Abstract. Ocean Alkalinity Enhancement (OAE) has been proposed as a method to remove carbon dioxide (CO_2) from the atmosphere and to counteract ocean acidification. It involves the dissolution of alkaline minerals such as quick lime, CaO , and hydrated lime, $\text{Ca}(\text{OH})_2$. However, a critical knowledge gap exists regarding their dissolution in natural seawater. Particularly, how much can be dissolved before secondary precipitation of calcium carbonate (CaCO_3) occurs is yet to be established. Secondary precipitation should be avoided as it reduces the atmospheric CO_2 uptake potential of OAE. Here we show that both CaO and $\text{Ca}(\text{OH})_2$ powders ($>63 \mu\text{m}$ of diameter) dissolved in seawater within a few hours. However, CaCO_3 precipitation, in the form of aragonite, occurred at a saturation (Ω_{Ar}) threshold of about 5. This limit is much lower than what would be expected for typical pseudo-homogeneous precipitation in the presence of colloids and organic materials. Secondary precipitation at unexpectedly low Ω_{Ar} was the result of so-called heterogeneous precipitation onto mineral phases, most likely onto CaO and $\text{Ca}(\text{OH})_2$ prior to full dissolution. Most importantly, this led to runaway CaCO_3 precipitation by which significantly more alkalinity (TA) was removed than initially added, until Ω_{Ar} reached levels below 2. Such runaway precipitation would reduce the CO_2 uptake efficiency from about 0.8 moles of CO_2 per mole of TA down to only 0.1 mole of CO_2 per mole of TA. Runaway precipitation appears to be avoidable by dilution below the critical Ω_{Ar} threshold of 5, ideally within hours of the addition to minimise initial CaCO_3 precipitation. Finally, model considerations suggest that for the same Ω_{Ar} threshold, the amount of TA that can be added to seawater would be more than three times higher at 5 °C than at 30 °C, and that equilibration to atmospheric CO_2 levels during mineral dissolution would further increase it by a factor of ~6 and ~3 respectively.

1 Introduction

Climate change is currently considered one of the largest threats to humankind (Hoegh-Guldberg et al., 2019; The Royal Society and Royal Academy of Engineering, 2018; Ipcc, 2021). Global mean temperature have increased by 1.0 °C since pre-
30 industrial times, and could reach +1.2-1.9 °C in the next 20 years, and +2.1-5.7 °C by the end of this century (Ipcc, 2021). Furthermore, up to 30% of anthropogenic CO₂ emissions have been taken up by the ocean through air-sea gas exchange, leading to a decrease in the average open ocean pH of 0.1 units in a process termed ocean acidification – OA (Canadell et al., 2007; Carter et al., 2019; Hoegh-Guldberg et al., 2007; Bates et al., 2012; Cyronak et al., 2014; Doney et al., 2009).

35 The CO₂ reduction pledges by the signatory states of the 2015 Paris Agreement aim to limit the negative impacts of global warming and OA on ecosystems and human societies by limiting warming to less than +2.0 °C, ideally around +1.5 °C, by the end of this century (Goodwin et al., 2018). However, current and pledged reductions will likely not be enough and additional mitigation strategies are being discussed, such as *ocean alkalinity enhancement* – OAE (Gattuso et al., 2015; Lenton and Vaughan, 2009; The Royal Society and Royal Academy of Engineering, 2018; Boyd et al., 2019). OAE is one with the highest
40 carbon dioxide removal potential, and modelling suggests that at a global scale, between 264 and 790 Gigatonnes (1 Gt = 1e12 kg) of atmospheric CO₂ could be removed by 2100 (Feng et al., 2017).

OAE typically relies on the dissolution of alkaline minerals in seawater, similar to what occurs during natural rock weathering (Kheshgi, 1995). In this regard, magnesium-rich minerals such as brucite, periclase or forsterite, and calcium-rich minerals such as quick and hydrated lime have been considered (Renforth and Henderson, 2017). The last two minerals are of particular
45 interest, due to their high solubility in seawater as well as their relatively rapid dissolution. Quick lime, also known as calcium oxide (CaO), is obtained by the calcination of limestone, mainly composed of calcium carbonate (CaCO₃) and present in large quantities in the Earth's crust (Kheshgi, 1995). Once heated to temperatures of ~1200 °C, each molecule of CaCO₃ breaks down into one molecule of CaO and one molecule of CO₂ (Kheshgi, 1995; Ilyina et al., 2013). CaO can then be hydrated into hydrated lime, also known as calcium hydroxide (Ca(OH)₂) (Kheshgi, 1995). The addition of either CaO or Ca(OH)₂ to
50 seawater leads to the dissociation of Ca(OH)₂ into one calcium Ca²⁺ and two hydroxyl ions OH⁻ (Feng et al., 2017; Harvey, 2008). Including the subsequent oceanic uptake of atmospheric CO₂, and ignoring the non-linearities of the seawater carbonate system, i.e., changes in total alkalinity, TA, and dissolved inorganic carbon, DIC, are not 1:1, a conceptual model of CaO and Ca(OH)₂ dissolution can be summarised as per:

55

This chemical equation suggests that each mole of CaO or Ca(OH)₂ reacts with two moles of CO₂ to produce one mole of Ca²⁺ and two moles of bicarbonate ions (HCO₃⁻). A different way to look at this is that adding Ca²⁺ to seawater increases TA by two moles per mole of Ca²⁺, while leaving the concentration of DIC unchanged (Wolf-Gladrow et al., 2007). This increases the pH, lowering the CO₂ concentration, [CO₂], and increasing the carbonate ion concentration, [CO₃²⁻] (Figure A 1, Appendix)

60 (Wolf-Gladrow et al., 2007; Dickson et al., 2007; Zeebe and Wolf-Gladrow, 2001). This in turn reduces the partial pressure of CO_2 ($p\text{CO}_2$) in seawater.

Depending on the amount of TA added and the initial seawater $p\text{CO}_2$, the water would either take up CO_2 from the atmosphere or degas less until equilibrium is restored, hence acting as a sink for atmospheric CO_2 . Factoring in carbonate system non-linearities, about 1.6 moles of atmospheric CO_2 could be taken up per mole of CaO or $\text{Ca}(\text{OH})_2$ (Köhler et al., 2010).
65 Furthermore, dissolving CaO and $\text{Ca}(\text{OH})_2$ can also counteract OA in two ways, raising the pH of seawater and raising the calcium carbonate saturation state by increasing both dissolved $[\text{Ca}^{2+}]$ and $[\text{CO}_3^{2-}]$. Therefore, OAE is a dual solution for both removing CO_2 from the atmosphere and changing ocean acidification trajectories (Feng et al., 2017; Harvey, 2008; Boyd et al., 2019). However, major knowledge gaps exist regarding OAE, considering most research to date has been based on conceptual and numerical modelling (Feng et al., 2016; Renforth and Henderson, 2017; González and Ilyina, 2016; Mongin et al., 2021). One of the major constraints is keeping CaCO_3 saturation state (Ω) of the seawater below a critical threshold, beyond
70 which CaCO_3 would precipitate inorganically. Such secondary precipitation would increase seawater $[\text{CO}_2]$ through decreasing $[\text{CO}_3^{2-}]$, and if all added alkalinity is being precipitated, only 1 mole of atmospheric CO_2 per mole of Ca^{2+} would be removed, instead of about 1.6 without. If even more CaCO_3 precipitates, the efficiency would be further reduced.

The critical threshold for Ω with respect to the CaCO_3 mineral phase calcite, Ω_{Ca} , has been determined experimentally for so-called pseudo-homogeneous precipitation, i.e., in the presence of colloids and organic materials (Marion et al., 2009; Morse and He, 1993). For a salinity of 35 and at a temperature of 21 °C, the critical Ω_{Ca} value is ~18.8. Assuming a typical open-ocean TA and DIC concentrations, i.e., ~2350 $\mu\text{mol kg}^{-1}$ and ~2100 $\mu\text{mol kg}^{-1}$ respectively (Dickson et al., 2007), this threshold would be reached by an increase in TA of ~810 $\mu\text{mol kg}^{-1}$, corresponding to a critical threshold for Ω_{CaCO_3} with respect to aragonite, i.e., Ω_{Ar} , of ~12.3. Furthermore, there are two other types of precipitation, i.e., homogeneous (in the absence of any
80 precipitation nuclei) and heterogeneous (in the presence of mineral phases), but these thresholds are poorly constrained (Marion et al., 2009).

A better understanding of dissolution and precipitation kinetics is needed to address knowledge gaps in OAE research. In order to do so, several dissolution experiments with CaO and $\text{Ca}(\text{OH})_2$ were carried out to determine 1) how much alkaline material can be dissolved without inducing CaCO_3 precipitation, 2) what causes CaCO_3 precipitation, and 3) how it can be avoided if
85 observed.

2 Material & Methods

2.1 Experimental setup

Two different calcium minerals were sourced, calcium oxide (CaO) powder from Ajax Finechem (CAS no 1305-78-8) and an industrial calcium hydroxide ($\text{Ca}(\text{OH})_2$) powder (Hydrated Lime 20kg, Dingo). The elemental composition of these powders
90 was analysed on Agilent 7700 Inductively Coupled Plasma Mass Spectrometer, coupled to a laser ablation unit NWR213 from

ESI. For that purpose, the samples were embedded in resin and calibrated against standard reference materials # 610 and #612 from the National Institute of Standards and Technology.

The dissolution experiments were conducted in natural seawater. The seawater was sampled about 200 to 300 m from the shore, avoiding collecting sand or silt, at Broken Head, New South Wales, Australia (28°42'12" S, 153°37'03" E). It was stored up to 14 days at 4 °C in the dark to slow bacterial metabolic activity before being sterile-filtered using a peristaltic pump, connected to a 0.2 µm Whatman Polycap 75 AS filter. For salinity measurements, about 200 mL of seawater were placed in a gas-tight polycarbonate container and allowed to equilibrate to room temperature overnight. The sample's conductivity was then measured using a measuring cell (Metrohm 6.017.080), connected to a 914 pH/Conductometer. The conductivity was recorded in millisiemens per cm (mS/cm), and the temperature in °C. Salinity was calculated according to Lewis and Perkin (1981) on the 1978 practical salinity scale.

2.2 OAE experiments

For each experiment, seawater was accurately weighed into high-quality borosilicate 3.3 2L or 5L Schott Duran beakers, and the temperature was controlled via a Tank Chiller Line TK 1000 set to 21 °C, feeding a re-circulation water jacket (Figure A 2, supplementary material). A magnetic stir bar was placed in the beaker, and the natural seawater was constantly stirred at ~200rpm. To minimise gas exchange, a floating lid with various sampling ports was placed on top. Finally, after one hour of equilibration, calculated amounts of alkaline compounds were added. Upon addition, samples for DIC and TA were taken in increasing time intervals to fully capture the dissolution kinetics and check for potential secondary precipitation. Furthermore, the pH was monitored for the first hour before alkalinity addition, and over 5 hours after addition to determine when alkalinity was fully released. Once the maximum TA was reached, the entire content of the beaker was carefully transferred to a clean Schott bottle of the corresponding volume. The bottles were kept in the dark for the duration of each experiment, i.e., up to 48 days, with the same constant stirring of ~200 rpm at 21 °C. Each bottle was exposed to UV light for at least 30 minutes after each sampling to avoid bacterial growth.

