Abstract

15 Advances in analytical chemistry have facilitated the characterization of dissolved organic matter (DOM), which has improved understanding of DOM sources and transformations in surface waters. For urban waters, however, where DOM diversity is likely high, the interpretation of DOM signatures is hampered by a lack of basic information. Here we explored the spatiotemporal variation of DOM composition in contrasting urban water bodies, based on spectrophotometry and fluorometry, size-exclusion chromatography and ultrahigh-resolution mass spectrometry, to
20 identify linkages between DOM signatures and potential drivers. The highly diverse DOM we observed distinguished lakes and ponds characterized by a high proportion of autochthonous DOM from rivers and streams with more allochthonous DOM. Seasonal variation was apparent in all types of water bodies, driven by the interaction between phenology and urban influences. Specifically, nutrient supply, the percentage of green space adjacent to the water bodies and point source pollution emerged as major urban drivers of DOM composition. Optical DOM properties also
25 revealed the influence of effluents from waste water treatment plants, suggesting their use in water-quality assessment and monitoring. Furthermore, optical measurements inform about processes both within water bodies and in their surroundings, which could improve the assessment of ecosystem functioning and integrity.

1 Introduction

30 Urban freshwaters typically receive high loads of organic carbon, nutrients and micropollutants, ranging from
pharmaceuticals and personal care products to industrial chemicals and more (Schwarzenbach et al., 2006). Although
routine wastewater treatment is increasingly effective, chemical stressors in urban freshwaters remain widespread.
Prominent reasons are pollution legacies (Baume and Marcinek, 1993 ; Ladwig et al., 2017) and continued uncontrolled
35 hydromorphological modifications. This includes the lateral and vertical disconnection from floodplains and aquifers
and results in large impacts on the extent and complexity of riverine habitat (White and Walsh, 2020). Furthermore,
the disruption of connectivity limits the self-purification capacity of urban surface waters (D'arcy et al., 2007), which
can lead to turbid water and visually unpleasant and potentially harmful algal blooms (Carpenter et al., 1998). This
and the resulting failure of citizens to recognize urban freshwaters as providers of ecosystem services (Huser et al.,
40 2016) calls for improved water management strategies that consider ecological in addition to hygienic and chemical
criteria (Gessner et al., 2014).

The concentration and chemical composition of dissolved organic matter (DOM), typically quantified as dissolved
organic carbon (DOC), are key characteristics of aquatic ecosystems. Both concentration and composition are governed
by allochthonous inputs and internal biological production and transformation processes (Williams et al., 2016).
45 Typically, however, water quality monitoring only considers concentration and bulk quality properties (e.g. biological
oxygen demand, BOD) as measures of DOM availability to, and degradation by, heterotrophic microbes (Jouanneau
et al., 2014). This narrow focus is at odds with the extreme diversity of DOM observed in freshwaters, where thousands
of compounds can be chemically distinguished (Kellerman et al., 2014; Peter et al., 2020; Stanley et al., 2012). This
high diversity and its spatio-temporal variation suggest much potential for DOM characteristics to provide insights
50 into the state of freshwater ecosystems in water quality assessment and monitoring.

Recent progress in analytical methods has increasingly enabled the detailed characterization of DOM to elucidate the
sources and fates in surface waters (Xenopoulos et al., 2021). Optical properties can inform not only about the chemical
characteristics of DOM but also, for example, about large-scale gradients in aquatic networks (Creed et al., 2015) or
the degree of aquatic-terrestrial ecosystem coupling (Sankar et al., 2020; Lambert et al., 2015; Yamashita et al., 2010;
55 Catalán et al., 2013). Fluorescence excitation-emission matrices (EEM) can be processed by parallel factor analysis
(PARAFAC) to identify independently fluorescing DOM components (Cory and Mcknight, 2005). Size-exclusion
chromatography partitions bulk DOM into molecular size fractions, which also tend to differ in origin and
bioavailability (Huber et al., 2011). Finally, the advent of ultrahigh-resolution mass spectrometry (FT-ICR-MS or
Orbitrap-MS) has greatly refined the characterization of DOM, revealing associations between compositional turnover
60 of DOM differing in molecular diversity and landscape-scale environmental gradients in lakes (Kellerman et al., 2014)
and rivers (Peter et al., 2020).

In the present study we explored variation in the chemical composition of DOM over time and space in contrasting
urban surface waters, hypothesizing that a detailed chemical characterization of DOM yields signatures of various

