) than in the low topography (4.73 g CO₂ m⁻² d⁻¹) in the rainy season, and CH₄ was higher in the low topography (0.13 g CH₄ m⁻² d⁻¹) than in the high topography (0.01 g CH₄ m⁻² d⁻¹) in the dry season. However, in the dry period, the low topography soil produced more CH₄. Soil organic matter, carbon and nitrogen ratio (C/N), and redox potential influenced the annual and seasonal variation of CO₂ emissions; however, they did not affect CH₄ fluxes. The mangrove soil of the Amazon estuary produced 35.40 Mg CO₂-eq ha⁻¹ y⁻¹. A total of 2.16 kg CO₂ m⁻² y⁻¹ needs to be sequestered by the mangrove ecosystem to counterbalance CH₄ emissions.

1 Introduction

Mangrove areas are estimated to be the main contributors to greenhouse gas emissions in marine ecosystems (Allen et al., 2011; Chen et al., 2012). However, mangrove forests are highly productive due to a high nutrient turnover rate (Robertson et al., 1992) and have mechanisms that maximize carbon gain and minimize water loss through plant transpiration (Alongi and Mukhopadhyay, 2015). A study conducted in 25 mangrove forests (between 30° latitude and 73° longitude) revealed that these forests are the

35 richest in carbon (C) storage in the tropics, containing on average 1,023 Mg C ha⁻¹ of
36 which 49 to 98% is present in the soil (Donato et al., 2011).

37 The estimated soil CO₂ flux in tropical estuarine areas is 16.2 Tg C y⁻¹ (Alongi, 2009).
38 However, soil efflux measurements from tropical mangroves revealed emissions
39 ranging from 2.9 to 11.0 g CO₂ m⁻² d⁻¹ (Castillo et al., 2017; Chen et al., 2014; Shiau
40 and Chiu, 2020). In situ CO₂ production is related to the water input of terrestrial,
41 riparian, and groundwater brought by rainfall (Rosentreter et al., 2018b). Due to the
42 periodic tidal movement, the mangrove ecosystem is daily flooded, leaving the soil
43 anoxic and consequently reduced, favoring methanogenesis (Dutta et al., 2013). Thus,
44 estuaries are considered hotspots for CH₄ production and emission (Bastviken et al.,
45 2011; Borges et al., 2015). Organic material decomposition by methanogenic bacteria in
46 anoxic environments, such as sediments, inner suspended particles, zooplankton gut
47 (Reeburgh, 2007; Valentine, 2011), and the impact of freshwater should change the
48 electron flow from sulfate-reducing bacteria to methanogenesis (Purvaja et al., 2004),
49 which also results in CH₄ formation. On the other hand, high salinity levels, above 18
50 ppt, may result in an absence of CH₄ emissions (Poffenbarger et al., 2011), since CH₄
51 dissolved in pores is typically oxidized anaerobically by sulfate (Chuang et al., 2016).
52 Currently the uncertainty in emitted CH₄ values in vegetated coastal wetlands is
53 approximately 30% (EPA, 2017). Soil flux measurements from tropical mangroves
54 revealed emissions range from 0.3 to 4.4 mg CH₄ m⁻² d⁻¹ (Castillo et al., 2017; Chen et
55 al., 2014; Kreuzwieser et al., 2003).

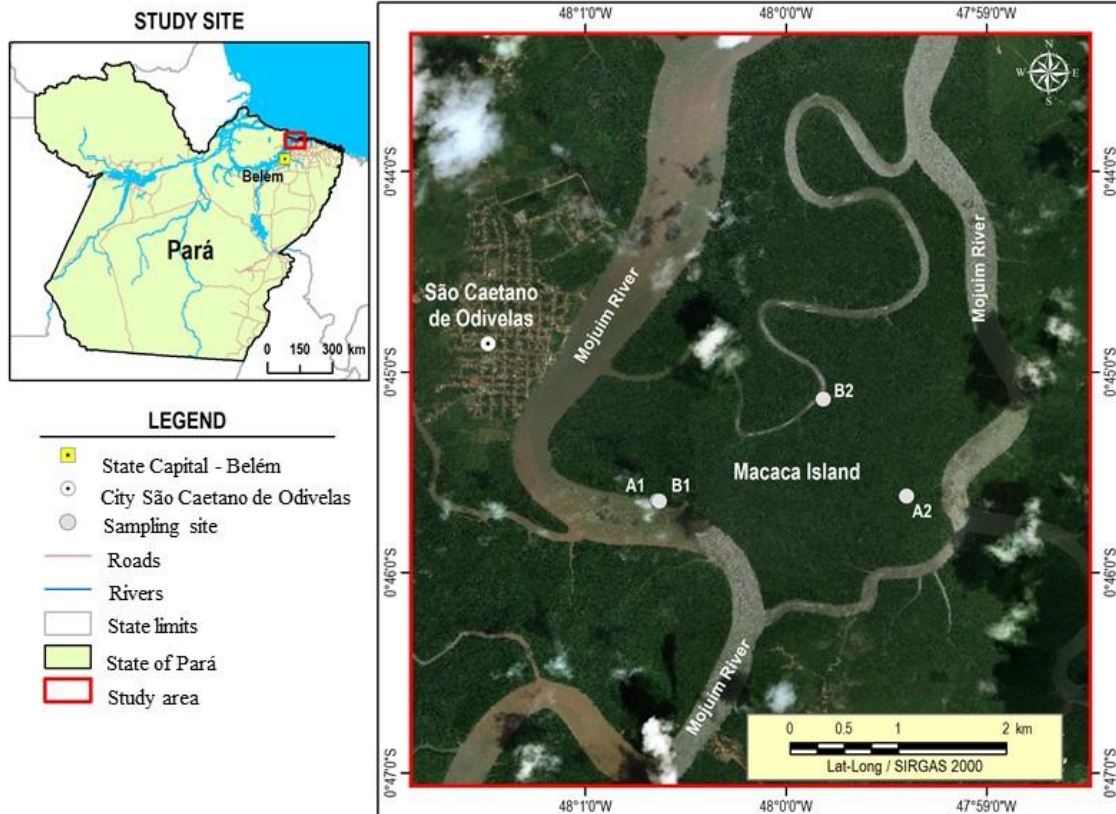

56 The production of greenhouse gases from soils is mainly driven by biogeochemical
57 processes. Microbial activities and gas production are related to soil properties,
58 including total carbon and nitrogen concentrations, moisture, porosity, salinity, and
59 redox potential (Bouillon et al., 2008; Chen et al., 2012). Due to the dynamics of tidal
60 movements, mangrove soils may become saturated and present reduced oxygen
61 availability, or suffer total aeration caused by the ebb tide. Studies attribute soil carbon
62 flux responses to moisture perturbations because of seasonality and flooding events
63 (Banerjee et al., 2016), with fluxes being dependent on tidal extremes (high tide and low
64 tide), and flood duration (Chowdhury et al., 2018). In addition, phenolic compounds
65 inhibit microbial activity and help keep organic carbon intact, thus leading to the
66 accumulation of organic matter in mangrove forest soils (Friesen et al., 2018).