2.2.1 CaO and Ca(OH)₂ dissolution

The additions of sieved CaO and Ca(OH)₂ were performed using a 63 µm mesh. The mesh was placed in a clean upside-down 50 mL Falcon tube cap, avoiding losing any material smaller than 63 µm when weighing, and the overall weight was recorded. Then, the mesh was placed above the Schott bottle, and mineral was added by gently tapping the side of the sieve. Finally, the sieve was placed in the same upside-down Falcon tube cap and the weight of the whole setup was recorded again, making sure that the desired amount had been added. The weighing steps were carefully performed to avoid material loss between the bottle and the balance, and was achieved in less than 5min. Two alkalinity additions, +250 and +500 µmol kg⁻¹ with each calcium powder were performed (Table 1).

2.2.2 Na₂CO₃ alkalinity and particles addition and filtration

A 1M solution of sodium carbonate (Na₂CO₃, CAS number 497-19-8) was freshly prepared before the experiment. Ultrapure Na₂CO₃ (CAS number 497-19-8) was accurately weighed into a clean 100 mL Schott bottle and made up to 100g with MilliQ (18.2 MΩ). The solution was then sonicated for 15 minutes with gentle shaking. The amount of Na₂CO₃ to be added was calculated so that a similar maximum Ω_{Ar} would be reached, i.e., ~7.7, as in the previous experiments with the highest addition of CaO and Ca(OH)₂. This required almost twice the alkalinity increase as before (Table 1), because Na₂CO₃ additions concomitantly increase DIC when dissociating in two sodium ions, i.e., Na⁺, and one CO₃²⁻, making the Ω_{CaCO_3} increase smaller. Calculations were done in CO₂SYS (see below).

In another, otherwise identical, experiment with the Na₂CO₃ solution, quartz powder was added after two days. The addition of quartz powder was similar to the sieved CaO and Ca(OH)₂ addition, i.e., through a 63 μm mesh. The amount of quartz particles added was determined to provide the same amount of mineral surface as for the Ca(OH)₂ experiments with a TA increase of 500 μmol kg⁻¹. It was calculated using densities and masses for Ca(OH)₂ and quartz, and assuming spherical particles with a diameter of 63 μm. Quartz powder was chosen as it does not dissolve on timescales relevant to the experiment and hence does not supply extra TA (Montserrat et al., 2017).

Finally, a particle filtering experiment was carried out using Ca(OH)₂ as the alkaline compound following the same setup as described above. Here we first added Ca(OH)₂ to increase TA by ~500 μmol kg⁻¹ (Table 1). After 4h of reaction, the entire content of the 2L Schott beaker was filtered through a nylon Captiva Econofilter (25mm) with a pore size of 0.45 μm into a clean 1L Schott bottle using a peristaltic pump. The bottle was filled from bottom to top, with overflow to minimise gas exchange.

2.2.3 Dilution experiments

A last set of experiments diluted alkalinity enriched samples with natural seawater over time, to test if secondary precipitation can be avoided through dilution. Ca(OH)₂ was added to reach a final alkalinity enrichment of 500 and 2000 μmol kg⁻¹. These initial concentrations were then diluted with NSW in several steps as described in the following.

For the experiment with a targeted TA increase of 500 μmol kg⁻¹, two 5L Schott bottles were filled with 5kg of natural seawater and placed on a magnetic stirring platform. Calculated amounts of Ca(OH)₂ were added to the first bottle, while the natural seawater in the second bottle was left for future dilutions. Both bottles were kept on the same bench under the same conditions, both stirring at a rate of ~200rpm, for the duration of the experiment. Ca(OH)₂ powder was added as described above using the 63 μm sieve. Following the Ca(OH)₂ addition, 1:1 dilutions were performed in 1L Schott bottles that were kept in the dark and placed on a magnetic platform at a stirring rate of ~200rpm. After each sampling, the bottles were exposed to UV light for at least 30 minutes. The second dilution experiment was set up like the first one, the only difference being that the targeted TA increase was 2000 μmol kg⁻¹. The dilution ratio was 1:7 to, again, reduce the targeted TA increase to 250 μmol kg⁻¹. All dilutions were performed 10 minutes, 1 hour, 1 day and 1 week after Ca(OH)₂ addition.

2.3 Carbonate chemistry measurements

155 Samples for TA and DIC were filtered through a nylon Captiva Econofilter (0.45 μm) using a peristaltic pump into 100 mL
Borosilicate 3.3 Schott DURAN glass stopper bottles. The bottles were gently filled from the bottom to top, using a 14-gauge
needle as described in Schulz et al. (2017), with at least half of their volume overflow (Dickson et al., 2007). 50 μL of saturated
mercuric chloride solution was added to each sample before being stored without headspace in the dark at 4 $^{\circ}\text{C}$. TA was
analysed via potentiometric titrations on an 848 Titrino Plus coupled to an 869 Compact Sample Changer from Metrohm using
0.05M HCl, with the ionic strength adjusted to 0.72 mol kg^{-1} , corresponding to a salinity of 35 with NaCl. Titrations and
160 calculations followed the open-cell protocols by Dickson et al. (2007). DIC was measured using an Automated Infra-Red
Inorganic Carbon Analyzer (AIRICA) coupled to a LICOR Li7000 Infra-Red detector as described in Gafar and Schulz (2018).
Measured values of TA and DIC were corrected using an internal Standard prepared as per Dickson et al. (2007) which had
been calibrated against Certified Reference Materials Batch #175 and #190 (Dickson, 2010).

2.4 Particulate Inorganic Carbon and Scanning Electron Microscopy (SEM)

165 Samples for total particulate carbon (TPC) and particulate organic carbon (POC) were collected at the end of some experiments
on pre-combusted (450 $^{\circ}\text{C}$) GF/F filters, and stored frozen until analysis. Then, POC filters were fumed with HCl for 2 hours
before drying over night at 60 $^{\circ}\text{C}$ while TPC filters were dried untreated. Both TPC and POC were quantified on an Elemental
Analyser Flash EA, Thermo Fisher, coupled to an Isotope Ratio Mass Spectrometer (IRMS), Delta V Plus. Particulate
inorganic carbon (PIC), or CaCO_3 , was calculated from the difference between TPC and POC. The results are reported in μmol
170 kg^{-1} with an uncertainty estimate calculated by an error propagation from the square root of the sum of the squared standard
deviations for TPC and POC. Finally, samples of CaO and $\text{Ca}(\text{OH})_2$ were analysed for their carbon content. This analysis
aimed to identify the presence and estimate the amount of particulate carbon, most likely CaCO_3 , in the respective mineral
powders.

175 When CaCO_3 was suspected to have precipitated in the experiments, samples for SEM analysis were taken. For that purpose,
10 to 15 mL of the sample water was collected on polycarbonate Whatman Cyclopore filters with a 0.2 μm pore size, and
rinsed with 50 mL of MilliQ. The filters were dried at 60 $^{\circ}\text{C}$ overnight and kept in a desiccator until analysis on a tabletop
Scanning Electron Microscope TM4000 Plus from Hitachi, coupled to an Energy Dispersive X-Ray (EDX) Analyser, allowing
to identify the morphotype and elemental composition of precipitates.

2.5 Carbonate chemistry calculations

180 Most seawater parameters were calculated using the CO_2SYS script for MATLAB® (MathWorks), using the dissociation
constants for carbonic acid by Lueker et al. (2000) and for boric acid by Uppstrom (1974). With two measured carbonate
chemistry parameters, i.e., DIC and TA, most of the others can be calculated straight away. An exception in our experiments

was that the addition of CaO and Ca(OH)₂ changes the calcium concentration and hence the salinity-based Ω_{CaCO_3} calculated by CO₂SYS is erroneous. Ω_{CaCO_3} is defined by the solubility product of CaCO₃ as:

185

$$\Omega_{CaCO_3} = \frac{[Ca^{2+}] \times [CO_3^{2-}]}{K_{sp}} \quad 2$$

where [Ca²⁺] and [CO₃²⁻] denote seawater concentration of Ca²⁺ and CO₃²⁻, and K_{sp} the solubility product for calcite or aragonite. To calculate saturation states, CO₂SYS was used to determine K_{sp} and [CO₃²⁻] from measured DIC and TA. The correct calcium concentration [Ca²⁺]_{corr} was estimated from measured salinity (Riley and Tongudai, 1967) plus half the amount of alkalinity that was generated during CaO or Ca(OH)₂ dissolution or lost due to CaCO₃ precipitation ΔTA :

190

$$[Ca^{2+}]_{corr} = \frac{0.02128}{40.087} \times \frac{Salinity}{1.80655} + \frac{\Delta TA}{2} \quad 3$$

The corrected Ω_{Ca} and Ω_{Ar} were then calculated from in-situ [CO₃²⁻], [Ca²⁺]_{corr} and K_{sp}. Please note that we have opted to rather report Ω_{Ar} than Ω_{Ca} since aragonite is more likely to be precipitated in natural seawater (Berner, 1975; Riebesell et al., 2011; Zeebe and Wolf-Gladrow, 2001).

195

3 Results

3.1 Chemical composition of CaO and Ca(OH)₂

The chemical composition of the CaO and Ca(OH)₂ powders were analysed for their major ions. As to be expected, both consisted mainly of calcium, with minor contributions by magnesium and silicon (see Table A 1, Appendix, for a more extensive list). Furthermore, CaO and Ca(OH)₂ contained about 9.4 ±0.1 mg g⁻¹ and 18.0 ±0.2 mg g⁻¹ of particulate carbon respectively, i.e., ~0.9% and ~1.8%.

200

3.2 CaO dissolution in filtered natural seawater

In the first CaO experiment with ~250 μmol kg⁻¹ TA addition, TA increased by ~200 μmol kg⁻¹ within the first 4 hours (Figure 1a). Following this increase, TA was stable over time. In contrast, DIC increased slowly over time, reaching about +50 μmol kg⁻¹ on day 47 of the experiment (Figure 1b). Finally, Ω_{Ar} showed a similar trend to the ΔTA , increasing from ~2.9 to ~5.1 within the first 4 hours before slowly decreasing to 5.0 as of day 47 (Figure 1c).

205

In the second CaO experiment with about 500 μmol kg⁻¹ TA addition, TA increased by ~410 μmol kg⁻¹ within the first 4 hours before slowly decreasing two days later (Figure 1a), followed by more rapid decreases over the following week, before slowing down and eventually reaching steady state at a ΔTA of about -540 μmol kg⁻¹. This corresponds to a total loss of TA of ~950

210 $\mu\text{mol kg}^{-1}$. Similarly, a slight decrease in DIC of $\sim 10 \mu\text{mol kg}^{-1}$ was observed over the first two days before a much more
considerable reduction in the following week before levelling off at a ΔDIC of about $\sim 465 \mu\text{mol kg}^{-1}$ (Figure 1b). Finally, Ω_{Ar}
increased rapidly during the first 4 hours of the experiment from 2.8 up to 7.6 (Figure 1c). Following this quick increase, Ω_{Ar}
decreased by 0.3 units within the first two days before rapidly dropping to 2.4 on day 13, and reaching ~ 1.8 on day 47,
corresponding to a reduction of 1.0 compared to the starting value.

215 **3.3 Ca(OH)₂ dissolution in filtered natural seawater**

In the first Ca(OH)₂ experiment with a TA addition of $\sim 250 \mu\text{mol kg}^{-1}$, TA increased by $\sim 220 \mu\text{mol kg}^{-1}$ after 4h of reaction,
before stabilising at a ΔTA of $\sim 210 \mu\text{mol kg}^{-1}$ for the rest of the experiment (Figure 2a). The DIC concentration increased
steadily following the TA addition by $\sim 70 \mu\text{mol kg}^{-1}$ until the end of the experiment (Figure 2b). Finally, Ω_{Ar} reached ~ 4.1
after 4 hours, slightly decreasing over time, down to 3.3 on day 28 (Figure 2c).