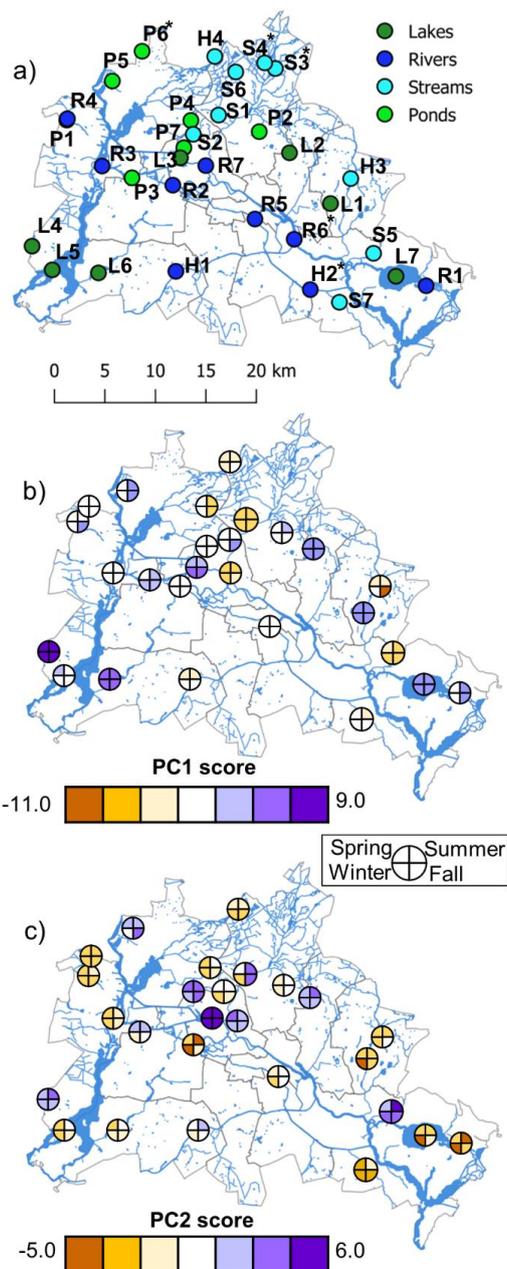

human influences. To this end, we explored linkages between chemical DOM composition and potential drivers
65 determining DOM signatures, including land cover, eutrophication and chemical pollution, which we captured by using
a suite of proxies. Our specific goals were to: (i) describe spatio-temporal patterns of DOM composition across a range
of urban freshwaters encompassing streams, rivers, ponds and lakes; (ii) identify environmental factors accounting for
the observed patterns; and thereby (iii) explore how information on DOM composition could be included in urban
freshwater assessment and monitoring.

70 2 Methods

2.1 Study sites

The study was conducted in 32 freshwater sites located in the city of Berlin, Germany. Nearly 6.5% of the municipal
area (889 km²) is covered by freshwaters. These comprise 60 lakes (>1 ha), about 500 ponds, two slow-flowing lowland
rivers, the Rivers Spree and Havel, and numerous streams, ditches and canals. Selection of the 32 study sites followed
75 a stratified random sampling design (Fig. 1a, Supporting Information Table S1). Based on geographical information
for Berlin's water bodies, we randomly selected 7 sites in each of 4 strata: lakes, ponds, rivers and streams. Monitoring
data on water chemistry (Berlin city administration, SenUVK 2009-2014) were used in a cluster analysis to identify
highly polluted sites. These were excluded from the pool used for randomly selecting study sites. Instead, two such
rivers (H1 and H2) and two streams (H3 and H4) were deliberately added as polluted sites to lengthen the
80 environmental gradient.

We repeatedly sampled all 32 sites in each of four campaigns conducted over an annual cycle, first in spring (April-
May 2016), then in summer (July-August 2016), autumn (September-October 2016) and winter (February-March
2017). We also obtained data on land use from the Berlin city administration (Senate Administration for Environment,
2017), which we used to calculate the proportion of paved and green areas within 50-m buffer strips adjacent to each
85 of the selected water bodies using open-source geoinformation software (QGIS Development Team, 2017, Open
Source Geospatial Foundation Project. <http://qgis.osgeo.org>).

90

Figure 1 Map of 32 sampling sites in the city of Berlin, including 7 lakes (dark green), 7 ponds (light green), 9 streams (light blue), and 9 rivers (dark blue), including two heavily polluted stream sites and two heavily polluted river sites (a), and PCA scores for these sites in four different seasons (b, c). Site codes are given in Table S1. Sites marked by asterisks (*) were restricted to 3 seasons and hence excluded from the PCA.

2.2 Physico-chemical field measurements and water sampling

95 During each field visit, we measured water temperature, pH, the dissolved oxygen (DO) concentration and electrical
conductivity using a hand-held WTW Multiprobe 3320 (pH320, OxiCal-SL, Cond340i, Weilheim, Germany) or a
smarTROLL probe (In-Situ, Fort Collins, CO, USA). We also collected integrative water samples (2 L) from the upper
0.5 m water layer for chlorophyll-*a* and DOM analyses. The water was kept cool in acid-washed polycarbonate Nalgene
bottles placed in a cooling box pending filtration in the laboratory (GF75, 0.3 μm average pore size; Advantec, Tokyo,
100 Japan) within 6 hours after sampling. Additional volumes of surface water were filtered through pre-combusted glass
fiber filters (GF75) directly in the field. These filters were placed into acid-washed pre-combusted (450 $^{\circ}\text{C}$, 4h) glass
vials (15-20 mL) sealed with a PTFE septum in a screw-cap for later measurements of dissolved organic carbon (DOC)
concentrations, DOM fluorescence and absorbance, and DOM molecular size distribution. The water passed through
the filter was collected in acid-washed polyethylene tubes for analyses of soluble reactive phosphorus (SRP), nitrate
105 (NO_3^-), nitrite (NO_2^-), ammonium (NH_4^+) and trace organic compounds (TrOCs). We also took unfiltered water
samples for total phosphorus (TP) analysis. For each variable, we collected three replicate samples at each site in each
season. We stored all samples in the dark in a cooling box during transport. To preserve samples and remove all
inorganic carbon, we acidified (pH 2) the water for DOC, NO_3^- , NO_2^- and NH_4^+ analyses with 2 M HCl within 6 hours
after sample collection. DOC concentrations and DOM fluorescence and absorbance were measured within 24 h.
110 Filtered water for analyses of SRP, NO_3^- , NO_2^- , NH_4^+ and TrOCs was frozen at -20°C .