67 The Amazonian coastal areas in the State of Pará (Brazil) cover 2,176.8 km² where
68 mangroves develop under the macro-tide regime (Souza Filho, 2005), representing
69 approximately 85% of the entire area of Brazilian mangroves (Herz, 1991). The
70 objective of this study is to investigate the monthly flux of CO₂ and CH₄ from the soil,
71 at two topographic heights, in a pristine mangrove area in the Mojuim River Estuary,
72 belonging to the Amazon biome. The gas fluxes were studied together with the analysis
73 of the vegetation structure and soil physical-chemical parameters.

74 **2 Material and Methods**

75 **2.1 Study site**

76 This study was conducted in the Amazonian coastal zone, Macaca Island (-0.746491
77 latitude and -47.997219 longitude), located in the Mojuim River estuary, at the
78 Mocapajuba Marine Extractive Reserve, municipality of São Caetano de Odivelas
79 (Figure 1), state of Pará (Brazil). The Macaca island has an area of 1,322 ha of pristine
80 mangroves, and belongs to a mangrove area of 2,177 km² in the state of Pará (Souza
81 Filho, 2005). The climate is type Am (tropical monsoon) according to the Köppen
82 classification (Peel et al., 2007). The climatological data were obtained from the
83 Meteorological Database for Teaching and Research of the National Institute of
84 Meteorology (INMET). The area has a rainy season from January to June (2,296 mm of
85 precipitation) and a dry season from July to December (687 mm). March and April were
86 the rainiest months with 505 and 453 mm of precipitation, while October and November
87 were the driest (53 and 61 mm, respectively). The minimum temperatures occur in the
88 rainy period (26 °C) and the maximum in the dry period (29 °C). The Mojuim estuary
89 has a macrotidal regime, with an average amplitude of 4.9 m during spring tide and 3.2
90 m during low tide (Rollnic et al., 2018). During the wet season the Mojuim River has a
91 flow velocity of 1.8 m s⁻¹ at the ebb tide and 1.3 m s⁻¹ at the flood tide, whereas in the
92 dry season, the maximum currents reach 1.9 m s⁻¹ at the flood and 1.67 m s⁻¹ at the ebb
93 tide (Rocha, 2015). The annual mean salinity of the river water is 26.95 PSU (Valentim
94 et al., 2018).

95

96 Figure 1. The Macaca Island located in the mangrove coast of Northern Brazil,
 97 Municipality of São Caetano de Odivelas (state of Pará), with sampling points at low
 98 (plot B1 and plot B2) and high (plot A1 and plot A2) topographies. Image Source: ©
 99 Google Earth

100 The Mojuim River region is geomorphologically formed by partially submerged river
 101 basins consequent of the increase in the relative sea level during the Holocene (Prost et
 102 al., 2001) associated with the formation of mangroves, dunes, and beaches (El-Robrini
 103 et al., 2006). Before reaching the estuary, the Mojuim River crosses an area of a dryland
 104 forest highly fragmented by family farming, forming remnants of secondary forest (<
 105 5.0 ha) of various ages (Fernandes and Pimentel, 2019). The population economically
 106 exploited the estuary, primarily by artisanal fishing, crab (*Ucides cordatus* L.)
 107 extraction, and oyster farms.

108 The flora of the mangrove area of Macaca Island is little anthropized and comprises the
 109 plant genera *Rhizophora*, *Avicenia*, *Laguncularia*, and *Acrostichum* (Ferreira, 2017;
 110 França et al., 2016). The estuarine plains are influenced by macrotide dynamics and can
 111 be physiographically divided into four sectors according to the different vegetation
 112 covers, associated with the landforms distribution, topographic gradient, tidal

113 inundation, and levels of anthropic transformation (França et al., 2016). The Macaca
114 Island is ranked as being from the fourth sector, which implies having woods of adult
115 trees of the genus *Ryzophora* with an average height of 10 to 25 m, is located at an
116 elevation of 0 to 5 m, and having silt-clay soil (França et al., 2016).

117 Four sampling plots were selected in the Macaca Island (Figure 1) on 19/05/2017, when
118 the moon was in the waning quarter phase: two plots where flooding occurs every day
119 (plots B1 and B2; Figure 1), called low topography (Top_Low), and two plots where
120 flooding occurs only at high tides during the solstice and on the high tides of the rainy
121 season of the new and full moons (plots A1 and A2; Figure 1), called high topography
122 (Top_High).

123 **2.2 Greenhouse gas flux measurements**

124 In each plot, eight Polyvinyl Chloride rings with 0.20 m diameter and 0.12 m height
125 were randomly installed within a circumference with a diameter of 20 m. The rings had
126 an area of 0.028 m² (volume of 3.47 L), were fixed 0.05 m into the ground, and
127 remained in place until the study was completed. Once a month, gas fluxes were
128 measured during periods of waning or crescent moon, as these are the times when the
129 soil in the low topography is more exposed. To avoid the influence of mangrove roots
130 on the gas fluxes, the rings were placed in locations without any seedlings or
131 aboveground mangrove roots. The CO₂ and CH₄ concentrations (ppm) were measured
132 using the dynamic chamber methodology (Norman et al., 1997; Verchot et al., 2000),
133 sequentially connected to a Los Gatos Research portable gas analyzer (Mahesh et al.,
134 2015). The device was calibrated monthly with a high quality standard gas (500 ppm
135 CO₂; 5 ppm CH₄). The rings were sequentially closed for three minutes with a PVC cap,
136 being connected to the analyzer through two 12.0 m polyethylene hoses. The gas
137 concentration was measured every two seconds and automatically stored by the
138 analyzer. CO₂ and CH₄ fluxes were calculated from the linear regression of
139 increasing/decreasing CO₂ and CH₄ concentrations within the chamber, usually between
140 one and three minutes after the ring cover was placed (Frankignoulle, 1988; McEwing
141 et al., 2015). The flux is considered zero when the linear regression reaches an R² <
142 0.30 (Sundqvist et al., 2014). However, in our analyses, most regressions reached R² >
143 0.70, and the regressions were weak and considered zero in only 6% of the samples. At
144 the end of each flux measurement, the height of the ring above ground was measured at

145 four equidistant points with a ruler. The seasonal data were analyzed by comparing the
146 average monthly fluxes in the wet season and dry season separately.

147 **2.3 Vegetation structure and biomass**

148 The floristic survey was conducted in October 2017 using circular 1,256.6 m² plots
149 (Kauffman et al., 2013) divided into four 314.15 m² subplots, which is the equivalent to
150 0.38 ha, at the same topographies as the gas flux analysis (Figure 1). We recorded the
151 diameter above the aerial roots, the diameter of the stem, and total height of all trees
152 with DBH (diameter at breast height; m) greater than 0.05m. The allometric equations
153 (Howard et al., 2014) to calculate tree biomass (aboveground biomass; AGB) were:
154 $AGB = 0.1282 * DBH^{2.6}$ ($R^2 = 0.92$) for *R. mangle*; $AGB = 0.140 * DBH^{2.4}$ ($R^2 = 0.97$)
155 for *A. germinans*; and Total AGB = $0.168 * \rho * DBH^{2.47}$ ($R^2 = 0.99$), where $\rho_{R. mangle} =$
156 0.87 ; $\rho_{A. germinans} = 0.72$ ($\rho =$ wood density).