220 In the second Ca(OH)₂ experiment with a TA addition of $\sim 500 \mu\text{mol kg}^{-1}$, TA increased by $\sim 440 \mu\text{mol kg}^{-1}$ within the first 4h
(Figure 2a). This was followed by a relatively steady decrease over the next 2 weeks, after which the decrease accelerated
before levelling off at a ΔTA of about $\sim 420 \mu\text{mol kg}^{-1}$ towards the end of the experiment. Overall, $\sim 860 \mu\text{mol kg}^{-1}$ of TA was
lost compared to the highest TA recorded. The DIC concentration decreased as well, dropping in a similar fashion as TA and
reaching a ΔDIC of about $\sim 395 \mu\text{mol kg}^{-1}$ compared to the initial DIC concentration (Figure 2b). Finally, Ω_{Ar} increased from
225 2.5 to 7.4 in the first 4 hours before decreasing, similarly to TA and DIC, reaching ~ 2.0 on day 42 (Figure 2c).

3.4 Na₂CO₃, particle filtration and addition

Three experiments assessed the influence of particles on CaCO₃ precipitation. In the first one, $\sim 1050 \mu\text{mol kg}^{-1}$ of TA was
added using a 1M Na₂CO₃ solution, designed to result in a similar maximum Ω_{Ar} as in the previous experiments when TA
precipitated (Table 1). Upon addition, TA increased by $\sim 1060 \mu\text{mol kg}^{-1}$ and DIC by $\sim 530 \mu\text{mol kg}^{-1}$ within minutes. For the
230 remainder of the experiment, ΔTA was fairly constant between 1060 and 1040 $\mu\text{mol kg}^{-1}$ (Figure 3a). In contrast, DIC slightly
increased over 42 days from a ΔDIC of $\sim 530 \mu\text{mol kg}^{-1}$ on day 1 to $\sim 560 \mu\text{mol kg}^{-1}$ on day 42 (Figure 3b). Finally, Ω_{Ar}
increased from ~ 2.3 to ~ 8.5 within minutes and slightly decreased to ~ 8.1 after 42 days of experiment (Figure 3c).

In the second experiment, the addition of aliquots of 1M Na₂CO₃ solution (Table 1) increased TA by $1070 \mu\text{mol kg}^{-1}$, while
DIC increased by $\sim 540 \mu\text{mol kg}^{-1}$ within minutes and remained stable (Figure 3a, 3b). Then, after 2 days, quartz was added.
235 While one day later ΔTA and ΔDIC remained unchanged, about a week later, ΔTA had decreased to $\sim 220 \mu\text{mol kg}^{-1}$ while
 ΔDIC had dropped to $\sim 120 \mu\text{mol kg}^{-1}$ (Figure 3a, 3b). Over the next month, ΔTA and ΔDIC kept on decreasing, although at a
slowing pace, reaching about ~ 200 and $\sim 110 \mu\text{mol kg}^{-1}$ respectively. Finally, Ω_{Ar} followed a similar trend, with an increase
from ~ 2.8 up to ~ 9.2 within the first 1.5 hours, and a pronounced decline to ~ 2.0 at the end of the experiment.

In the last experiment, Ca(OH)₂ was added for a TA increase of $500 \mu\text{mol kg}^{-1}$ (Table 1), a level at which a significant TA
240 decrease had been observed after 5 hours previously (Figure 2a). In contrast, however, upon filtration of the entire experimental
bottle content after reaching $\sim 470 \mu\text{mol kg}^{-1}$ at the 4-hour mark, ΔTA remained relatively constant between 465 and $470 \mu\text{mol}$

kg⁻¹ over the following 48 days of experiment (Figure 3a). Δ DIC increased from ~ 5 to $55 \mu\text{mol kg}^{-1}$ after filtration (Figure 3b). Finally, Ω_{Ar} increased from ~ 2.8 to ~ 8.2 within the first 1.5 hours, and then slightly decreased to ~ 7.5 over the 48 days of experiment (Figure 3c).

245 3.5 Dilution experiments

3.5.1 500 $\mu\text{mol kg}^{-1}$ addition

In this set of experiments with a TA addition of $\sim 500 \mu\text{mol kg}^{-1}$ by $\text{Ca}(\text{OH})_2$, Δ TA increased similarly to the other $\text{Ca}(\text{OH})_2$ experiment to $\sim 450 \mu\text{mol kg}^{-1}$ after 2 hours. These changes in TA were followed by a decline to $\sim 320 \mu\text{mol kg}^{-1}$ after 14 days, although the latter being a slightly slower decrease than previously (Figure 4a, 4d). After a first increase in Δ DIC by $\sim 10 \mu\text{mol kg}^{-1}$ on day 1, it steadily decreased to about $-20 \mu\text{mol kg}^{-1}$ after two weeks (Figure 4b, 4e). Finally, Ω_{Ar} was calculated, to increase from ~ 2.7 to ~ 7.8 after 2 hours, before steadily decreasing to ~ 6.4 on day 14 (Figure 4c, 4f).

After 10 minutes, 1 hour, 1 day, and 1 week, dilutions of the $\sim 500 \mu\text{mol kg}^{-1}$ of TA by $\text{Ca}(\text{OH})_2$ addition were performed. In these diluted samples, Δ TA remained relatively stable over time, until the end of the experiments on day 29, regardless of dilution time (Figure 4a, 4d). Upon dilution, Δ TA was reduced, being very similar for the 10 minutes, 1 hour and 1 day dilutions. Overall, Δ TA in the 1 week dilution, however, was slightly lower. In all dilutions, Δ DIC increased over time, ranging between $\sim 20 \mu\text{mol kg}^{-1}$ and $\sim 60 \mu\text{mol kg}^{-1}$, independent of dilution timing. Finally, Ω_{Ar} showed similar trends like Δ TA, reaching between ~ 4.8 and ~ 5.2 , slightly decreasing over time until end of the experiment.

3.5.2 2000 $\mu\text{mol kg}^{-1}$ addition

Similarly to the previous experiment, this experiment consisted of a TA increase of $\sim 2000 \mu\text{mol kg}^{-1}$ by $\text{Ca}(\text{OH})_2$ addition. The TA only increased to $\sim 1/3$ of the theoretical alkalinity addition, i.e., $\sim 725 \mu\text{mol kg}^{-1}$ within the first two hours (Figure 4a, 4d). Following this increase, TA rapidly decreased during the first day, reaching a Δ TA of about $-1260 \mu\text{mol kg}^{-1}$, and $-1440 \mu\text{mol kg}^{-1}$ in the following week (Figure 4a, 4d). From then on, TA appeared to stabilise up to day 14, before slightly increasing until day 21. A similar trend was observed for Δ DIC, decreasing by $\sim 580 \mu\text{mol kg}^{-1}$ within the first two hours, before radically dropping to about $-1590 \mu\text{mol kg}^{-1}$ on day 1, and $-1660 \mu\text{mol kg}^{-1}$ after 7 days (Figure 4b, 4e). Over the remaining 41 days, Δ DIC then increased by $\sim 210 \mu\text{mol kg}^{-1}$, although remaining about $1450 \mu\text{mol kg}^{-1}$ under the starting DIC concentration. Finally, Ω_{Ar} reached up to ~ 16.7 after 2 hours of reaction, followed by a rapid drop down to ~ 3.2 on day 1 and ~ 2.0 on day 14, while slightly increasing the following 34 days, varying between 2.0 and 2.1 (Figure 4c, 4f).

Dilutions were performed after 10 minutes, 1 hour, 1 day and 1 week after $\text{Ca}(\text{OH})_2$ addition, in this case in a 1:7 ratio. Concerning Δ TA, Δ DIC and Ω_{Ar} , the 10 minutes and 1 hour dilutions showed similar responses, as did the 1 day and 1 week dilutions. Upon dilution, Δ TA reached values $\sim 240 \mu\text{mol kg}^{-1}$ after the 10 minutes and 1 hour dilutions, and about -160 to $-190 \mu\text{mol kg}^{-1}$ for the 1 day and 1 week dilutions. With the exception of one data point in the 1 week dilution time data, Δ TA remained relatively constant throughout all dilution experiments (Figure 4a, 4d). DIC changes were similar to the TA changes,

with very similar values reached for the 10 minutes and 1 hour dilutions, as opposed to the 1 day and 1 week ones (Figure 4b, 4e). In all dilutions, ΔDIC slowly increased over time. Finally, Ω_{Ar} dropped to ~ 5.0 - 5 in the 10 minutes and 1 hour dilutions, while it dropped to ~ 2.3 - 2.8 (1:7) in the 1 day and 1 week dilution. In all experiments, Ω_{Ar} decreased slightly over time after dilutions (Figure 4c, 4f).

3.6 Particulate inorganic carbon

With the exception of the ~ 1050 TA addition by Na_2CO_3 plus quartz particles, measured PIC in experiments was always higher than estimates from measured ΔTA (Table 2). Furthermore, PIC estimated from the theoretically maximum TA increase upon full mineral dissolution, $\Delta\text{TA}_{\text{Theo}}$, was always higher than estimated PIC from ΔTA , by about 30% in the $\sim 500 \mu\text{mol kg}^{-1}$ TA additions, and almost 90% in the $\sim 2000 \mu\text{mol kg}^{-1}$ TA addition.

4 Discussion

This study presents the first results on the dissolution of CaO and $\text{Ca}(\text{OH})_2$ in natural seawater in the context of ocean alkalinity enhancement. In some of our experiments, secondary precipitation was detected. More specifically, we observed “runaway CaCO_3 precipitation” at TA additions equal or higher than $500 \mu\text{mol kg}^{-1}$, i.e., not only was the added TA completely removed, but significant portions of residual seawater TA as well, until a new steady state was reached. This would vastly reduce the desired CO_2 removal potential by OAE and should therefore be avoided. Hence, in a set of experiments, we simulated ocean mixing to test required timescales to avoid secondary CaCO_3 precipitation for applications that initially had TA additions above the critical threshold.

4.1 Identifying CaCO_3 precipitation and the problem of not measured precipitation

CaCO_3 precipitation can occur via three pathways, i.e., heterogeneous, homogeneous and pseudo-homogeneous nucleation and precipitation (Marion et al., 2009; Chen et al., 2005; Wolf et al., 2008). Heterogeneous precipitation relies on the presence of existing solid mineral phases. This differs from homogeneous precipitation, characterised by the formation of CaCO_3 crystals from Ca^{2+} and CO_3^{2-} ions present in the solution in the absence of any nucleation surfaces (Chen et al., 2005; Wolf et al., 2008). Finally, the last type of precipitation, termed pseudo-homogeneous, is similar to homogeneous nucleation, however it occurs on nuclei other than solid minerals such as colloids, organic particles or glassware in a laboratory setting (Marion et al., 2009). Concerning the Ω_{CaCO_3} thresholds beyond which CaCO_3 precipitation is expected to occur, the lowest would be for heterogeneous and the highest for homogeneous, with pseudo-homogeneous nucleation in between.