2.3 DOM characterization

DOM absorbance and fluorescence were simultaneously determined on an Aqualog instrument (Horiba Ltd, Kyoto,
Japan). We used the absorbance spectra to calculate several indexes (Table A2): the specific UV absorption (SUVA_{254})
as a proxy for DOM aromaticity (Weishaar et al., 2003), the ratio of absorbance at 250 and 365 nm (E2:E3) as an
115 (inverse) indicator of molecular size (Peuravuori and Pihlaja, 1997), the ratio of E4:E6 as an indicator of humification
(Chen et al., 1977), the short-wavelength slope within the wavelength region of 275-295 nm (Helms et al., 2008) as an
inverse correlate with molecular weight and aromaticity, and the ratio of slopes (SR) computed from short and long
wavelength regions (Loiselle et al., 2009) as another negative correlate with DOM molecular weight. We used the
fluorescence data to compute the freshness index β/α (Table A2) (Wilson and Xenopoulos, 2009), which indicates the
120 relative importance of recently produced DOM (Parlanti et al., 2000). Furthermore, we calculated the fluorescence
index (FIX) as the ratio of fluorescence intensities at the emission wavelengths of 470 and 520 nm (obtained at
excitation wavelength of 370 nm), which has proved useful to distinguish the relative contributions of terrestrial
(FIX~1.4) and aquatic (FIX~1.9) sources of DOM (Mcknight et al., 2001). Finally, we computed the humification
index (HIX) as a proxy for humic substances (Ohno, 2002). Fluorescence excitation-emission matrices (EEMs) were
125 used for PARAFAC analysis, a multivariate three-way modeling approach decomposing EEMs into individual
fluorophores (Bro, 1997; Stedmon and Bro, 2008). We derived 8 components from a total of 116 EEMs and compared
their loading spectra with the OpenChrom/OpenFluor database (<http://www.openfluor.org>) (Murphy et al., 2014). See
Supporting Information for details of data processing, including PARAFAC analysis.

130 The molecular size distribution of DOM was analyzed by liquid size-exclusion chromatography in combination with
UV and IR detection of organic carbon and UV detection of organic nitrogen (LC-OCD-OND) (Huber et al., 2011).
We determined concentrations of three molecular size fractions: humic-like substances (HS-C and HS-N reported in
mg C L⁻¹ and mg N L⁻¹, respectively), high-molecular weight non-humic substances (reported as HMWS-C and
HMWS-N, in mg C L⁻¹ and mg N L⁻¹) and low-molecular weight substances (LMWS, in mg C L⁻¹).

135 To examine the molecular composition of DOM, we used ultrahigh-resolution Fourier-Transform Ion Cyclotron Mass
Spectrometry (FT-ICR-MS). We extracted DOM on Agilent Bond Elut PPL solid-phase columns (Dittmar et al., 2008)
from 1 L of filtered water acidified to pH 2. We then diluted extracts to 10 µg L⁻¹ C in 1/1 ultrapure water/methanol
before broadband mass spectrometry on a 15 Tesla Solarix FT-ICR-MS (Bruker Daltonics, Bremen, Germany) in
electrospray ionization negative mode (300 accumulated scans, ion accumulation time of 0.1 s, flow rate of 240 µL/h).
140 We performed internal mass calibration and exported the raw mass lists from 150 to 1000 Da for further data processing
using previously established R code (Del Campo et al., 2019). Briefly, we first applied a method detection limit similar
to Riedel & Dittmar (Riedel and Dittmar, 2014) before aligning m/z values across samples (Del Campo et al., 2019).
Subsequently, we assigned chemical formulas to mean m/z values assuming single-charged deprotonated molecular
ions and Cl-adducts for a maximum elemental combination of C₁₀₀H₂₅₀O₈₀N₄P₂S₂, respecting chemical constraints and
using rigorous mass error assessments, stable isotope confirmation and homologous series assessment (Del Campo et
145 al., 2019). More detail of the FT-ICR-MS methods can be found in the Supplement material. To condense the mass-
spectrometric information, we derived 12 molecular groups (Lesaulnier et al., 2017) based on elemental composition
and calculated the average molecular mass, number of formulas (molecular richness) and total intensity for each of
them. In addition, we computed the double-bond equivalents (DBE) and the aromaticity index (AI) as indicators of
unsaturated compounds (Koch and Dittmar, 2006), and the molecular lability boundary (MLB) as a measure of lability
150 (D'andrilli et al., 2015).

2.4 Additional water-chemical analyses

We determined total DOC concentrations by high-temperature catalytic combustion and infrared spectrometry on a
TOC-V Analyzer (Shimadzu, Kyoto, Japan). NO₃⁻, NO₂⁻ and NH₄⁺ were analyzed on a FIAcompact (MLE GmbH,
Dresden, Germany). TP was measured using the same technique with unfiltered water samples that were digested with
155 K₂S₂O₈ (30 min at 134 °C). We measured chlorophyll-*a* concentrations spectrophotometrically (HITACHI U2900;
Tokyo, Japan) following hot ethanol extraction (Jespersen and Christoffersen, 1987) of three GF75 filters from each
individual water sample. Concentrations of 18 trace organic compounds (TrOCs) were determined by HPLC-MS/MS
(Shimadzu, Kyoto, Japan) (Zietzschmann et al., 2016). These included chemicals such as acesulfame (a sweetener),
benzotriazole (a corrosion inhibitor), and drug residues like carbamazepine and gabapentin (Table B1).

160 2.5 Data analysis

We used repeated-measures ANOVA to test for differences among types of water bodies and seasonal sampling periods
(referred to as seasons hereafter) for a variety of response variables; there was non-significant interaction between
water body type and season. Further, we assessed the importance of seasonal variation in each water body type by

165 computing a respective variance component using a type-II ANOVA (aka variance component analysis) for data from
each water body type with season and site-ID as random factors; this approach assesses temporal variation as a fraction
of total variation within each water body type.

For constrained multivariate analyses we considered land cover adjacent to the water bodies, trophic state and
micropollutant load as drivers of variation in DOM chemical composition. We used the percentages of urban green
and paved areas as a proxy for land cover and assessed trophic state based on concentrations of TP, NH_4^+ , NO_3^- and
170 chlorophyll *a*. Finally, the first axis of a principal component analysis (PCA) based on the TrOC dataset was used as
a proxy for micropollutant load.