157 **2.4 Soil sampling and environmental characterization**

158 Four soil samples were collected with an auger at a depth of 0.10 m in all the studied
159 plots for gas flux measurements (Figure 1) in July 2017 (beginning of the dry season)
160 and January 2018 (beginning of the rainy season). Before the soil samples were
161 removed, pH and redox potential (Eh; mV) were measured with a Metrohm 744
162 equipment by inserting the platinum probe directly into the intact soil at a depth of 0.10
163 m (Bauza et al., 2002). The soil samples collected in the field were transported to the
164 laboratory (Chemical Analysis Laboratory of the *Museu Paraense Emílio Goeldi*) in
165 thermal boxes containing ice. The soil samples were analyzed on the day after collection
166 at the laboratory, and the samples were kept in a freezer. Salinity (Sal; ppt) was
167 measured with PCE-0100, and soil moisture (Sm; %) by the residual gravimetric
168 method (EMBRAPA, 1997).

169 Organic Matter (OM; g kg⁻¹), Total Carbon (T_C; g kg⁻¹) and Total Nitrogen (T_N; g kg⁻¹)
170 were calculated by volumetry (oxidoreduction) using the Walkley-Black method
171 (Kalembasa and Jenkinson, 1973). Microbial carbon (C_{mic}; mg kg⁻¹) and microbial
172 nitrogen (N_{mic}; mg kg⁻¹) were determined through the 2.0 min of Irradiation-extraction
173 method of soil by microwave technique (Islam and Weil, 1998). Microwave heated soil
174 extraction proved to be a simple, fast, accurate, reliable, and safe method to measure
175 soil microbial biomass (Araujo, 2010; Ferreira et al., 1999; Monz et al., 1991). The C_{mic}
176 was determined by dichromate oxidation (Kalembasa and Jenkinson, 1973; Vance et al.,

177 1987). The N_{mic} was analyzed following the method described by Brookes et al. (1985),
178 changing fumigation to irradiation, which uses the difference between the amount of T_N
179 in irradiated and non-irradiated soil. We used the flux conversion factor of 0.33
180 (Sparling and West, 1988) and 0.54 (Almeida et al., 2019; Brookes et al., 1985), for
181 carbon and nitrogen, respectively. Particle size analysis was performed separately on
182 four soil samples collected at each flux plot, in the two seasons (October 2017 and
183 March 2018), according to EMBRAPA (1997).

184 At each gas flux measurement, environmental variables such as air temperature (T_{air} ,
185 °C), relative humidity (RH, %), and wind speed (W_s , $m\ s^{-1}$) were quantified with a
186 portable thermo-hygrometer (model AK821) at the height of 2.0 m above the soil
187 surface. Soil temperature (T_s , °C) was measured with a portable digital thermometer
188 (model TP101) after each gas flux measurement. Daily precipitation was obtained from
189 an automatic precipitation station installed at a pier on the banks of the Mojuim River in
190 São Caetano das Odivelas (coordinates: -0.738333 latitude; -48.013056 longitude).

191 **2.5 Statistical analyses**

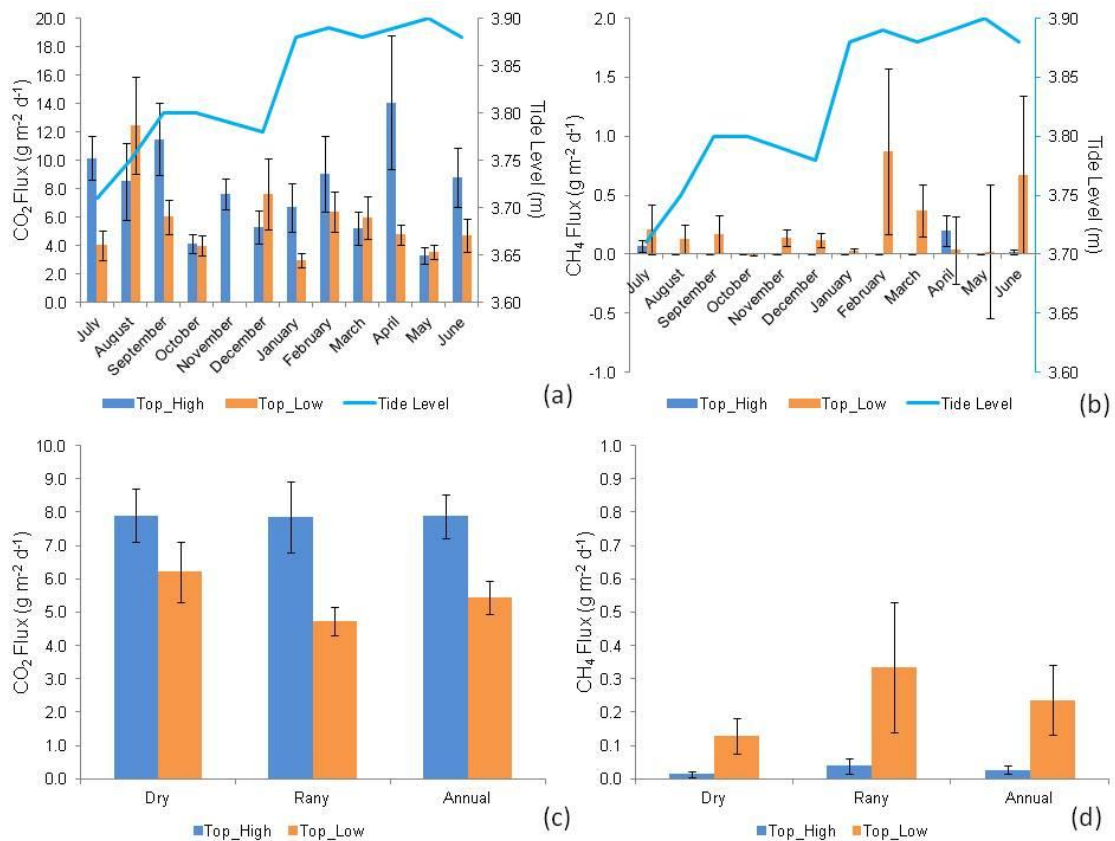

192 On the Macaca Island, two treatments were allocated (low and high topography), with
193 two plots in either treatment. In each plot, eight chambers were randomly distributed,
194 which were considered sample repetitions. The normality of the data of CH_4 and FCO_2
195 flux, and soil physicochemical parameters was evaluated using the Shapiro-Wilks
196 method. The soil CO_2 and CH_4 flux showed a non-normal distribution. Therefore, we
197 used the non-parametric ANOVA (Kruskal-Wallis, $p < 0.05$) to test the differences
198 between the two treatments among months and seasons. The physicochemical
199 parameters were normally distributed. Therefore, a parametric ANOVA was used to test
200 the statistical differences ($p < 0.05$) between the two treatments among months and
201 seasons. Pearson correlation coefficients were calculated to determine the relationships
202 between soil properties and gas fluxes in the months (dry and wet season) when the
203 chemical properties of the soil were analyzed at the same time as gas fluxes were
204 measured. Statistical analyses were performed with the free statistical software Infostat
205 2015®.