When 1 mole of CaCO_3 is precipitated, the TA of the solution decreases by 2 moles because of the removal of CO_3^{2-} ions, accounting for 2 moles of TA (Equation 1). Simultaneously, the loss of 1 mole of CO_3^{2-} ions decrease the DIC concentration by 1 mole. Hence, any loss of TA and DIC following a 2:1 ratio can be linked to CaCO_3 precipitation. When CaCO_3 precipitation was suspected in our experiments, SEM and particulate inorganic carbon samples were taken to confirm the

presence of CaCO_3 and to identify which morphotypes were predominant. In the $+250 \mu\text{mol kg}^{-1}$ TA additions by CaO and $\text{Ca}(\text{OH})_2$, both appeared to fully dissolve without inducing CaCO_3 precipitation, as TA and Ω_{Ar} quickly increased within
305 minutes until reaching their respective maximum after about a day and remaining stable over weeks (Figure 1a and 1c, Figure 2a and 2c). A slight increase in DIC was observed over time, expected when atmospheric CO_2 is ingassing from the headspace. This in turn lead to slowly decreasing Ω_{CaCO_3} at constant TA, when increasing DIC and $[\text{CO}_2]$, lowering the pH and $[\text{CO}_3^{2-}]$ (Equation 2). The reason why the measured TA increase was slightly below the theoretically expected one is most likely a combination of impurities present (in the case of CaO , a significant fraction could be hydrated), and loss of the finely ground
310 material during the weighing and sieving process despite all efforts. On average, $\sim 25\text{-}27\%$ of alkalinity added was not measured in the experiments with CaO , and about $13\text{-}17\%$ in the experiments with $\text{Ca}(\text{OH})_2$ (Table 1, Figure 1 and Figure 2). In contrast, in the $+500 \mu\text{mol kg}^{-1}$ TA additions by CaO and $\text{Ca}(\text{OH})_2$ additions, TA started decreasing after about 4 hours, upon the initial increase. This decrease in TA was accompanied by a decrease in DIC. In the CaO experiment (exactly the same conclusions could be reached for the $\text{Ca}(\text{OH})_2$ experiment), TA reached a maximum of about $+410 \mu\text{mol kg}^{-1}$ after 4
315 hours of reaction, before dropping to about $-560 \mu\text{mol kg}^{-1}$ after 34 days, constituting an overall loss of about $-970 \mu\text{mol kg}^{-1}$. If this TA loss would be by CaCO_3 precipitation, DIC should be reduced by half this amount, i.e., about $-485 \mu\text{mol kg}^{-1}$. And indeed, measured DIC loss was exactly the same, suggesting that TA was precipitated in the form of CaCO_3 . Although a perfect match, a caveat here is that the DIC loss is underestimated as of concurrent ingassing of CO_2 from the head space, becoming visible when precipitation ceases towards the end (Figure 1b). Hence, the DIC loss should have been higher,
320 requiring also higher TA removal than actually measured. This discrepancy can be explained by the fact that the maximum increase in TA from full dissolution of CaO or $\text{Ca}(\text{OH})_2$ cannot be measured in the presence of concurrent CaCO_3 precipitation. This is mostly evident in the $+2000 \mu\text{mol kg}^{-1}$ TA addition (Figure 4), where DIC decreases due to CaCO_3 precipitation, yet TA increases due to higher $\text{Ca}(\text{OH})_2$ dissolution rates. It also explains why estimated PIC calculated from measured TA changes are smaller than actually measured PIC concentrations (Table 2). In the experiment with $1\text{M Na}_2\text{CO}_3$ and quartz
325 particles, both estimated PIC have similar results. However, the measured PIC is about twice as low. This could be explained by a combination of precipitation on both the quartz particles and bottle walls. In this sense, trying to estimate CaCO_3 precipitation from measured changes in TA, without considering theoretical TA generation by dissolution or actual PIC measurements, might underestimate total precipitation. Finally, next to impurities and issues with mineral handling, the reason why measured seawater PIC concentrations are in between the other estimates lies in the fact that a small portion of the CaCO_3
330 precipitated on the bottle walls, at least in the $2000 \mu\text{mol kg}^{-1}$ TA experiment. While being a laboratory artefact, this has no practical consequences as in a natural setting, the TA would eventually precipitate in the water column.

4.2 The presence of mineral phases enhances CaCO_3 precipitation

An interesting finding in our experiments was that whenever CaCO_3 precipitation was observed, it continued even if the solution dropped below an Ω_{Ar} of $\sim 4\text{-}5$, levels at which no precipitation was observed in the $+250 \mu\text{mol kg}^{-1}$ TA addition
335 experiments. Furthermore, in all these experiments, precipitation decreased and seemingly ceased at a Ω_{Ar} of $\sim 1.8\text{-}2.0$. It

appears that when CaCO_3 is initially precipitated, CaCO_3 continues to precipitate in a runaway fashion, even if Ω_{Ar} drops below levels where precipitation would not be initiated in natural seawater. This is to be expected as precipitation rates of CaCO_3 into CaCO_3 mineral phases are directly related to Ω_{CaCO_3} , decreasing exponentially until reaching zero at an Ω_{CaCO_3} value of 1 (Zhong and Mucci, 1989; Morse et al., 2007). However, why did precipitation occur at a much lower Ω_{CaCO_3} , i.e. $\Omega_{\text{Ar}} \sim 7.5$, than expected, i.e., ~ 12.3 (Marion et al., 2009)? It is known that the presence of particles in suspension can initiate and accelerate CaCO_3 precipitation (Millero et al., 2001; Morse et al., 2003; Wurgaft et al., 2021). It is unlikely that the presence of CaCO_3 impurities in CaO (less than 1% carbon) and $\text{Ca}(\text{OH})_2$ (less than 2% carbon) from imperfect calcination would have caused precipitation, as the presence of CaCO_3 mineral phases should have caused precipitation at any saturation state above 1, i.e., also in the $+250 \mu\text{mol kg}^{-1}$ TA addition experiments. Furthermore, modelling precipitation using experimentally determined Ω_{Ar} and surface area dependant aragonite precipitation rates onto CaCO_3 mineral phases suggests that once precipitation becomes analytically detectable, it should proceed very rapidly before levelling off, i.e., within a couple of days (Zhong and Mucci, 1989). However, that is in contrast to what we observed here. We observed the bulk of precipitation occurring over a period of at least a week, with apparent differences between the different dissolving minerals (i.e., CaO, $\text{Ca}(\text{OH})_2$ and quartz, although it is acknowledged that experiments were not replicated).

Another explanation is heterogeneous precipitation on not yet dissolved CaO and $\text{Ca}(\text{OH})_2$ particles (or other impurities), leading to CaCO_3 crystal formation and initiating runaway precipitation. The Ω_{Ar} threshold for this process would depend on lattice compatibility of the mineral phases (Tang et al., 2020). For instance, CaCO_3 precipitation has been observed at any saturation states above 1 when introducing CaCO_3 seed particles. In contrast, the addition of quartz particles did not trigger precipitation at an Ω_{Ar} of up to 3.5 (Lioliou et al., 2007). For that to occur, Ω_{Ar} would need to be further increased. And indeed, above an Ω_{Ar} of ~ 9.2 , CaCO_3 precipitation did actually occur (Figure 3). The reason for an initially slower but then more rapid precipitation could be a combination of exponentially increasing CaCO_3 surface area, as well as concomitantly increasing lattice compatibility (Lioliou et al., 2007; Pan et al., 2021). The filtration of TA enriched seawater supports this idea. Not yet dissolved mineral phases that could facilitate early nucleation are removed, preventing runaway CaCO_3 precipitation (Figure 3).

Needle-shaped aragonite precipitation onto quartz particles (Figure 5c and 5d) was directly observed by SEM imaging, and confirmed by EDX analysis, identifying the larger base mineral to be rich in silicon, a key characteristic of quartz, and the needle-shaped particles composed of carbon, oxygen and calcium (Chang et al., 2017; Ni and Ratner, 2008; Pan et al., 2021). In contrast, aragonite precipitation in the $+500 \mu\text{mol kg}^{-1}$ TA addition by CaO and $\text{Ca}(\text{OH})_2$ did not reveal any insoluble base-element other than Ca, suggesting initial CaCO_3 precipitation onto CaO and $\text{Ca}(\text{OH})_2$ (Figure 5a and 5b). In some situations (Figure 5b), round crystals were also observed, suggesting the presence of vaterite (Chang et al., 2017). However, aragonite crystals represented the majority of CaCO_3 observed by SEM. Early CaCO_3 precipitation onto CaO and $\text{Ca}(\text{OH})_2$ particles, providing some sort of coating could also, or at least partially, explain why maximum measured TA was lower than theoretically anticipated.

4.3 Impacts of CaCO₃ precipitation on OAE potential

370 From an OAE perspective, CaCO₃ precipitation is an important chemical reaction that needs to be avoided. When CaCO₃
precipitates, TA and DIC decrease in a 2:1 fashion. Simultaneously, dissolved [CO₃²⁻] and Ω_{CaCO_3} are decreasing, and [CO₂]
is increasing, impacting OAE potential. Considering typical open ocean TA and DIC concentrations of 2350 and 2100 μmol
kg⁻¹ respectively, at a salinity of 35 and a temperature of 19 °C, this water mass would have a pCO₂ close to atmospheric
375 equilibrium, ~416 ppm, a pH_T value (total scale) of ~8.04, and an Ω_{Ar} of ~2.80. Without CaCO₃ precipitation, an addition of
500 μmol kg⁻¹ TA would lower pCO₂ to ~92 μatm and increase pH_T and Ω_{Ar} to about 8.61 and 8.45 respectively. If fully
equilibrated with the atmosphere, DIC would increase by about 420 μmol kg⁻¹, leading to a pH_T and Ω_{Ar} 0.07 and 1.10 higher
than prior to the addition, respectively (Table 3). The resulting OAE efficiency would be 0.83 mole of atmospheric CO₂
absorbed per mole of TA, very similar to estimates by Köhler et al. (2010). Considering that CaCO₃ is the base material for
CaO and Ca(OH)₂, and the fact that 2 moles of TA are produced per mole of mineral dissolution, ~0.7 tonnes of CO₂ could be
380 captured per tonne of source material, assuming CO₂ capture during the calcination process. At a global-scale, using all
available ship capacity and assuming a slow discharge of 1.7 to 4.0 Gt of Ca(OH)₂ per year, between 1.2 and 2.8 Gt of CO₂
per year could be absorbed by the ocean (Caserini et al., 2021). Similarly, following the models from Feng et al. (2016) with
a constant addition of Ca(OH)₂ at 10 Gt.year⁻¹, we could expect to absorb about 7 Gt of CO₂ per year. This would eventually
lead to more than 546 Gt of CO₂ by 2100 if implemented in 2022.

385 However, these substantial numbers assume a complete dissolution without CaCO₃ precipitation. If as much CaCO₃
precipitates as TA was added, only 0.50 mole of DIC can be absorbed per mole of TA after equilibration with atmospheric
pCO₂ (Table 3). This represent a decrease by nearly 40% in OAE potential. Similarly, assuming runaway CaCO₃ precipitation
until $\Omega_{\text{Ar}} = 2.0$ decreases the OAE potential further by almost 90%. Then, only ~0.11 mole of DIC would be absorbed per mole
of TA added (Table 3). Finally, secondary CaCO₃ precipitation higher than TA addition will lead to pH_T and Ω_{CaCO_3} levels
390 lower than initial ones. For instance, runaway precipitation for a TA addition of 500 μmol kg⁻¹ will see pH_T drop by about 0.1
from 8.04 to 7.93 and Ω_{Ar} from 2.80 to 1.66, significantly enhancing ongoing ocean acidification (Table 3). Runaway CaCO₃
precipitation for a TA addition of 1000 μmol kg⁻¹ would even see Ω_{Ar} drop below 1. Under such conditions, aragonite, an
important biomineral for a variety of marine organisms, e.g., sessile corals, benthic molluscs and planktonic pteropods, would
start to dissolve (Zeebe and Wolf-Gladrow, 2001; Riebesell et al., 2011). In summary, runaway CaCO₃ precipitation in OAE
395 has to be avoided as not only reducing CO₂ uptake efficiency significantly but also enhancing ocean acidification. Keeping
track of OAE efficiency from changes in TA concentrations can be challenging as CaCO₃ precipitation can be underestimated
as described earlier, requiring new and clever monitoring strategies to ensure effective dilutions take place.