We followed a three-step approach to analyze the spatio-temporal patterns of DOM composition: First we identified
major axes of variation in DOM composition by a PCA based on quantitative indicators of DOM, analytically
accessible fractions thereof or quantitative proxies: DOC concentration, all absorbance and fluorescence data, absolute
175 component-specific fluorescence intensities from PARAFAC, and the results from size-exclusion chromatography.
Only the 27 sites sampled in all four seasons were included in this analysis. All variables were standardized to a mean
of zero with a variance of 1 to ensure equal weightings, and projected onto the ordination space using Pearson
correlations of the variables with PCA axes in a distance biplot *sensu* Legendre and Legendre (2012). To explore
spatial patterns, we mapped PC1 and PC2 scores onto Berlin's landscape using QGIS (QGIS Development Team,
180 2017, Open Source Geospatial Foundation Project; <http://qgis.osgeo.org>).

Second, we used the same dataset as dependent matrix in a redundancy analysis (RDA) with the set of potential drivers
described above as predictor variables. We started with the full RDA model and forward-selected drivers (Legendre
and Legendre, 2012). For hypothesis tests in the RDA, permutations were restricted to account for repeated
measurements at the same sites across seasons by first permuting sets of four seasonal measurements across sites and
185 then permuting across seasons within each site. To check our ability to identify drivers behind major variation observed
in DOM composition, we used Procrustes analysis to assess the similarity of PCA and RDA ordinations, including a
permutation-based test of the non-randomness of the achieved superimposition (Mardia, 1979; Peres-Neto and
Jackson, 2001).

Third, we exploited results of the FT-ICR-MS to facilitate interpretation of the two major axes of variation in DOM
190 chemical composition resulting from the PCA. The FT-ICR-MS data were only available for three seasons and were
purely compositional (relative intensities), as the many thousands of compounds contained in the spectra cannot be
calibrated to yield concentrations. To link the quantitative and compositional datasets, we correlated scores of PCA
axes with compound-specific relative intensities of the mass spectra. The compound-specific correlation coefficients
were then used as color codes in van Krevelen plots, which locate chemical formulae identified by FT-ICR-MS in a
195 space defined by oxygen richness (O:C) and saturation (H:C). FT-ICR-MS-derived information such as the richness
or average weight of specific molecular groups were also projected onto the PCA ordination space as arrows, provided
correlation coefficients were >0.2 . All statistical analyses and graphs were made with R 3.2.4 (R Core Team, 2016).

3. Results

3.1 Physico-chemical characteristics

200 Among all physico-chemical variables, only DOC concentration and temperature differed significantly among types
of water bodies ($p < 0.05$ and $p < 0.001$, respectively). Temperature varied strongly across seasons, but still proved
significantly different among water body types, with lakes and rivers being warmer than ponds and streams. DOC
concentrations did not vary across seasons, but were significantly higher in ponds and streams than in lakes and rivers.
205 Ponds also showed the highest chlorophyll-*a* concentrations and rivers the lowest, but these differences were not
significant.

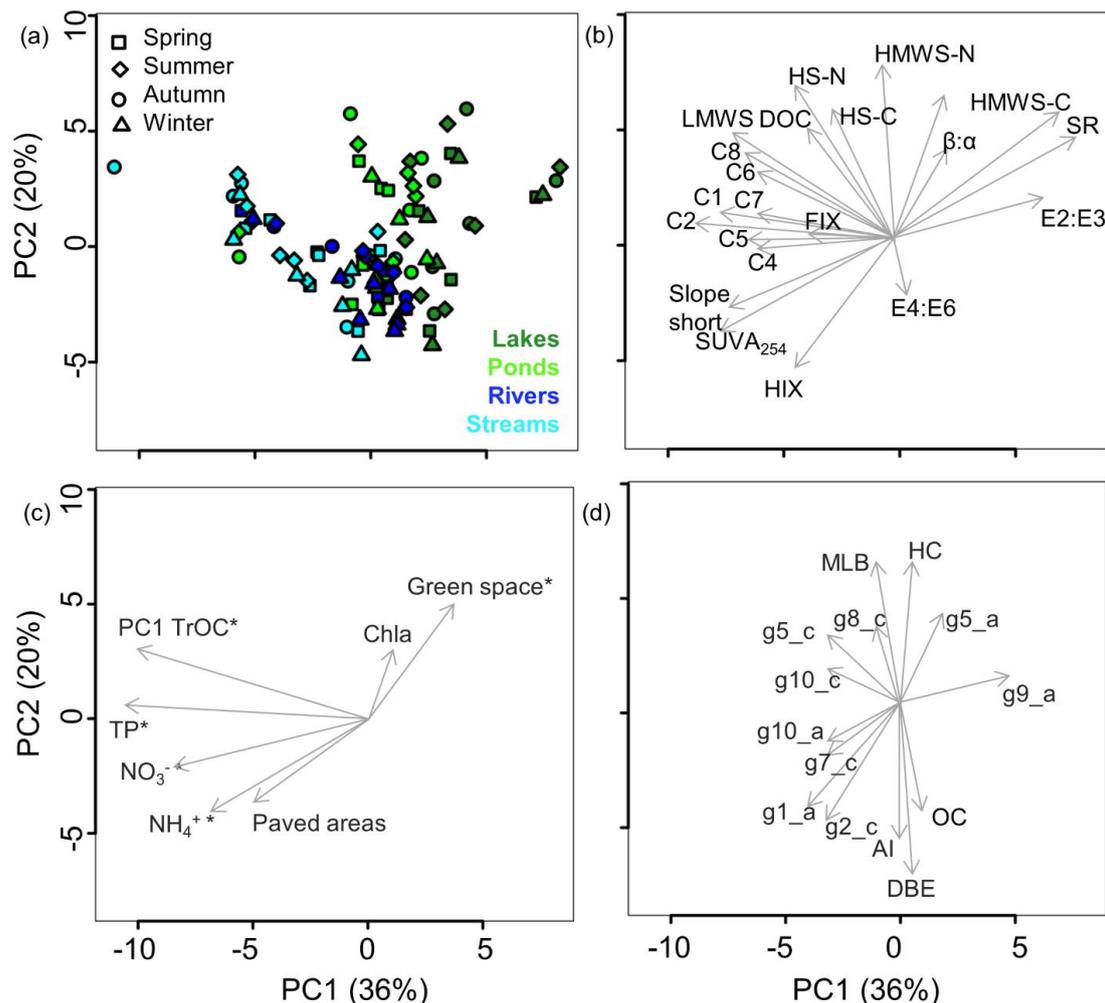

Separate ANOVAs for each water body type showed that seasonal variation in TP and NH_4^+ concentrations was highest
in rivers and streams. Seasonal variation in NO_3^- concentrations was generally high, but systematic differences were
neither detected among seasons nor sites (Table A1). Seasonal variation of chlorophyll-*a* concentrations was also high
and similar across types of water bodies.