206 **3 Results**

207 **3.1 Carbon dioxide and methane fluxes**

208 CO₂ fluxes differed significantly between topographies only in January (H = 3.915; p =
 209 0.048), July (H = 9.091; p = 0.003), and November (H = 11.294; p < 0.001) (Figure 2;
 210 Supplementary Information, SI 1), with generally higher fluxes at the high topography
 211 than at the low topography. At the high topography, CO₂ fluxes were significantly
 212 higher (H = 24.510; p = 0.011) in July compared to August and December, March,
 213 October, and May, not differing from the other months of the year. Similarly, at the low
 214 topography, CO₂ fluxes were statistically higher (H = 19.912; p = 0.046) in September
 215 and February than in January and November, not differing from the other months. We
 216 found a mean monthly flux of 7.9 ± 0.7 g CO₂ m⁻² d⁻¹ (mean ± standard error) and 5.4 ±
 217 0.5 g CO₂ m⁻² d⁻¹ at the high and low topographies, respectively.

218

219

220 Figure 2. CO₂ (a) and CH₄ (b) fluxes (g CO₂ or CH₄ m⁻² d⁻¹) monthly (July 2018 to June
 221 2019) (n = 16). Seasonal (Dry and Rany) and annual fluxes of CO₂ (c) and CH₄ (d), at

222 high (Top_High) and low (Top_Low) topographies (n = 96), in a mangrove forest soil
223 compared to tide level (Tide Level). The bars represent the standard error of the mean.

224 The CH₄ fluxes were statistically different between topographies only in November (H
225 = 9.276; p = 0.002) and December (H = 4.945; p = 0.005), with higher fluxes at the low
226 topography (Figure 2; SI 1). At the high topography, CH₄ fluxes were significantly (H =
227 40.073; p < 0.001) higher in April and July compared to the other months studied, and
228 in November CH₄ was consumed from the atmosphere (Figure 2; SI 1). Similarly, CH₄
229 fluxes at the low topography did not vary significantly among months (H = 10.114; p =
230 0.407).

231 Greenhouse gas fluxes (Figure 2) were only significantly different between
232 topographies in the dry season (Figure 3), period when CO₂ fluxes were higher (H =
233 7.378; p = 0.006) at the high topography and CH₄ fluxes at the low topography (H =
234 8.229; p < 0.001). In the Macaca Island, the mean annual fluxes of CO₂ and CH₄ were
235 6.659 ± 0.419 g CO₂ m⁻² d⁻¹ and 0.132 ± 0.053 g CH₄ m⁻² d⁻¹, respectively. During the
236 study year, the CO₂ flux from the mangrove soil ranged from -5.06 to 68.96 g CO₂ m⁻²
237 d⁻¹ (mean 6.66 g CO₂ m⁻² d⁻¹), while the CH₄ flux ranged from -5.07 to 11.08 g CH₄ m⁻²
238 d⁻¹ (mean 0.13 g CH₄ m⁻² d⁻¹), resulting in a total carbon rate of 1.92 g C m⁻² d⁻¹ or 7.00
239 Mg C ha⁻¹ y⁻¹ (Figure 2).

240 **3.2 Weather data**

241 There was a marked seasonality during the study period (Figure 2), with 2,155.0 mm of
242 precipitation during the rainy period and 1,016.5 mm during the dry period. The highest
243 tides occurred in the period of greater precipitation (Figure 3) due to the rains. However,
244 the rainfall distribution was different from the climatological normal (Figure 3). The
245 precipitation in the rainy season was 553.2 mm below and in the dry season was 589.1
246 mm above the climatological normal. Thus, in the period studied, the dry season was
247 rainier and the rainy season drier than the climatological normal, which may be a
248 consequence of the La Niña event (Wang et al., 2019).

249

250

251 Figure 3. Monthly climatological normal in the municipality of Soure (1981-2010, mm),
 252 monthly precipitation (mm), and maximum tide height (m) from 2017 to 2018, in the
 253 municipality of São Caetano de Odivelas (PA).

254 T_{air} was significantly higher (LSD = 0.72, $p = 0.01$) at the high (31.24 ± 0.26 °C) than at
 255 the low topography (30.30 ± 0.25 °C) only in the rainy season (Figure 4a). No
 256 significant variation in T_s was found between topographies in either season (Figure 4b).
 257 RH was significantly higher (LSD = 2.55, $p = 0.01$) at the high topography ($70.54 \pm$
 258 0.97%) than at the low topography ($66.85 \pm 0.87\%$) only in the rainy season (Figure 4c).
 259 W_s (Figure 4d) was significantly higher (LSD = 0.15, $p < 0.00$) at the low (0.54 ± 0.06
 260 $m s^{-1}$) than at the high topography ($0.24 \pm 0.04 m s^{-1}$) also in the rainy season.

261

262 Figure 4. a) Air temperature (°C), b) soil temperature (°C), c) relative humidity (%), and
 263 d) wind speed (m s⁻¹) at high and low topographies, from July 2017 to June 2018 in a
 264 mangrove area in the Mojuim River estuary. Bars highlighted in grey correspond to the
 265 rainy season (n = 16). The bars represent the standard error.

266 3.3 Soil characteristics

267 Silt concentration was higher at the low topography (LSD: 14.763; p= 0.007) and clay
 268 concentration was higher at the high topography plots (LSD: 12.463; p= 0.005), in both
 269 seasons studied (Table 1). Soil particle size analysis did not differ statistically (p > 0.05)
 270 between the two seasons (Table 1). Soil moisture did not vary significantly (p > 0.05)
 271 between topographies at each season, or between seasonal periods at the same
 272 topography (Table 1). The pH varied statistically (LSD: 5.950; p= 0.006) only at the
 273 low topography when the two seasons were compared, being more acidic in the dry
 274 period (Table 1). The pH values were significantly (LSD: 0.559; p= 0.008) higher in the
 275 dry season (Table 1). No variation in Eh was identified between topographies and
 276 seasons (Table 1), although it was higher in the dry season than in the rainy season.
 277 However, Sal values were higher (LSD: 3.444; p = 0.010) at the high topography than at
 278 the low topography in the dry season (Table 1). In addition, Sal was significantly higher

279 in the dry season than in the rainy season, in both high (LSD: 2.916; $p < 0.001$) and low
280 (LSD: 3.003; $p < 0.001$) topographies (Table 1).

281 Table 1. Analysis of Sand (%), Silt (%), Clay (%), Moisture (%), pH, Redox Potential (Eh, mV) and salinity (Sal; ppt) in the mangrove soil of
 282 high and low topographies, and in the rainy and dry seasons (Macaca island, São Caetano das Odivelas). Numbers represent the mean \pm standard
 283 error of the mean. Lower case letters compare topographies in each seasonal period and upper-case letters compare the same topography between
 284 seasonal periods. Different letters indicate statistical difference (LSD, $p < 0.05$).