4.4 Avoiding CaCO₃ precipitation by dilution and other TA addition strategies

While above considerations stress the importance for monitoring CaCO₃ precipitation, they do not take into account the natural
400 dilution that would occur in the wake of ships releasing TA in the ocean, or by natural mixing of TA-enriched water with

surrounding seawater (Caserini et al., 2021; Feng et al., 2017; Mongin et al., 2021). In our experiments, a 1:1 dilution of seawater in which CaCO_3 precipitation was taking place upon a $500 \mu\text{mol kg}^{-1}$ TA addition was seemingly stopped, even if initiated only after one week. This comes a bit at a surprise as precipitation nuclei would only be diluted by half, hence reducing surface area and precipitation rates by a factor of 2. However, as Ω_{Ar} is significantly reduced simultaneously, precipitation rates are further reduced by a factor of 10 (see Figure A 4). Hence, overall precipitation would see a reduction by a factor of 20. This however, should slow down continuing precipitation initially, if on CaCO_3 particles, but not completely inhibit it (Zhong and Mucci, 1989). A possible explanation could be that dilution would have lowered Ω_{Ar} below the critical threshold for overcoming lattice mismatch, as most of the aragonite precipitation appears to be on the original seed mineral itself rather than on the newly formed aragonite (compare Figure 5c and 5d).

Overall, CaCO_3 precipitation can be avoided if the TA+ $500 \mu\text{mol kg}^{-1}$ enriched sample is diluted 1:1, reaching an Ω_{Ar} of ~ 5.0 . The quicker dilution takes place, the less CaCO_3 would precipitate prior. Similar results were found for a TA addition of $+2000 \mu\text{mol kg}^{-1}$, i.e., the ability to stop precipitation at an Ω_{Ar} of ~ 5.0 , after a 1:7 dilution. However, only the 10 minutes and 1 hour dilutions seem to be suitable in an OAE context, as much more rapidly occurring aragonite precipitation at a higher initial Ω_{Ar} of about 16.7 would significantly reduce the CO_2 uptake efficiency. Furthermore, the difficulty to monitor precipitation from simple TA measurements (as described above) would also mean that verification of permanent CO_2 removal is problematic. Hence, in order to assign carbon credits, TA additions have to be done in a way that rule out secondary CaCO_3 precipitation. This is the case for any type of TA addition, and is not specific to quick and hydrated lime.

Adding TA from land, as modelled by Feng et al. (2017), shows that the more TA is added, the higher coastal Ω_{Ar} would be. Staying clearly below the Ω_{Ar} 5 threshold, up to ~ 550 Gt of carbon in the form of CO_2 could be removed from the atmosphere by 2100, corresponding to a reduction of about 260 ppm (Feng et al., 2017). The critical Ω_{Ar} threshold beyond which secondary CaCO_3 precipitation would be observed could be higher for other minerals, theoretically allowing for higher TA additions. However, it has to be kept in mind that in waters with high sediment load, often found in coastal settings, CaCO_3 could precipitate onto other mineral particles than those added to increase TA. This has been observed in river plumes (Wurgaft et al., 2021), on the Bahama Banks by resuspended sediments (Bustos-Serrano et al., 2009) and in the Red Sea following flash flood deposition of resuspended sediments and particles (Wurgaft et al., 2016). Hence, even with minerals potentially allowing for higher TA additions, an Ω_{Ar} threshold of 5 might be safer to adopt. However, atmospheric CO_2 removal could be increased if TA would also be added to the open ocean, e.g., on ships of opportunity. Here, additions could be much higher as ship movement and rapid mixing within its wake would significantly dilute added TA (Caserini et al., 2021; Köhler et al., 2013) as opposed to coastal point source.

Finally, another option to increase atmospheric CO_2 uptake would be to not add mineral to seawater directly, but to first equilibrate it with air or CO_2 enriched flumes to atmospheric pCO_2 levels while dissolving. This would allow reaching an Ω_{Ar} of 5 when equilibrated with the atmosphere, as opposed to 3.3 when equilibration is slow and passive, after $+250 \mu\text{mol kg}^{-1}$ TA increase (Table 3). In this case, nearly 1000 instead of $250 \mu\text{mol kg}^{-1}$ of TA could be added, allowing for almost 4 times the amount of atmospheric CO_2 to be removed (this number is highly sensitive to temperature, and ranges between ~ 3 and ~ 6

435 between 30 and 5 °C). However, this represent an extra step, which appears to be far more time and cost consuming than a simple mineral addition. It has also to be kept in mind that for the same Ω_{Ar} threshold, the amount of TA that can be added will increase with lower temperature, as of higher CO₂ solubility and hence naturally lower Ω_{Ar} in colder waters. At a salinity of 35 and at 5 °C, about three times as much TA can be dissolved as opposed to a temperature of 30 °C.

5 Conclusions

440 *Ocean alkalinity enhancement* is a promising negative emission technology. In order to maximise carbon dioxide (CO₂) uptake efficiency, secondary calcium carbonate (CaCO₃) precipitation has to be avoided. Here, we show that an increase of total alkalinity (TA) by 500 $\mu\text{mol kg}^{-1}$ led to aragonite precipitation, reducing the CO₂ uptake potential from about 0.8 moles per mole of alkalinity added to less than 0.2 moles. Precipitation was most likely onto CaO and Ca(OH)₂ mineral phases prior to full dissolution. In contrast, an addition of 250 $\mu\text{mol kg}^{-1}$ of TA did not result in CaCO₃ precipitation, suggesting that an
445 aragonite saturation state (Ω_{Ar}) of about 5 is a safe upper limit. This is probably also the case for other minerals that would theoretically allow for higher TA additions as of potential precipitation onto naturally present mineral phases, such as resuspended sediments in coastal settings. Safely increasing the amount of TA that could be added to the ocean involves expanding to the open ocean by ships of opportunity, allowing major mixing and dilution of enriched seawater, equilibrating the seawater to atmospheric CO₂ levels during mineral dissolution, and targeting low rather than high temperature regimes.

450 Data availability

Data will be made available on a publicly available repository upon final publication.

Author contributions

CAM and KGS designed the initial experiments. All co-authors contributed to the initial data analysis and designing of follow-up experiments. CAM performed most of the sampling, and the data analyses with the help of KGS. CAM wrote the paper
455 with KGS, with inputs from their respective fields of expertise by all co-authors.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

460 We would like to thank Marian Bailey for her help with ICPMS sample preparation, as well as Dr Nick Ward for his help with preliminary X-ray Diffraction analyses of the calcium powders. We are also thankful to Dr Matheus Carvalho de Carvalho for the particulate carbon analyses and Nadia Toppler for her help arranging the use of the SEM.

Financial support

465 This research is part of the PhD project of CAM that is funded by a Cat. 5 – SCU Grad School scholarship from the Southern Cross University, Lismore, Australia. The ICPMS analyses were made possible by the Australian Research Council grants number LE200100022 by RJB and KGS, and LE120100201 obtained by RJB.

Table 1: Summary of experimental conditions. Please note that for comparability, more TA was added in the liquid than the sieved approaches to match the theoretical increases in calcium carbonate saturation state (see Methods section for details).

TA Agent	TA target ($\mu\text{mol kg}^{-1}$)	Comments	Amount added in mg (or mL*)	Amount of natural seawater in kg	mg kg^{-1} (or mL kg^{-1} *)	Theoretical TA addition ($\mu\text{mol kg}^{-1}$)	Experiment duration	Additional samples apart from TA and DIC
Sieved calcium minerals experiments								
CaO	250	Sieved in	15.50	2015.90	7.69	274.21	47 days	N/A
CaO	500	Sieved in	30.60	2004.50	15.27	544.42	47 days	TPC, POC and SEM samples
Ca(OH) ₂	250	Sieved in	19.90	2001.90	9.94	268.34	28 days	N/A
Ca(OH) ₂	500	Sieved in	37.40	2004.20	18.66	503.73	42 days	TPC, POC and SEM samples
Na₂CO₃, particles and filtration experiments								
Na ₂ CO ₃	1050	1M Na ₂ CO ₃ solution	1.05*	2000.60	0.52	1050.32	42 days	N/A
Na ₂ CO ₃	1050	1M Na ₂ CO ₃ solution, plus quartz powder after 2 days	1.05*	2000.30	0.5	1050.16	48 days	TPC, POC and SEM samples
Ca(OH) ₂	500	Sieved in, filtered after 4 hours	39.30	2004.30	19.61	529.30	48 days	N/A
Dilution experiments								
Ca(OH) ₂	500	1:1 dilution after 10min, 1 hour, 1 day and 1 week	101.60	5132.50	19.80	534.36	14 days	TPC, POC and SEM samples
Ca(OH) ₂	2000	1:7 dilution after 10min, 1 hour, 1 day and 1 week	155.90	2003.80	77.80	2100.21	48 days	TPC, POC and SEM samples

Table 3: Simulations of the changes in TA, DIC, Ω_{Ar} , pCO_2 and pH_T (total scale) after TA increases of 250, 500 and 1000 $\mu mol\ kg^{-1}$, assuming complete mineral dissolution without precipitation, a complete dissolution followed by as much $CaCO_3$ precipitated as the amount of TA added, and a complete dissolution followed by $CaCO_3$ precipitation until reaching an Ω_{Ar} of 2.0, before CO_2 re-equilibration to initial pCO_2 . For each scenario, the amount of moles of CO_2 absorbed per moles of TA added has been calculated for comparison. The 500 $\mu mol\ kg^{-1}$ TA addition simulation is shown in Figure A 3, Appendix. *Note: the value for Ω_{Ar} is rounded to 1.00 but calculated at 0.997.

	Starting Conditions (salinity = 35 19 °C)	TA +250 $\mu mol\ kg^{-1}$ No $CaCO_3$ precipitation	TA +500 $\mu mol\ kg^{-1}$				TA +1000 $\mu mol\ kg^{-1}$			
			No $CaCO_3$ Prec.	$CaCO_3$ Prec. = TA added	$CaCO_3$ Prec. until Ω_{Ar} of 2	CO_2 uptake to pCO_2 ~416 μatm	No $CaCO_3$ Prec.	$CaCO_3$ Prec. = TA added	$CaCO_3$ Prec. until Ω_{Ar} of 2	CO_2 uptake to pCO_2 ~416 μatm
TA ($\mu mol\ kg^{-1}$)	2350	2600	2850	2350	1748	1748	3350	2350	1320	1320
DIC ($\mu mol\ kg^{-1}$)	2100	2100	2100	1850	1549	1588	2100	1600	1085	1216
Ω_{Ar}	2.80	5.53	8.45	5.34	2.00	1.66	14.57	7.89	2.00	1.00*
pCO_2 (μatm)	416.2	175.1	91.5	135.6	319.2	416.4	29.6	48.2	144.81	416.7
pH_T	8.04	8.38	8.61	8.42	8.02	7.93	8.97	8.73	8.20	7.82
After re-equilibration, i.e., pCO_2 ~416 μatm										
Final TA ($\mu mol\ kg^{-1}$)	2350	2600	2850	2350	1748	NA	3350	2350	1320	NA
Final DIC ($\mu mol\ kg^{-1}$)	2100	2309	2517	2100	1588	NA	2926.5	2100	1216	NA
Final Ω_{Ar}	2.80	3.34	3.90	2.80	1.66	NA	5.14	2.80	1.00*	NA
Final pH_T	8.04	8.08	8.11	8.04	7.93	NA	8.17	8.04	7.82	NA
CO_2 uptake (mole/mole TA)	NA	0.84	0.83	0.50	0.08	NA	0.83	0.50	0.13	NA