210 The analysis of TrOCs identified acesulfame, a widely used artificial sweetener (Buerge et al., 2009), in 72 out of a
total of 120 samples taken at 32 sites across all seasons (Table B1). Similarly, two corrosion inhibitors included in the
analysis, benzotriazole and methylbenzotriazole (Cotton and Scholes, 1967; Tamil Selvi et al., 2003), occurred in 68
and 63 samples, respectively. Fifteen other TrOCs were detected in at least 2 and up to 62 samples (Table B1). Rivers
showed the highest concentrations throughout the year. The first principal component of the PCA considering all
215 TrOCs explained 61% of the total variance (Fig. B1) and separated streams and rivers with higher concentrations from
ponds and lakes where concentrations of TrOCs were lower and often undetectable, particularly in ponds (Table B2).

3.2 DOM composition

PARAFAC modeling resulted in 8 components referred to as C1-C8 (Table A3, Fig. A1). Components C6 and C8
were previously found to be protein-like, whereas all other components have been reported as humic-like (Table A3).
220 In contrast to the standard physico-chemical variables we measured and the size-exclusion chromatography (Table
A6), the PARAFAC components and absorbance and fluorescence indices generally showed significant differences
among water body types (Table A4 and A5).

The first axis of the PCA analyzing spatio-temporal patterns of DOM chemical composition explained 36% of the total
variance (Fig. 2). PC1 was largely defined by the negative loadings for C2 and C1 (representing humic substances
225 originating from waste water treatment), the short-wavelength slope, SUVA_{254} and LMWS (Fig. 2b). Furthermore,
PC1 correlated positively with the absorption slope ratio, E2:E3 (molecular size), β/α and HMWS-C. This axis
separated water body types, from lakes on the right to ponds, rivers, and finally streams on the left. The optical proxies
identified PC1 as a gradient spanning from lakes, where DOM had lower aromaticity and contained more freshly
produced material, to streams, which showed high aromaticity and low proportions of fresh DOM. Pond P4, which
230 was identified as an outlier because of particularly high NH_4^+ concentrations, also showed a rather distinct DOM
composition.

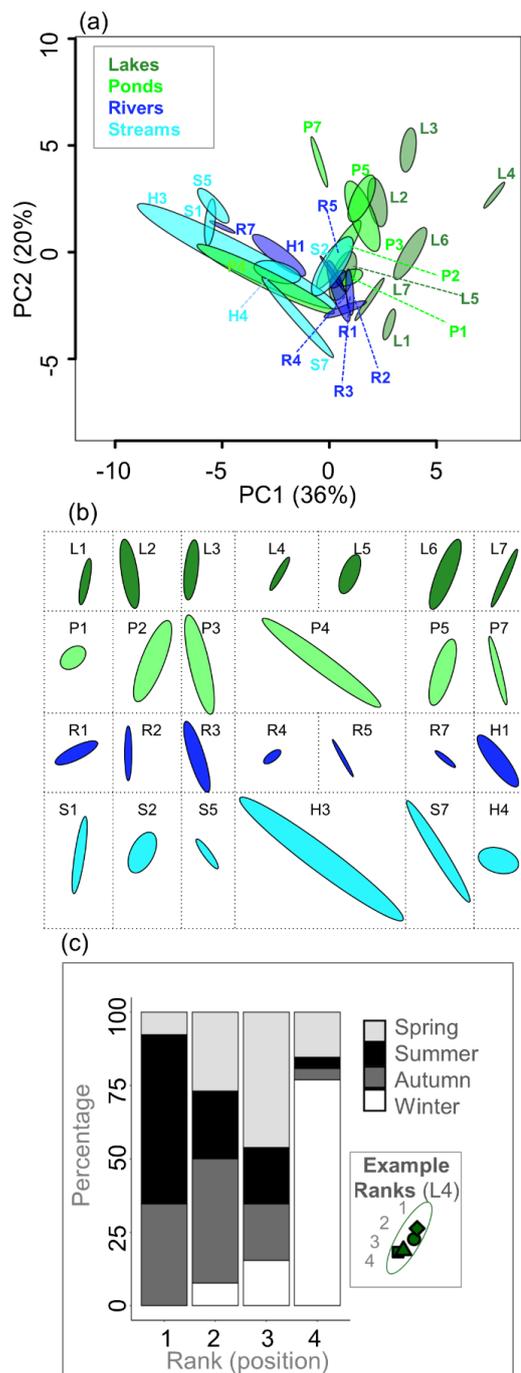

235 Figure 2 Ordination of sites (a) by PCA based on DOM characteristics (b): (i) indices derived from measurements of
 absorbance (E2:E3 indicating molecular size, E4:E6 representing the humification ratio, the slope ratio SR, and SUVA₂₅₄)
 and fluorescence (freshness index $\beta:\alpha$, fluorescence index FIX, short-wavelength slope, and humification index HIX), (ii)
 PARAFAC components C1 to C8, and (iii) data from size exclusion chromatography (humic-like substances HS, high-
 240 molecular weight non-humic substances HMWS, low-molecular weight substances LMWS). (c) RDA constraints mapped
 onto the PCA ordination, with the significant constraints marked by an asterisk (*). (d) FT-ICR-MS-derived indices and
 molecular groups mapped onto the PCA ordination representing only groups correlated with PC1 or PC2 ($r > 0.2$; oxygen
 richness O:C, saturation level indicated by H:C, double-bond equivalents DBE, aromaticity index AI, molecular lability
 boundary MLB, molecular groups g1 and g2 indicating black carbon without and with heteroatoms, g5 consisting of
 245 unsaturated aliphatics, g7 representing saturated fatty acids, g8 and g9 denoting carbohydrates without and with
 heteroatoms N, S or P, and g10 comprising peptides). The molecular group measures are either average masses (am) or
 counts of molecules (co).