Season	Topography	Sand (%)	Silt (%)	Clay (%)	Moisture (%)	pH	Eh (mV)	Sal (ppt)
Dry	High	12.1 \pm 1.4 ^{aA}	41.8 \pm 3.3 ^{bA}	46.1 \pm 2.6 ^{aA}	73.1 \pm 6.6 ^{aA}	5.5 \pm 0.2 ^{aA}	190.25 \pm 45.53 ^{aA}	35.25 \pm 1.11 ^{aA}
	Low	9.7 \pm 2.5 ^{aA}	63.6 \pm 6.1 ^{aA}	26.6 \pm 5.2 ^{bA}	86.9 \pm 3.4 ^{aA}	5.3 \pm 0.3 ^{aA}	106.38 \pm 53.76 ^{aA}	30.13 \pm 1.16 ^{bA}
	Mean	10.9 \pm 1.4 ^A	52.7 \pm 4.4 ^A	36.4 \pm 3.8 ^A	80.0 \pm 4.0 ^A	5.4 \pm 0.2 ^A	148.31 \pm 35.71 ^A	32.69 \pm 1.02 ^A
Rainy	High	12.1 \pm 1.4 ^{aA}	41.8 \pm 3.3 ^{bA}	46.1 \pm 2.6 ^{aA}	88.9 \pm 3.5 ^{aA}	4.9 \pm 0.4 ^{aA}	92.50 \pm 56.20 ^{aA}	7.50 \pm 0.78 ^{aB}
	Low	9.7 \pm 2.5 ^{aA}	63.6 \pm 6.1 ^{aA}	26.6 \pm 5.2 ^{bA}	88.6 \pm 3.7 ^{aA}	4.4 \pm 0.1 ^{aB}	36.25 \pm 49.97 ^{aA}	8.13 \pm 0.79 ^{aB}
	Mean	10.9 \pm 1.4 ^A	52.7 \pm 4.4 ^A	36.4 \pm 3.8 ^A	88.7 \pm 2.5 ^A	4.6 \pm 0.2 ^B	64.38 \pm 37.04 ^A	7.81 \pm 0.54 ^B

285

286 The C_{mic} did not differ between topographies in the two seasons (Table 2). However, T_C
287 was significantly higher in the low topography in the dry season (LSD: 5.589; $p <$
288 0.000) and in the rainy season (LSD: 5.777; $p = 0.024$). In addition, C_{mic} was higher in
289 the dry season in both the high (LSD: 11.325; $p < 0.010$) and low (LSD: 9.345; $p <$
290 0.000) topographies (Table 2). N_{mic} did not vary between topographies seasonally.
291 However, N_{mic} in the high (LSD: 9.059; $p = 0.013$) and low topographies (LSD: 4.447;
292 $p = 0.001$) was higher during the dry season (Table 2). The C/N ratio (Table 2) was
293 higher in the low than in the high topography in both the dry (LSD: 3.142; $p < 0.000$)
294 and rainy seasons (LSD: 3.675; $p = 0.033$). However, only in the low topography was
295 the C/N ratio higher (LSD: 1.863; $p < 0.000$) in the dry season than in the rainy season
296 (Table 2). Soil OM was higher at the low topography in the rainy (LSD: 9.950; $p =$
297 0.024) and in the dry seasons (LSD: 9.630; $p < 0.000$). Only in the lowland topography
298 was the OM concentration higher in the dry season than in the rainy season (Table 2).

299 Table 2. Seasonal and topographic variation in microbial Carbon (C_{mic} ; $mg\ kg^{-1}$), microbial Nitrogen (N_{mic} , $mg\ kg^{-1}$), Total Carbon (T_C ; $g\ kg^{-1}$),
 300 Total Nitrogen (N_T ; $g\ kg^{-1}$), Carbon/Nitrogen ratio (C/N) and Soil Organic Matter (OM; $g\ kg^{-1}$). Numbers represent the mean (\pm standard error).
 301 Lower case letters compare topographies at each season, and upper-case letters compare the topography between seasons.

Season	Topography	C_{mic} $mg\ kg^{-1}$	N_{mic} $mg\ kg^{-1}$	T_C $g\ kg^{-1}$	T_N $g\ kg^{-1}$	C/N	OM $g\ kg^{-1}$
Dry	High	22.12 \pm 5.22 ^{aA}	12.76 \pm 4.20 ^{aA}	14.12 \pm 2.23 ^{bA}	1.43 \pm 0.06 ^{aA}	9.60 \pm 1.20 ^{bA}	24.35 \pm 3.84 ^{bA}
	Low	26.34 \pm 4.23 ^{aA}	10.34 \pm 2.05 ^{aA}	26.44 \pm 1.35 ^{aA}	1.56 \pm 0.04 ^{aA}	16.98 \pm 0.84 ^{aA}	45.59 \pm 2.32 ^{aA}
	Mean	24.23 \pm 3.29 ^A	11.55 \pm 2.28 ^A	20.28 \pm 2.03 ^A	1.49 \pm 0.04 ^A	13.29 \pm 1.19 ^A	34.97 \pm 3.50 ^A
Rainy	High	7.40 \pm 0.79 ^{aB}	0.75 \pm 0.41 ^{aB}	11.46 \pm 2.48 ^{bA}	1.32 \pm 0.04 ^{aA}	8.42 \pm 1.70 ^{bA}	19.75 \pm 4.27 ^{bA}
	Low	5.95 \pm 1.06 ^{aB}	1.23 \pm 0.28 ^{aB}	18.27 \pm 1.06 ^{aB}	1.46 \pm 0.06 ^{aA}	12.47 \pm 0.22 ^{aB}	31.51 \pm 1.83 ^{aB}

302

303 **3.4 Vegetation structure and biomass**

304 Only the species *R. mangle* and *A. germinans* were found in the floristic survey carried
305 out. The DBH did not vary significantly between the topographies for either species
306 (Table 3). However, *R. mangle* had a higher DBH than *A. germinaris* at both high
307 (LSD: 139.304; $p = 0.037$) and low topographies (LSD: 131.307; $p = 0.001$). The basal
308 area (BA) and AGB did not show significant variation (Table 3). A total aboveground
309 biomass of $322.1 \pm 49.6 \text{ Mg ha}^{-1}$ was estimated.

310

311 Table 3: Summed Diameter at Breast Height (DBH; cm), Basal Area (BA; m² ha⁻¹) and Aboveground Biomass (AGB; Mg ha⁻¹) at high and low
 312 topographies in the mangrove forest of the Mojuim River estuary. Numbers represent the mean ± standard error of the mean. Lower case letters
 313 compare topographic height for each species, and upper-case letters compare species at each topographic height, using Tukey's test (p < 0.05).