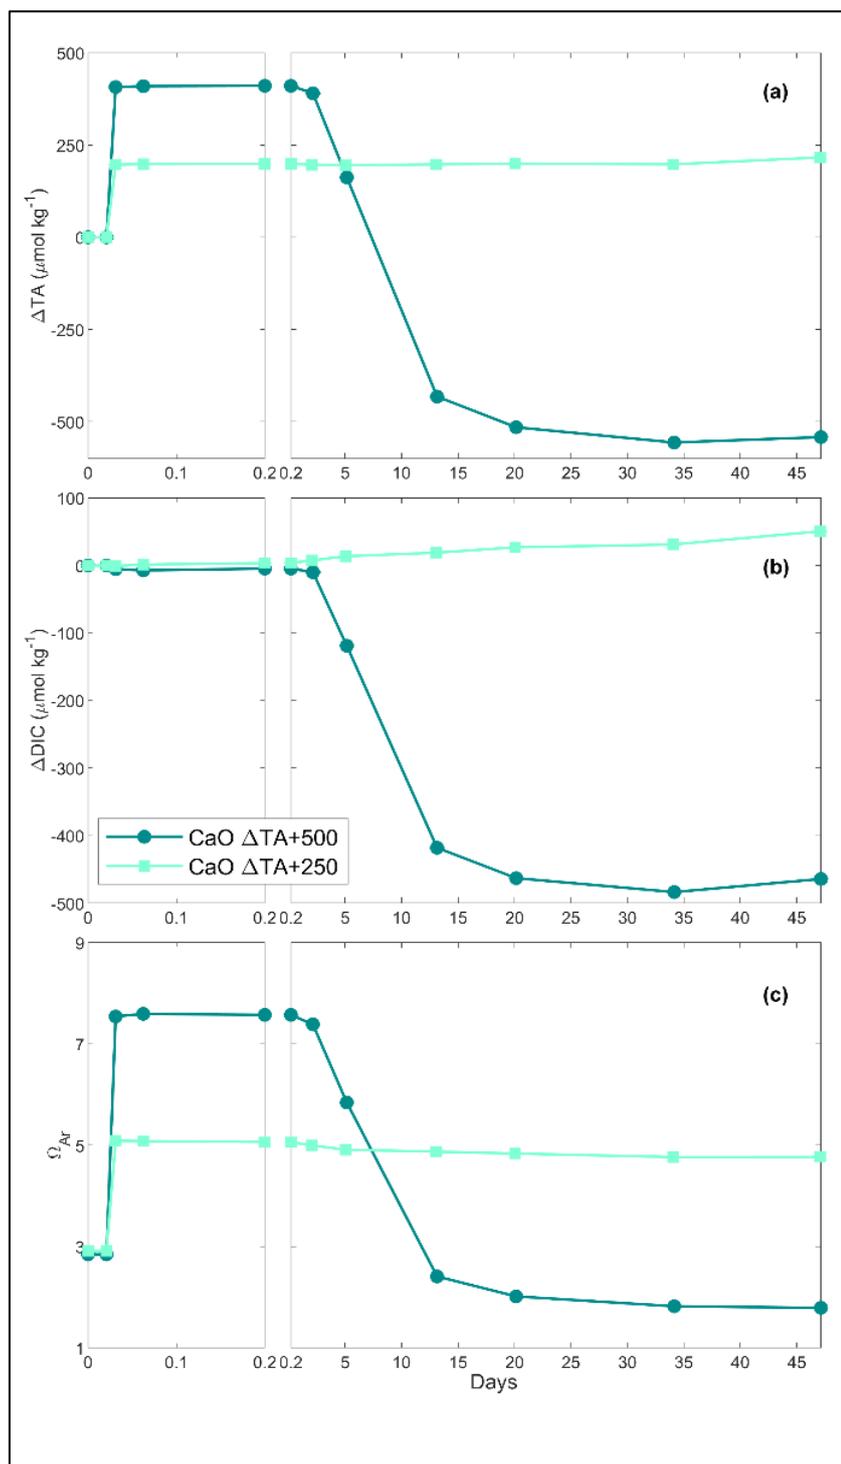

Figure 1: Changes in TA (a), DIC (b) and Ω_{Ar} (c) over time following two CaO additions.

590

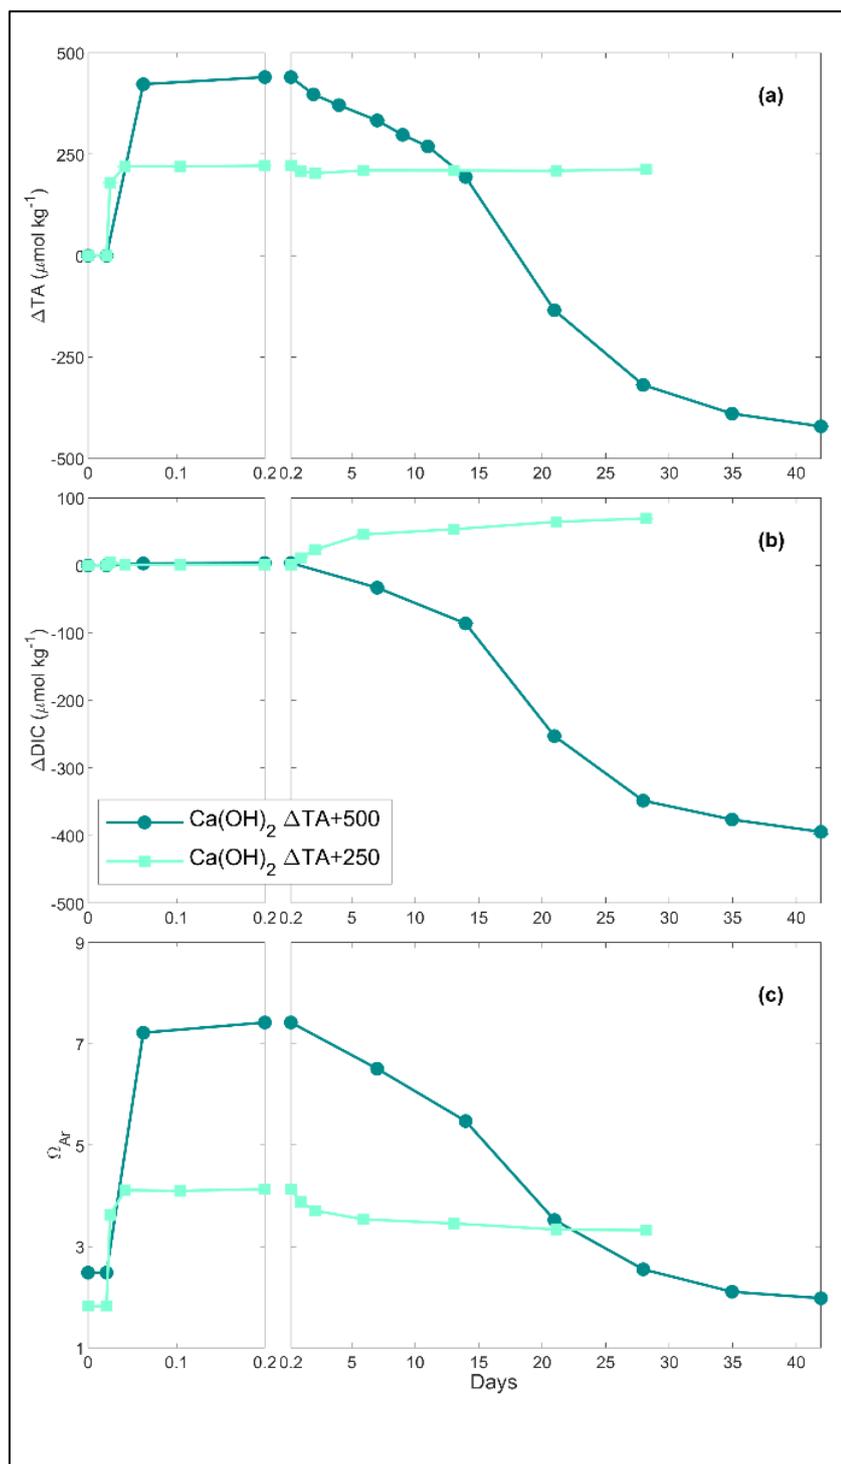

Figure 2: Changes in TA (a), DIC (b) and Ω_{Ar} (c) of the samples over time following two Ca(OH)_2 additions.

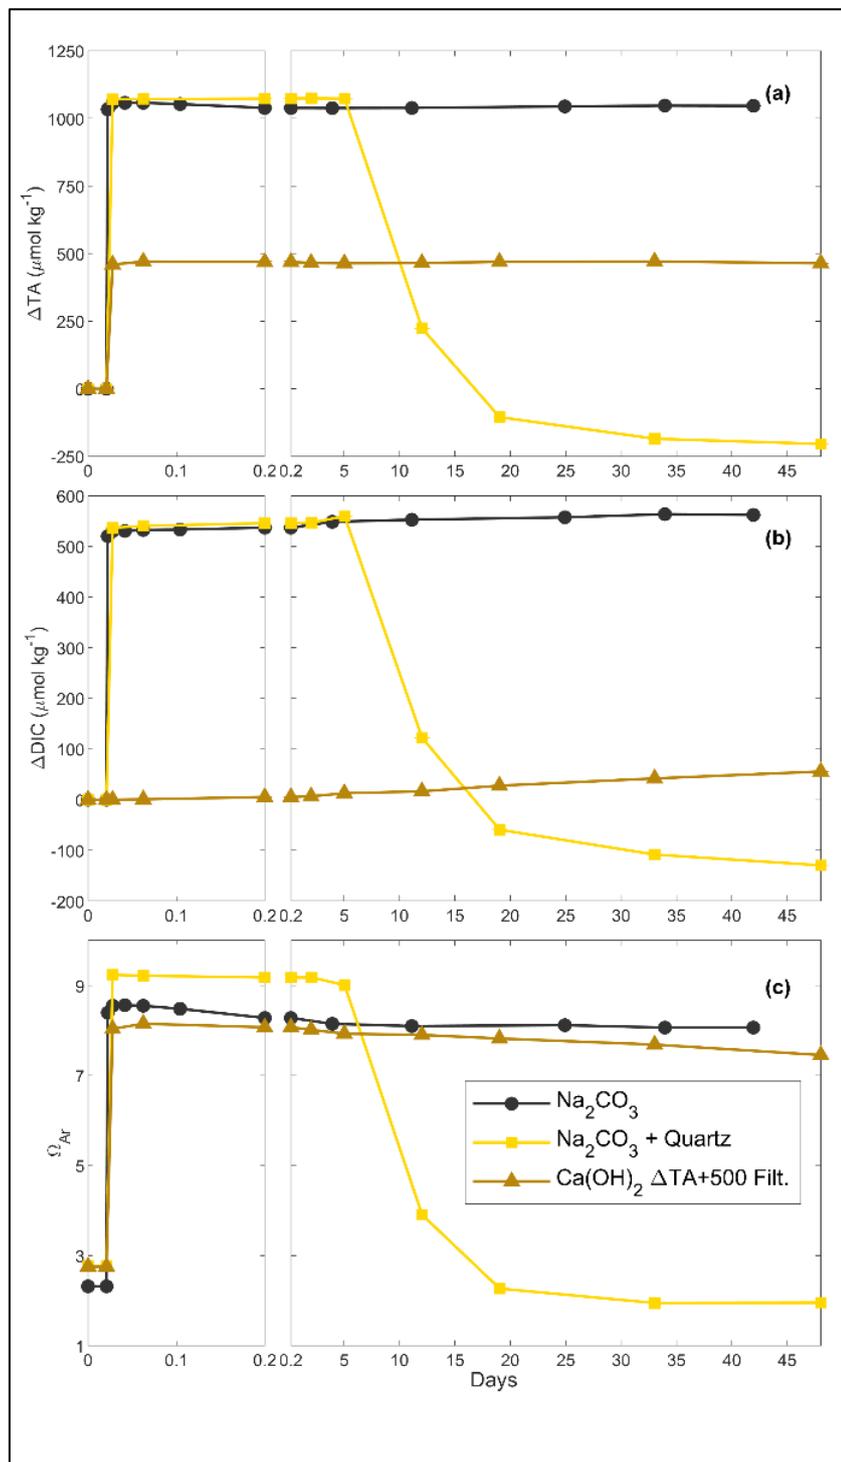

Figure 3: Changes in TA (a), DIC (b) and Ω_{Ar} (c) over time following additions of Na_2CO_3 , Na_2CO_3 plus quartz particles and $\text{Ca}(\text{OH})_2$ followed by a filtration step (see Methods for details).