245

PC2 explained an additional 20% of the total variance and correlated positively with HMWS (mg N/L) and β/α , and negatively with HIX. An exploration of spatio-temporal variation by plotting site-specific PC scores (Fig. 3) identified PC2 as the axis capturing temporal variation, with the four seasons aligning vertically at most sites. Winter and summer had the lowest and highest PC2 scores, respectively, with transitional seasons located in between. Thus, higher proportions of humic substances in winter contrast with more labile DOM in summer. In agreement with the variable-specific seasonal variance components, the degree of seasonal differentiation differed among water body types also in multivariate space, being higher in streams and ponds than in the larger lakes and rivers (Fig. 3b). Except for sites P4 and H3, two water bodies behaving exceptionally also in many other respects, seasonal variability was poorly reflected by PC1, which largely captured variation among individual water bodies or water body types, separating flowing from standing waters. Visual inspection of PCA scores mapped across Berlin (Fig. 1b,c) did not reveal a spatial signature transcending types of water bodies. RDA identified the areal percentage of green space adjacent to the water bodies, TP, NH_4^+ , NO_3^- and the first axis of the PCA based on TrOCs as significant predictors of DOM composition (Fig. C1). The resulting PCA and RDA ordinations for DOM were significantly correlated (Procrustes rotation 0.73, $p < 0.001$), suggesting that the considered predictors were indeed major drivers of variation in DOM chemical composition.

260

Figure 3 (a) PCA biplot based on DOM absorbance and fluorescence indices, PARAFAC components and size exclusion chromatography data from 4 contrasting types of urban freshwater bodies, including lakes, ponds, rivers, and streams, in

265 addition to two streams and two rivers specifically selected as highly polluted sites. Each of the ellipses represents one
sampling site that was visited 4 times, once in each season. Site codes are given in Table S1. (b) Visual comparison of site-
specific seasonal variation based on the size, shape and orientation of ellipses, plotted separately per site. (c) Seasonal
variation across sites illustrated by ranking the sampling dates at each site according to the PC2 scores, as shown in the
inset. The stacked histograms show frequencies of the seasons across the four ranks. Summer samples tend to produce high
scores at most sampling sites, whereas winter samples tend to score low.

270 High-resolution mass spectrometric analyses of samples from three seasons provided additional insights into the
chemical composition of DOM. Overall, we detected 6446 molecular formulas, most of them representing molecular
groups typical of humic material derived from soils. This includes highly unsaturated O-rich compounds, polyphenols
and other aromatic structures, followed by unsaturated aliphatic polyphenols, and polycyclic aromates with aliphatic
chains. The van Krevelen plots revealed a positive correlation of lignin-like molecules and carbohydrates with PC1 of
DOM and identified these molecules as abundant in lakes (Fig. A2). In contrast, the negative association of proteins
275 with PC1 was typical of streams. Information on the molecular groups identified by FT-ICR-MS and projected on the
PCA space (Fig. 2d) showed carbohydrates and sugars containing N, S or P to be positively related to PC1.
Furthermore, PC1 was negatively related to black carbon, polyphenols and polycyclic aromatic compounds with
aliphatic chains, which are all typical of soil-derived humic material, as well as with unsaturated aliphatics, saturated
fatty acids and peptides, indicating that all of these molecular groups were more important in streams. Lastly, the
280 computed molecular lability boundary (MLB), carbohydrates, sugars without heteroatoms (N, S or P) and unsaturated
aliphatics were positively related to PC2, while AI, DBE, black carbon and polyphenols were negatively related to
PC2.

4. Discussion

4.1 Spatial patterns and drivers of DOM signatures

285 Our results show that the chemical composition of DOM in contrasting surface waters of the metropolitan area of
Berlin, Germany, is highly diverse. This reflects both aquatic-terrestrial linkages and DOM transformations within the
aquatic systems (Fonvielle et al., 2021) and suggests a high ecosystem-level functional diversity across the urban
aquatic network. Clear differences among the four types of water bodies we investigated were due to distinct signatures
of streams and rivers vs. ponds and lakes. This was revealed especially by the first principal component (PC1) of a
290 PCA (Fig. 2), which reflects the dominant gradient defined by variation in DOM composition across the 32 urban sites
included in the study.

Stream DOM exhibited higher aromaticity (as indicated by $SUVA_{254}$) and lower amounts of recently produced, low-
molecular DOM (as indicated by the freshness index or the slope ratio) than lakes at the opposite end of the gradient.
This pattern matches results from agricultural streams near Berlin, where $SUVA_{254}$ values up to $3 \text{ L m}^{-1} \text{ mg}^{-1}$ have
295 been reported (Graeber et al., 2012) and from an urban river in southwestern Korea ($SUVA_{254}$ values of $2.5 \text{ L m}^{-1} \text{ mg}^{-1}$)
(Park, 2009). The distinct signature is also reflected in other DOM components, such as the fluorophore C2, which
was more important in streams and identified as terrestrial humic material (Murphy et al., 2011). Streams also showed
higher levels of humic-like (C1) and protein-like (C8) compounds, whereas higher values of the freshness index
characterized lakes. These patterns consistently indicate that the arrangement of sites along PC1 reflects a gradient of

300 allochthonous vs autochthonous sources of DOM. A corollary of this finding is that despite the potentially pervasive
influence of the urbanized surroundings, urban streams in particular are more tightly linked to the terrestrial
environment than urban lakes, just as is the case for flowing and standing waters in natural landscapes (Larson et al.,
2014).