Specie	Topography	N ha ⁻¹	DBH (cm)	BA (m ² ha ⁻¹)	AGB (Mg ha ⁻¹)
<i>Rhizophora mangle</i>	High	302.4±20.5	238.8±24.9 ^{aA}	17.3±2.0 ^{aA}	219.3±25.7 ^{aA}
	Low	310.4±37.6	283.5±45.0 ^{aA}	24.2±4.3 ^{aA}	338.7±62.9 ^{aA}
<i>Avicennia germinans</i>	High	47.7±20.5	86.8±51.2 ^{aB}	13.8±9.2 ^{aA}	135.3±94.7 ^{aA}
	Low	15.9±9.2	46.1±29.3 ^{aB}	11.8±8.8 ^{aA}	136.0±108.3 ^{aA}
Total	High	350.2±18.4	325.6±33.6 ^a	31.1±7.5 ^a	304.5±99.8 ^a
	Low	346.2±41.0	296.0±23.7 ^a	30.0±4.1 ^a	330.8±60.4 ^a

314 The equations for biomass estimates (AGB) were: *R. mangle* = 0.1282*DBH^{2.6}; *A. germinans* = 0.14*DBH^{2.4}; and Total = 0.168*ρ*DBH^{2.47}, where ρ_{*R. mangle*} = 0.87; ρ_{*A. germinans*}
 315 = 0.72 (Howard et al., 2014).

316

317 **3.5 Drivers of greenhouse gas fluxes**

318 In the rainy season, CO₂ efflux was correlated with T_{air} (Pearson = 0.23, p = 0.03), RH
319 (Pearson = -0.32, p < 0.00) and T_s (Pearson = 0.21, p = 0.04) only at the low
320 topography. In the dry season CO₂ flux was correlated with T_s (Pearson = 0.39, p <
321 0.00) at the low topography. The dry season was the period in which we found the
322 greatest amount of significant correlations between CO₂ efflux and soil chemical
323 parameters, while the C:N ratio, OM, and Eh were correlated with CO₂ efflux in both
324 seasons (Table 4). The negative correlation between T_C, N_T, C/N, and OM, along with
325 the positive correlation of N_{mic} with soil CO₂ flux, in the dry period, indicates that
326 microbial activity is a decisive factor for CO₂ efflux (Table 4). Soil moisture in the
327 Mojuim River mangrove forest negatively influenced CO₂ flux in both seasons (Table
328 4). However, soil moisture was not correlated with CH₄ flux. No significant correlations
329 were found between CH₄ efflux and the chemical properties of the soil in the mangrove
330 of the Mojuim River estuary (Table 4).

331

332 Table 4. Correlation coefficient (Pearson) of CO₂ and CH₄ fluxes with chemical parameters of the soil in a mangrove area in the Mojuim River
 333 estuary.

337

338 4 Discussion

339 4.1 Carbon dioxide and methane flux

340 It is important to consider that the year under study was rainier in the dry season (2017)
341 and less rainy in the wet season (2018) when the climatological average is concerned
342 (1981-2010) (Figure 3). Perhaps this variation is related to the effects of global climate
343 changes. Under these conditions, negative and positive fluxes of the two greenhouse
344 gases were found (negative values represent gas consumption). The negative CO₂ flux is
345 apparently a consequence of the increased CO₂ solubility in tidal waters or of the
346 increased sulfate reduction, as described in the literature (Borges et al., 2018;
347 Chowdhury et al., 2018; Nóbrega et al., 2016). Fluctuations in redox potential altered
348 the availability of the terminal electron acceptor and donor, and the forces of recovery
349 of their concentrations in the soil, such that a disproportionate release of CO₂ can result
350 from the alternative anaerobic degradation processes such as sulfate and iron reduction
351 (Chowdhury et al., 2018). The soil carbon flux in the mangrove area in the Amazon
352 region was within the range of findings for other tropical mangrove areas (2.6 to 11.0 g
353 CO₂ m⁻² d⁻¹; Shiau and Chiu, 2020). However, the mean flux of 6.2 mmol CO₂ m⁻² h⁻¹
354 recorded in this Amazonian mangrove was much higher than the mean efflux of 2.9
355 mmol CO₂ m⁻² h⁻¹ recorded in 75 mangroves during low tide periods (Alongi, 2009).

356 An emission of 0.01 Tg CH₄ y⁻¹, 0.6 g CH₄ m⁻² d⁻¹ (Rosentreter et al., 2018a), or 26.7
357 mg CH₄ m⁻² h⁻¹ has been reported for tropical latitudes (0 and 5°). In our study, the
358 monthly average of CH₄ flux was higher at the low (7.3 ± 8.0 mg CH₄ m⁻² h⁻¹) than at
359 the high topography (0.9 ± 0.6 mg C m⁻² h⁻¹), resulting in 0.1 g CH₄ m⁻² d⁻¹ or 0.5 Mg
360 CH₄ ha⁻¹ y⁻¹ (Figure 2). Therefore, the CH₄-C fluxes from the mangrove soil in the
361 Mojuim River estuary were much lower than expected. It is known that there is a
362 microbial functional module for CH₄ production and consumption (Xu et al., 2015) and
363 diffusibility of CH₄ (Sihi et al., 2018), and this module considers three key mechanisms:
364 acetoclastic methanogenesis (acetate production), hydrogenotrophic methanogenesis (H₂
365 and CO₂ production), and aerobic methanotrophy (CH₄ oxidation and O₂ reduction).
366 The average emission from the soil of 8.4 mmol CH₄ m⁻² d⁻¹ was well below the fluxes
367 recorded in the Bay of Bengal, with 18.4 mmol CH₄ m⁻² d⁻¹ (Biswas et al., 2007). In the
368 Amazonian mangrove studied the mean annual carbon equivalent efflux was 429.6 mg
369 CO_{2-eq} m⁻² h⁻¹. This value is insignificant compared to the projected erosion losses of
370 103.5 Tg CO_{2-eq} ha⁻¹ y⁻¹ for the next century in tropical mangrove forests (Adame et al.,

371 2021). These higher CO₂ flux concomitantly with lower CH₄ flux in this Amazonian
372 estuary are probably a consequence of changes in the rainfall pattern already underway,
373 where the dry season was wetter and the rainy season drier when compared to the
374 climatological normal. The most recent estimate between latitude 0° to 23.5° S shows
375 an emission of 2.3 g CO₂ m⁻² d⁻¹ (Rosentreter et al., 2018b). However, the efflux in the
376 mangrove of the Mojuim River estuary was 6.7 g CO₂ m⁻² d⁻¹. For the same latitudinal
377 range, Rosentreter et al. (2018c) estimated an emission of 0.6 g CH₄ m⁻² d⁻¹, and we
378 found an efflux of 0.1 g CH₄ m⁻² d⁻¹.