595

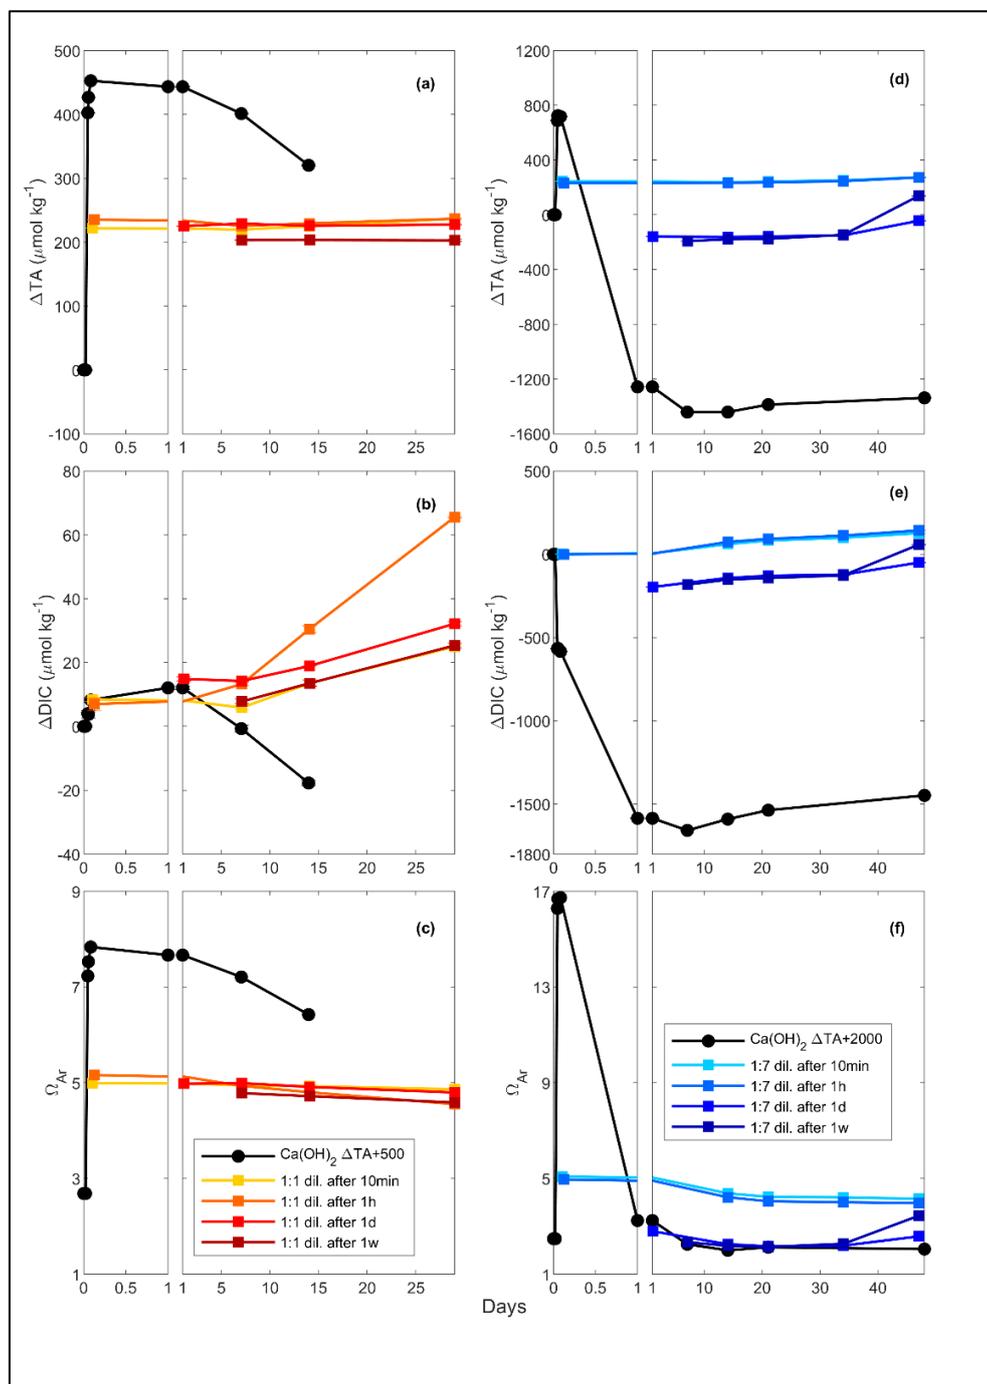

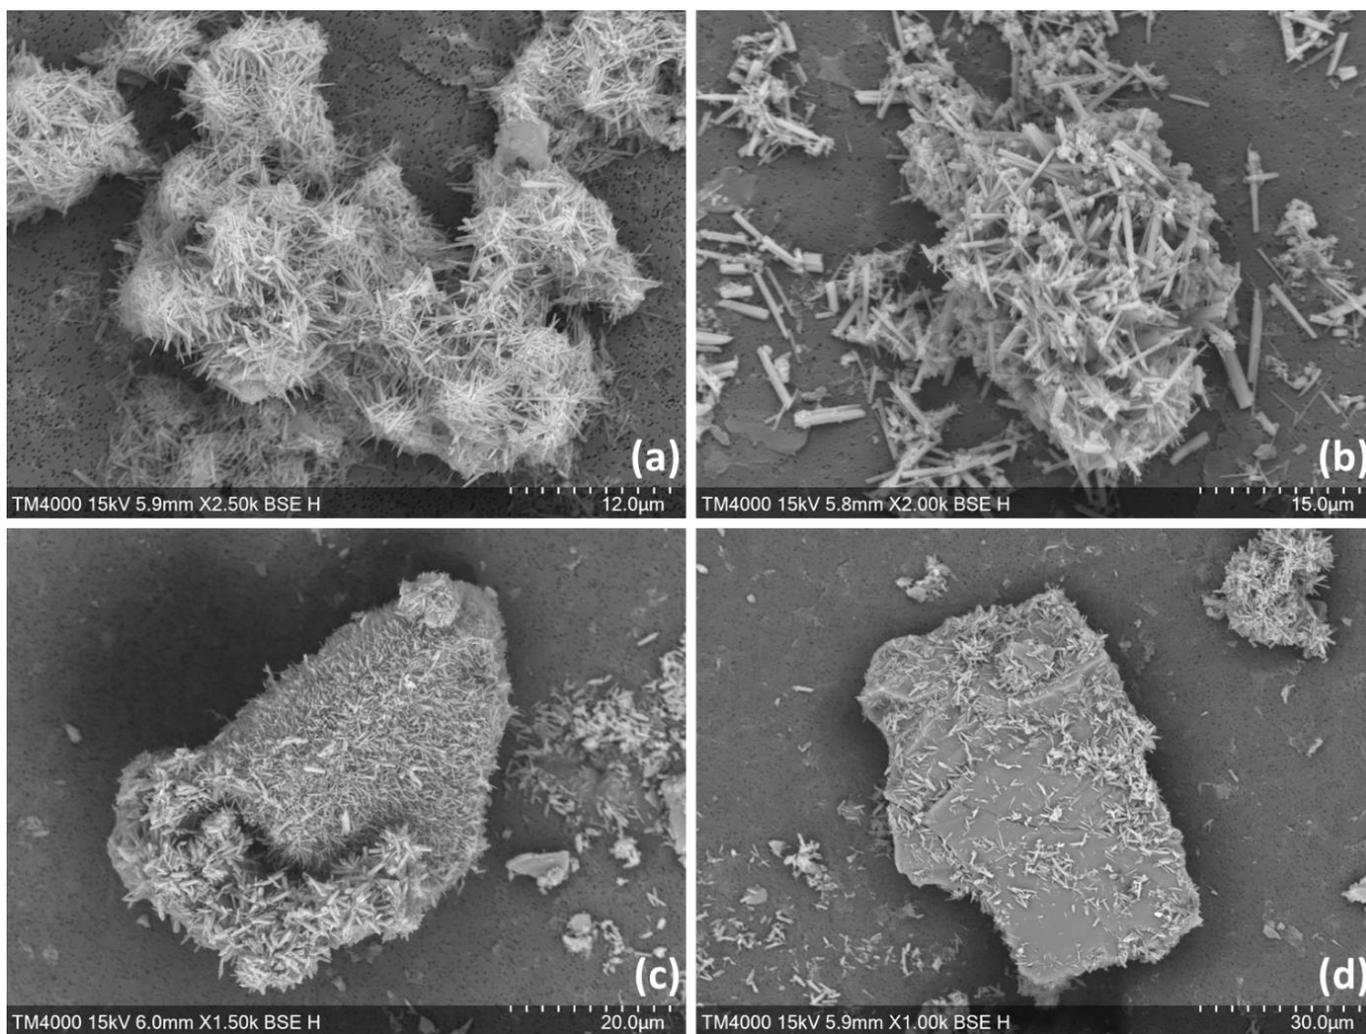

Figure 4: Changes in TA (a and d), DIC (b and e) and Ω_{Ar} (c and f) following a TA addition of 500 and 2000 $\mu\text{mol kg}^{-1}$ respectively, by Ca(OH)_2 (black line), as well as following a 1:1 dilution or the 500 $\mu\text{mol kg}^{-1}$ TA addition (red and yellow lines) and a 1:7 dilution for the 2000 $\mu\text{mol kg}^{-1}$ TA addition (blue lines). The dilutions were performed after 10 minutes, 1 hour, 1 day and 1 week and earlier dilutions are represented by lighter colours.

600

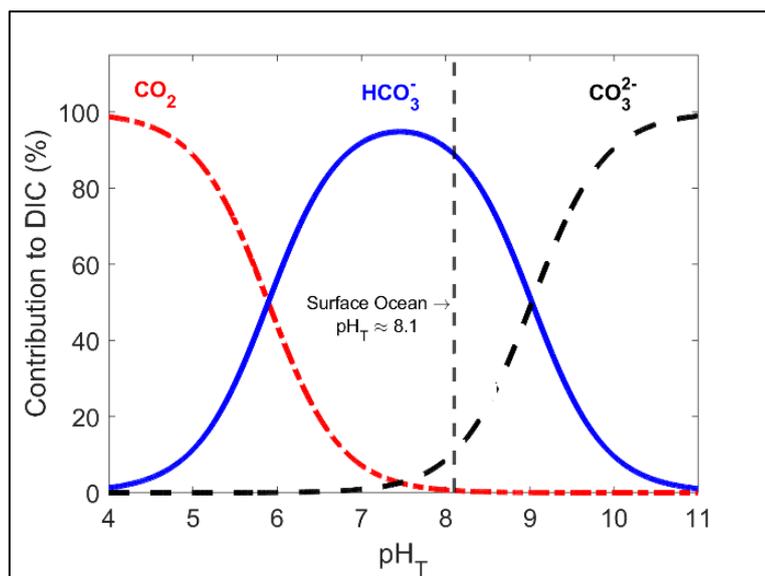

605 **Figure 5:** SEM images from experiments with an increase in TA of $\sim 500 \mu\text{mol kg}^{-1}$ by CaO (a), $\text{Ca}(\text{OH})_2$ (b) and with a TA increase of $\sim 1050 \mu\text{mol kg}^{-1}$ by 1M Na_2CO_3 , followed by quartz particles addition ((c) and (d)).