In contrast to natural landscapes, however, the linkage of urban waters with their terrestrial surroundings is mediated
305 by paved surfaces and engineered flow paths, including roof run-off into rain gutters, extensive (partially leaky)
sanitation networks and sewage overflows in WWTPs following heavy rainfall or snowmelt. The urban gradient from
allochthonous to autochthonous DOM sources we document could thus be driven by surface run-off rather than soil
seepage and subsequent delivery of DOM to surface waters via groundwater. This interpretation is supported by higher
levels of proteins (Fig. 2) characterizing the urban streams and rivers, as opposed to soil-derived humic DOM
310 signatures typical of unimpacted streams and rivers (Hutchins et al., 2017). The proteins could originate from surface
runoff integrating various sources of urban pollution but they might also derive from WWTPs, as implied by the nature
of some of the PARAFAC components we identified (Table A3). For instance, the humic fluorophore C2 has been
reported in WWTP effluents that may be discharged into urban surface waters (Murphy et al., 2011). Point-source
inputs were also identified as drivers of DOM composition by the influence of TrOCs in our RDA and their correlations
315 with C2 and C8, all of which are components of WWTP effluents.

Lakes differ from streams by a typically greater importance of autochthonous production fostered by abundant
nutrients. Elevated nutrient concentrations should hence coincide with DOM signatures indicative of autochthonous
carbon sources, as found in agricultural streams, where the freshness index $\beta:\alpha$ indicating autotrophic activity was
related to high nitrogen concentrations (Wilson and Xenopoulos, 2009). This pattern contrasts with the negative
320 relation between nitrogen concentration and the proportion of fresh DOM found across our study sites, where high
nutrient concentrations were instead strongly related to DOM components of WWTP effluents. This typically resulted
in an allochthonous DOM character at high-nitrogen sites.

Similarly, the TP concentration was significantly related to DOM composition in our RDA, where phosphorus-rich
water bodies also proved to have more allochthonous than autochthonous DOM. This points to inputs from urban
325 surface runoff rather than groundwater inflow where long flow paths and residence times provide ample opportunities
for phosphorus immobilization. As with N, additional phosphorus may derive from WWTP effluents, as suggested by
the positive relationship between TP concentration and the fluorophore C2 as a putative tracer of WWTP effluents
(Murphy et al., 2011). Overall, the negative relationships between nutrient availability and the importance of
autochthonous components in the DOM pool suggests that while streams and rivers may efficiently collect N and P
330 from the urban environment; lakes are more efficient at channeling nutrients into autochthonous production. Thus, the
autochthonous DOM signature in urban lakes appears to be largely independent of nutrient supply and rather be
facilitated by longer water residence times, higher water temperature and favorable light conditions.

Our results on urban surfaces driving urban allochthonous DOM composition meet our expectation that land cover
notably influences the composition of DOM in urban surface waters (Williams et al., 2016; Sankar et al., 2020). This
335 conclusion is supported by results from our RDA, which identified the presence of green spaces in the perimeter of the

water bodies as a significant influence. However, the relationship between land cover and DOM composition must be interpreted with caution because all lakes were situated in areas with green spaces in their surroundings, whereas streams ran through areas dominated by buildings and paved surfaces. The urban running waters, more than lakes and ponds, thus received high surface runoff during rain events, including high inputs of pollutants and allochthonous DOM. Given the evident negative relationship between green space and paved surface areas ($R=-0.47$, $p<0.001$), green spaces might be used as an inverse proxy for paved surfaces influencing DOM signatures in urban surface waters. However, since paved surface area per se did not emerge as a significant predictor in our RDA, land cover can at best partly account for the observed variation in DOM composition across the contrasting urban sites we investigated.

Except for ponds and some lakes, all investigated water bodies had direct surface water connections, which could result in spatial autocorrelation (Peterson et al., 2006). In addition, spatial patterns may arise from the prominent land cover gradients in Berlin, ranging from forested areas to densely populated urban centers. Since the sampling design of our study does not lend itself to a formal analysis of spatial autocorrelation, we explored spatial patterns with DOM proxies in maps (Fig. 1b,c) but found no obvious relationships. Instead, type-specific characteristics of the water bodies were pronounced, largely independent of hydrological connections. Factors potentially contributing to the resulting heterogeneity across the surface waters in the city include specific local stressors such as point-source inputs of pollutants, spatially variable urban surface runoff delivering allochthonous DOM, and hydraulic-engineering structures such as sluices. Thus our map of DOM composition (Fig. 1b,c) could be interpreted as visualizing urban heterogeneity in aquatic ecosystem diversity and condition.

4.2 Seasonal patterns and drivers of DOM signatures

Seasonal variation in DOM signatures occurred in all types of water bodies mostly independent from variation among the four water body types. With a few exceptions, P4 and H3 being the most prominent examples, seasonal variation of DOM composition was consistent across all water body types. (Fig. 3a,b), Assessed separately at each site (Fig. 3b), DOM was generally fresher in summer and autumn than in winter and spring, as indicated by higher ratios of $\beta:a$ and more HMWS-N as indicators of polysaccharides and proteins (Thurman, 1985), whereas humic matter was more abundant in winter, and the pattern in spring was not clear-cut. Our rank-based analysis of PC2 scores (Fig. 3c) suggests a consistent seasonal pattern of changes in DOM composition across sites, which emerged even though the variation within individual sites was limited along PC2.