379 **4.2 Drivers of greenhouse gas fluxes**

380 Mangrove areas are periodically flooded, with a larger flood volume during the syzygy
381 tides, especially in the rainy season. The hydrological condition of the soil is determined
382 by the microtopography and can regulate the respiration of microorganisms (aerobic or
383 anaerobic), being a decisive factor in controlling the CO₂ efflux (Dai et al., 2012;
384 Davidson et al., 2000; Ehrenfeld, 1995). No significant influence on CO₂ flux was
385 observed due to the low variation in high tide level throughout the year (0.19 m) (Figure
386 2), although it was numerically higher at the high topography. However, tidal height
387 and the rainy season resulted in a higher CO₂ flux (rate high/low =1.7) at the high
388 topography (7.86 ± 0.04 g CO₂ m⁻² d⁻¹) than at the low topography (4.73 ± 0.34 g CO₂
389 m⁻² d⁻¹) (Figure 2; SI 1). This result may be due to the root systems of most flood-
390 tolerant plants remaining active when flooded (Angelov et al., 1996). Still, the high
391 topography has longer flood-free periods, which only happens when the tides are
392 syzygy or when the rains are torrential.

393 CO₂ efflux was higher in the high topography than in the low topography in the rainy
394 season (when soils are more subject to inundation), i.e., 39.8% lower in the forest soil
395 exposed to the atmosphere for less time. Measurements performed on 62 mangrove
396 forest soils showed an average flux of 2.87 mmol CO₂ m⁻² h⁻¹ when the soil was
397 exposed to the atmosphere, while 75 results on flooded mangrove forest soils showed an
398 average emission of 2.06 mmol CO₂ m⁻² h⁻¹ (Alongi, 2007, 2009), i.e., 28.2% less than
399 for the dry soil. This reflects the increased facility gases have for molecular diffusion
400 than fluids, and the increased surface area available for aerobic respiration and chemical
401 oxidation during air exposure (Chen et al., 2010). Some studies attribute this variation
402 to the temperature of the soil when it is exposed to tropical air (Alongi, 2009), which
403 increases the export of dissolved inorganic carbon (Maher et al., 2018). However,

404 although despite the lack of significant variation in soil temperature between
405 topographies at each time of year (Figure 4b), there was a positive correlation (Pearson
406 = 0.15, $p = 0.05$) between CO₂ efflux and soil temperature at the low topography.

407 Some studies show that CH₄ efflux is a consequence of the seasonal temperature
408 variation in mangrove forest under temperate/monsoon climates (Chauhan et al., 2015;
409 Purvaja and Ramesh, 2001; Whalen, 2005). However, in your study CH₄ efflux was
410 correlated with Ta (Pearson = -0.33, $p < 0.00$) and RH (Pearson = 0.28, $p = 0.01$) only
411 in the dry season and at the low topography. The results show that the physical
412 parameters do not affect the fluxes in a standardized way, and their greater or lesser
413 influence depends on the topography and seasonality.

414 A compilation of several studies showed that the total CH₄ emissions from the soil in a
415 mangrove ecosystem range from 0 to 23.68 mg C m⁻² h⁻¹ (Shiau and Chiu, 2020), and
416 our study showed a range of -0.01 to 31.88 mg C m⁻² h⁻¹ (mean of 4.70 ± 5.00 mg C m⁻²
417 h⁻¹). The monthly CH₄ fluxes were generally higher at the low (0.232 ± 0.256 g CH₄ m⁻²
418 d⁻¹) than at the high (0.026 ± 0.018 g CH₄ m⁻² d⁻¹) topography, especially during the
419 rainy season when the tides were higher (Figure 2). Only in the dry season was there a
420 significantly higher production at the low than at the high topography (Figure 2; SI 1).
421 The low topography produced 0.0249 g C m⁻² h⁻¹ more to the atmosphere in the rainy
422 season than in the dry season (Figure 2), and a similar seasonal pattern was recorded in
423 other studies (Cameron et al., 2021).

424 The mangrove soil in the Mojuim River estuary is rich in silt and clay (Table 1), which
425 reduces sediment porosity and fosters the formation and maintenance of anoxic
426 conditions (Dutta et al., 2013). In addition, the lack of oxygen in the flooded mangrove
427 soil favors microbial processes such as denitrification, sulfate reduction,
428 methanogenesis, and redox reactions (Alongi and Christoffersen, 1992). A significant
429 amount of CH₄ produced in wetlands is dissolved in the pore water due to high pressure,
430 causing supersaturation, which allows CH₄ to be released by diffusion from the
431 sediment to the atmosphere and by boiling through the formation of bubbles.

432 Studies show that the CO₂ flux tends to be lower with high soil saturation (Chanda et
433 al., 2014; Kristensen et al., 2008). A total of 395 Mg C ha⁻¹ was found at the soil surface
434 (0.15 m) in the mangrove of the Mojuim River estuary, which was slightly higher than
435 the 340 Mg C ha⁻¹ found in other mangroves in the Amazon (Kauffman et al., 2018),
436 however being significantly 1.8 times greater at the low topography (Table 2). The finer

437 soil texture at the low topography (Table 1) reduces groundwater drainage which
438 facilitates the accumulation of C in the soil (Schmidt et al., 2011).

439 **4.3 Mangrove biomass**

440 Only the species *R. mangle* and *A. germinans* were found in the floristic survey carried
441 out, which is aligned with the results of other studies in the same region (Menezes et al.,
442 2008). Thus, the variations found in the flux between the topographies in the Mojuim
443 River estuary are not related to the mangrove forest structure, because there was no
444 difference in the aboveground biomass. Since there was no difference in the species
445 composition, the belowground biomass is not expected to differ either (Table 3).

446 Assuming that the amount of carbon stored is 42.0% of the total biomass (Sahu and
447 Kathiresan, 2019), the mangrove forest biomass of the Mojuim River estuary stores
448 127.9 and 138.9 Mg C ha⁻¹ at the high and low topographies, respectively. This result is
449 lower than the 507.8 Mg C ha⁻¹ estimated for Brazilian mangroves (Hamilton and
450 Friess, 2018), but are near the 103.7 Mg C ha⁻¹ estimated for a mangrove at Guará's
451 island (Salum et al., 2020), 108.4 Mg C ha⁻¹ for the Bragantina region (Gardunho,
452 2017), and 132.3 Mg C ha⁻¹ in French Guiana (Fromard et al., 1998). Thus, the biomass
453 found in the Mojuim estuary does not differ from the biomass found in other
454 Amazonian mangroves. The estimated primary production for tropical mangrove forests
455 is 218 ± 72 Tg C y⁻¹ (Bouillon et al., 2008).

456 **4.4 Biogeochemical parameters**

457 During the seasonal and annual periods, CH₄ efflux was not significantly correlated
458 with chemical parameters (Table 5), which is similar to the observed in another study
459 (Chen et al., 2010). Flooded soils present reduced gas diffusion rates, which directly
460 affects the physiological state and activity of microbes, by limiting the supply of the
461 dominant electron acceptors (e.g., oxygen), and gases (e.g., CH₄) (Blagodatsky and
462 Smith, 2012). The importance of soil can be reflected in bacterial richness and diversity
463 compared to pore spaces filled with water (Banerjee et al., 2016). On the other hand,
464 increasing soil moisture provides the microorganisms with essential substrates such as
465 ammonium, nitrate, and soluble organic carbon, and increases gas diffusion rates in the
466 water (Blagodatsky and Smith, 2012). Biologically available nitrogen often limit marine
467 productivity (Bertics et al., 2010), and thus can affect CO₂ fluxes to the atmosphere.
468 However, a mangrove fertilization experiment showed that CH₄ emission rates were not

469 affected by N addition (Kreuzwieser et al., 2003). A higher concentration of C_{mic} and
470 N_{mic} in the dry period (Table 2), both in the high and low topographies, indicated that
471 microorganisms are more active when the soil spends more time aerated in the dry
472 period (Table 2), time when only the high tides produce anoxia in the mangrove soil
473 mainly in the low topography. Under reduced oxygen conditions, in a laboratory
474 incubated mangrove soil, the addition of nitrogen resulted in a significant increase in the
475 microbial metabolic quotient, showing no concomitant change in microbial respiration,
476 which was explained by a decrease in microbial biomass (Craig et al., 2021).