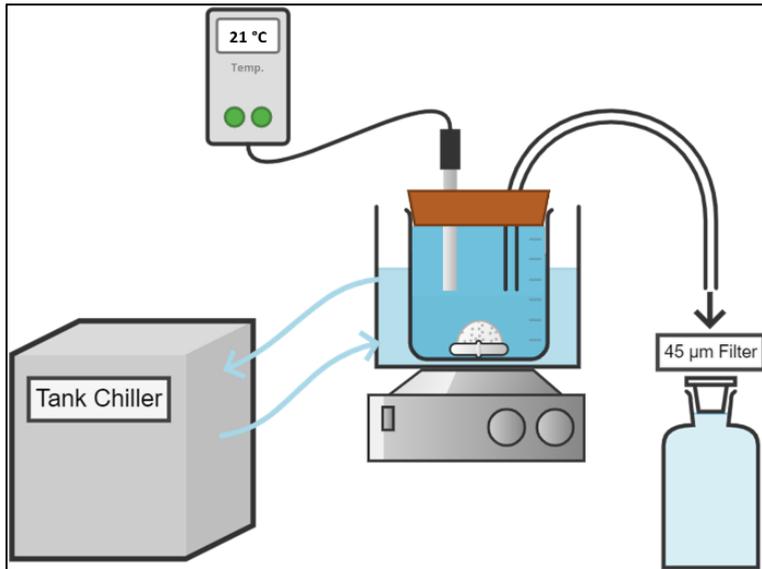

Appendix

610 **Table A 1: Main chemical composition of the CaO and Ca(OH)₂ powders used for the TA increase experiments determined by ICPMS analysis.**

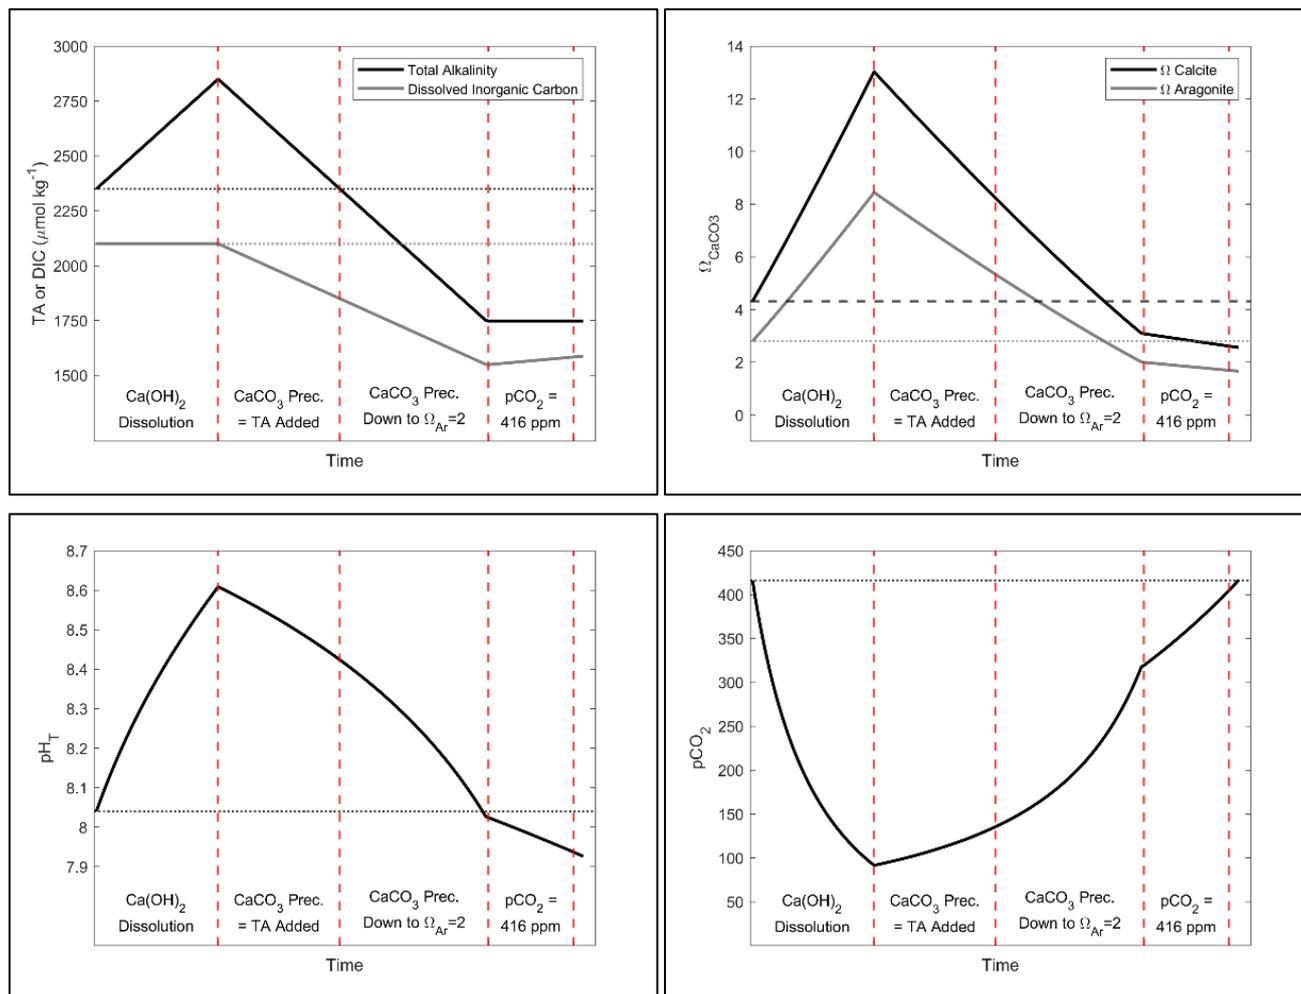

CaO Powder			Ca(OH) ₂ Powder		
Element	mg g ⁻¹	St. Dev.	Element	mg g ⁻¹	St. Dev.
Calcium	545.15	70.92	Calcium	529.79	117.30
Magnesium	2.10	0.23	Magnesium	6.87	1.98
Silicon	2.02	1.79	Silicon	2.70	1.12
Aluminium	0.50	0.19	Aluminium	1.98	0.77
Iron	0.32	0.10	Iron	0.91	0.34
Manganese	0.11	0.01	Potassium	0.43	0.23
Potassium	0.03	0.00	Titanium	0.07	0.03
Phosphorus	0.02	0.02	Manganese	0.05	0.01
Titanium	0.02	0.01	Phosphorus	0.04	0.01
Chromium	0.01	0.01	Bromine	0.03	0.01

615 **Figure A 1: Relative contribution of dissolved CO₂, HCO₃⁻ and CO₃²⁻ to total dissolved inorganic carbon in seawater as a function of pH_T (total scale), also known as Bjerrum plot (based on the carbonic acid equilibrium constant from Mehrbach et al. (1973) and refitted by Dickson and Millero (1987)), at 25 °C and salinity of 35, with the current surface ocean pH average represented by the dashed line (pH_T ~8.1).**

620 **Figure A 2: Conceptual diagram of the experimental setup used for the dissolution of alkaline minerals**

625

Figure A 3: Simulation of the changes in TA, DIC, Ω_{Ca} , Ω_{Ar} , pCO_2 and pH_T after addition of $500 \mu\text{mol kg}^{-1}$ of alkalinity. Four important steps are presented: first assuming the complete $\text{Ca}(\text{OH})_2$ dissolution without CaCO_3 precipitation, second assuming as much CaCO_3 precipitation as the amount of TA added, third assuming CaCO_3 precipitation happening until reaching $\Omega_{Ar} = 2.0$ and fourth CO_2 uptake until equilibrium is reached between atmospheric and seawater pCO_2 of ~ 416 ppm.

630

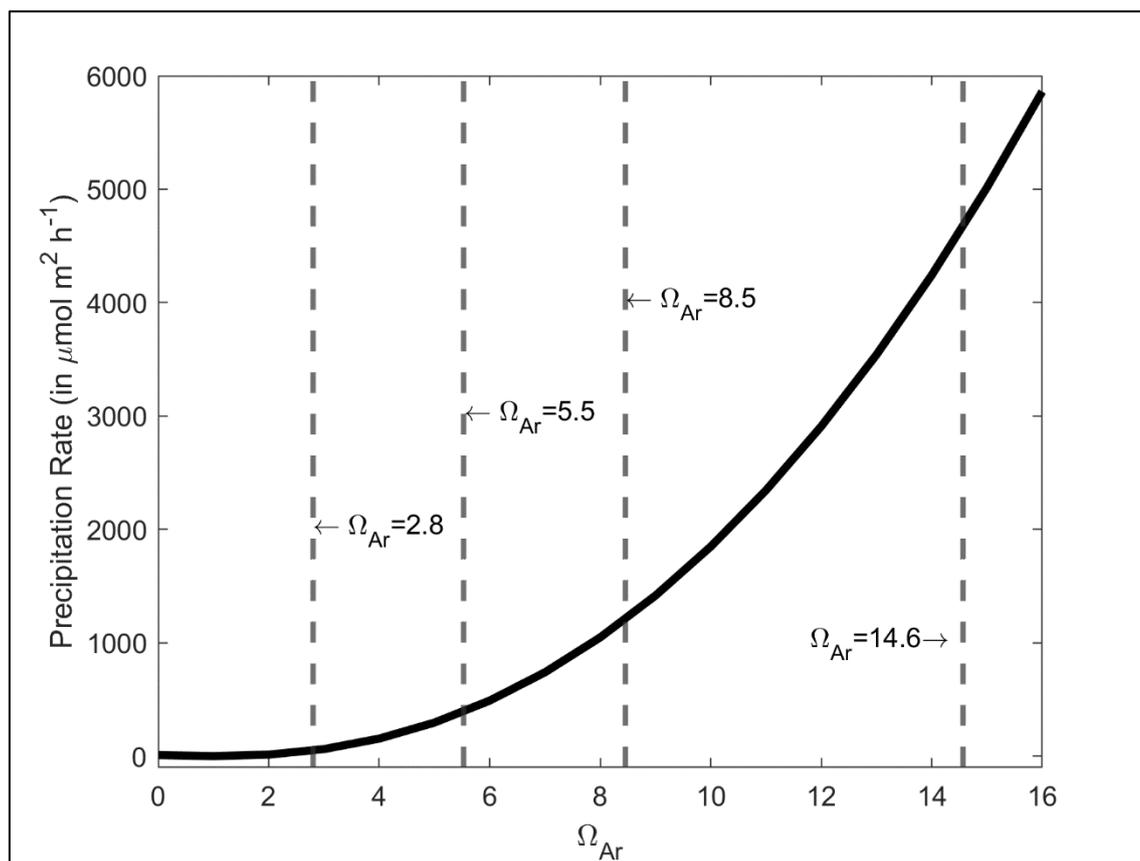

Figure A 4: Aragonite precipitation rate onto CaCO_3 seed crystals in $\mu\text{mol m}^{-2} \text{h}^{-1}$ as a function of Ω_{Ar} , based on the calculation of Zhong and Mucci (1989) at 25 °C and for a salinity of 35. The values of Ω_{Ar} for the starting conditions, following a +250, +500 and +1000 $\mu\text{mol kg}^{-1}$ TA increase are presented by the grey dashed lines, i.e., 2.8, 5.5, 8.5 and 14.6 respectively.