477 The high OM concentration at the two topographic locations (Table 2), at the two
478 seasons studied, and the respective negative correlation with CO_2 flux (Table 5) confirm
479 the importance of microbial activity in mangrove soils (Gao et al., 2020). Also, CH_4
480 produced in flooded soils can be converted mainly to CO_2 by the anaerobic oxidation of
481 CH_4 (Boetius et al., 2000; Milucka et al., 2015; Xu et al., 2015) which may contribute to
482 the higher CO_2 efflux in the Mojuim River estuary compared to other tropical
483 mangroves (Rosentreter et al., 2018b). The belowground C stock is considered the
484 largest C reservoir in a mangrove ecosystem, and it results from the low OM
485 decomposition rate due to flooding (Marchand, 2017).

486 The higher water salinity influenced by the tidal movement in the dry season (Table 1)
487 seems to result in a lower CH_4 flux at the low topography (Dutta et al., 2013; Lekphet et
488 al., 2005; Shiau and Chiu, 2020). High SO_4^{2-} concentration in the marine sediments
489 inhibits methane formation due to competition between SO_4^{2-} reduction and
490 methanogenic fermentation, as sulfate-reducing bacteria are more efficient at using
491 hydrogen than methanotrophic bacteria (Abram and Nedwell, 1978; Kristjansson et al.,
492 1982), a key factor fostering reduced CH_4 emissions. At high SO_4^{2-} concentrations
493 methanotrophic bacteria use CH_4 as an energy source and oxidize it to CO_2 (Coyne,
494 1999; Segarra et al., 2015), increasing the efflux of CO_2 and reduced CH_4 (Megonigal
495 and Schlesinger, 2002; Roslev and King, 1996). This may explain the high CO_2 and low
496 CH_4 efflux found throughout the year at the high and, especially, at the low
497 topographies (Figure 3).

498 Studies in coastal ecosystems in Taiwan have reported that methanotrophic bacteria can
499 be sensitive to soil pH, and reported an optimal growth at pH ranging from 6.5 to 7.5
500 (Shiau et al., 2018). The higher soil acidity in the Mojuim River wetland (Table 1) may
501 be inhibiting the activity of methanogenic bacteria by increasing the population of

502 methanotrophic bacteria, which are efficient in CH₄ consumption (Chen et al., 2010;
503 Hegde et al., 2003; Shiau and Chiu, 2020). In addition, the pneumatophores present in
504 *R. mangle* increase soil aeration and reduce CH₄ emissions (Allen et al., 2011; He et al.,
505 2019). Spatial differences (topography) in CH₄ emissions in the soil can be attributed to
506 substrate heterogeneity, salinity, and the abundance of methanogenic and
507 methanotrophic bacteria (Gao et al., 2020). Increases in CH₄ efflux with reduced
508 salinity were found as a consequence of intense oxidation or reduced competition from
509 the more energetically efficient SO₄²⁻ and NO₃⁻ reducing bacteria when compared to the
510 methanogenic bacteria (Biswas et al., 2007). This fact can be observed in the CH₄ efflux
511 in the mangrove of the Mojuim River, because there was an increased CH₄ production
512 especially in the low topography in the rainy season (Figure 3), when water salinity is
513 reduced (Table 1) due to the increased precipitation. However, we did not find a
514 correlation between CH₄ efflux and salinity, as previously reported (Purvaja and
515 Ramesh, 2001). More detailed studies on CH₄ efflux and on its relationship with
516 methanotrophic bacteria and abiotic factors (mainly ammonia and sulfate) are needed
517 due to the average flux of 4.70 mg C m⁻² h⁻¹ and the extreme monthly and seasonal
518 variations.

519 **5 Conclusions**

520 Seasonality was important for CH₄ efflux but did not influence CO₂ efflux. The
521 differences in fluxes may be an effect of global climate changes on the terrestrial
522 biogeochemistry at the plant-soil-atmosphere interface, as indicated by the deviation in
523 precipitation values from the climatology normal, making it necessary to extend this
524 study for more years. Using the factor of 23 to convert the global warming potential of
525 CH₄ to CO₂ (IPCC, 2001), the CO₂ equivalent emission was 35.4 Mg CO_{2-eq} ha⁻¹ yr⁻¹.
526 Over a 100-year time period, a radiative forcing due to the continuous emission of 0.05
527 kg CH₄ m⁻² y⁻¹ found in this study, would be offset if CO₂ sequestration rates were 2.16
528 kg CO₂ m⁻² y⁻¹ (Neubauer and Megonigal, 2015).

529 Microtopography should be considered when determining the efflux of CO₂ and CH₄ in
530 mangrove forests in an Amazon estuary. The low topography in the mangrove forest of
531 Mojuim River had a higher concentration of organic carbon in the soil. However, it did
532 not produce a higher CO₂ efflux because it was negatively influenced by soil moisture,
533 which was indifferent to CH₄ efflux. MO, C/N ratio, and Eh were critical in soil
534 microbial activity, which resulted in a variation in CO₂ flux during the year and

535 seasonal periods. Thus, the physicochemical properties of the soil are important for CO₂
536 flux, especially in the rainy season. Still, they did not influence CH₄ fluxes.

537 *Data availability:* The data used in this article belong to the doctoral thesis of Saul
538 Castellón, within the Postgraduate Program in Environmental Sciences, at the Federal
539 University of Pará. Access to the data can be requested from Dr. Castellón
540 (saularmarz22@gmail.com), which holds the set of all data used in this paper.

541 *Author contributions:* SEMC and JHC designed the study and wrote the article with the
542 help of JFB, MR, MLR, and CN. JFB assisted in the field experiment. MR provided
543 logistical support in field activities.

544 *Competing interests:* The authors declare that they have no conflict of interest

545 *Acknowledgements:* The authors are grateful to the Program of Alliances for Education
546 and Training of the Organization of the American States and to Coimbra Group of
547 Brazilian Universities, for the financial support, as well as to Paulo Sarmiento for the
548 assistance at laboratory analysis, and to Maridalva Ribeiro and Lucivaldo da Silva for
549 the fieldwork assistance. Furthermore, the authors would like to thank the Laboratory of
550 Biogeochemical Cycles (Geosciences Institute, Federal University of Pará) for the
551 equipment provided for this research.