At least four potential processes could account for the observed seasonal turnover in DOM composition: exudates of aquatic primary producers, microbial and sunlight-induced transformation of DOM, and terrestrial inputs from riparian vegetation (Spencer et al., 2009; Cory et al., 2015), all of which could be influenced by the urban environment. Seasonal variation in light conditions could be important in influencing DOM composition by primary producers, independent of nutrient supply (see above), and temperature changes might also play a role, especially in determining rates of microbial DOM transformations. Pulses of leaf litter falling or swept or blown into urban water bodies could be an additional source of DOM varying with season (Gessner et al., 1999). This holds particularly for urban green spaces and water courses lined by woody riparian vegetation. However, quantification of the relative importance of different drivers of seasonal patterns remains difficult based on the data currently available for urban settings.

The ponds and streams included in our study showed higher and less predictable seasonal turnover than the lakes and rivers, as revealed by the pattern along PC2 (Fig. 3). This indicates that the nature and degree of aquatic-terrestrial coupling in urban settings leaves an imprint on the turnover of DOM. Surveys of DOM dynamics should hence be more informative about ecosystem conditions than assessments based on single grab samples or averaged data. Inputs of DOM from WWTP effluents may also be captured by the seasonal patterns, although that influence is likely variable, as indicated by considerable seasonal turnover of DOM at site H3 contrasting with a minimal turnover at sites S5 and R7 (small ellipses in Fig. 3b), despite the influence of WWTP effluents at those sites.

4.3 DOM composition as a potential basis for urban surface water monitoring

The fact that our analysis of DOM composition revealed behavior of individual water bodies underlines the potential usefulness of DOM descriptors as ecosystem-scale functional indicators that could be included in regular water-quality assessment and monitoring. Some sites deviated from the general pattern observed for water bodies of the same type. P4, for example, was formerly connected to a sewage farm and appeared to be influenced by previously unrecognized storm water runoff that likely delivered inputs during heavy rain. The site was characterized by high levels of nutrients, especially NH_4^+ , and a distinct DOM composition. Similarly, S5, located immediately downstream of a WWTP, although not specifically selected as a highly polluted site, also showed a distinct DOM composition as reflected by its highly negative PC1 score (Fig. 2a), indicating that the allochthonous influence was likely the strongest among all sites. Site R7 showed the same pattern as S5, and although not initially recognized as being affected by a WWTP, its DOM composition revealed that it had actually received WWTP effluents, which happened since the end 2015 (Nega et al., 2019). The distinct signatures at these individual sites are thus a promising starting point for incorporating information on DOM composition in water-quality assessment and monitoring. Notably, DOM optical indexes are highly cost-effective to apply and yield information that is not easily obtained by classic approaches. Robustness of such assessments would further increase when they are based on continuous time series. This could strengthen the implementation of current legal frameworks such as the EU Water Framework Directive aiming at an integrative water-quality assessment, including of urban water bodies.

5. Conclusion

The composition of DOM collected in a suite of contrasting water bodies in a large metropolitan area, the city of Berlin in Germany, is diverse, varying widely in molecular size and other features related to the degree of allochthonous inputs and conveying a distinct urban character. DOM features clearly differentiated water body types, from lakes with highly abundant autochthonous DOM to streams with more allochthonous DOM. Seasonal variation of DOM is prevalent in all water body types but likely driven not only by phenology but also by distinctly urban drivers such as nutrient supply, WWTP inputs, reduced leaf litter input or flashy runoff from sealed surfaces. Nutrient supply, the percentage of green space and concentrations of trace organic pollutants (as proxies for point source influences) were identified as major drivers of DOM composition. Notably, easily measured optical data on DOM were sufficient to detect WWTP effluents, a result that was confirmed by data on TrOC. This suggests that DOM analyses could be a useful starting point in water-quality monitoring. Optical analyses of DOM are inexpensive and easily implemented, and could be complemented by more sophisticated and potentially automated analyses such as the mass-spectrometric

quantification of TrOCs. DOM composition can inform about processes both within water bodies and in the terrestrial surroundings, therefore, water-quality assessments could benefit from integrating information on DOM composition.

410 Robustness of the assessments would increase if based on time series or even continuous monitoring, knowledge and technology for which are readily available. This could strengthen current assessments as implemented in legal frameworks such as the EU Water Framework Directive, which aims at an integrative assessment of the “ecological status” of water bodies.

Appendix A includes tables that complement the physico-chemical and dissolved organic composition information.

415 **Table A1: Physico-chemical characteristics (mean \pm SD and % variance explained) of four contrasting types of water bodies in the city of Berlin. Means and standard deviations were computed across all seasons and sites. The percentages of variance explained (% Var) refer to the effect of season within each water body type, calculated by type-II ANOVA (aka variance component analysis), with season treated as a random factor. F-values refer to results of repeated-measures ANOVAs testing for differences among water body types (** $p < 0.001$, * $p < 0.05$, ns = not significant).**

Table A2: Absorbance and Fluorescence indices definition.

Variable	Definition
SUVA ₂₅₄	Proxy for DOM aromaticity (Weishaar et al., 2003)
E2:E3	Ratio of absorbance at 250 and 365 nm, as an (inverse) indicator of molecular size (Peuravuori and Pihlaja, 1997)
E4:E6	Indicator of humification (Chen et al., 1977)
Slope short	Short-wavelength slope within the wavelength region of 275-295 nm as an inverse correlate with molecular weight and aromaticity (Helms et al., 2008)
SR	Ratio of slopes (SR) computed from short and long wavelength regions as another negative correlate with DOM molecular weight (Loiselle et al., 2009)
FIX	Fluorescence index (FIX) as the ratio of fluorescence intensities at the emission wavelengths of 470 and 520 nm (obtained at excitation wavelength of 370 nm), which has proved useful to distinguish the relative contributions of terrestrial (FIX~1.4) and aquatic (FIX~1.9) sources of DOM (Mcknight et al., 2001)
HIX	Humification index (HIX) as a proxy for humic substances (Ohno, 2002)
β/α	Freshness index β/α (Wilson and Xenopoulos, 2009), which indicates the relative importance of recently produced DOM (Parlanti et al., 2000)

425 **Table A3: Designation, excitation (Ex) and emission (Em) wavelengths of PARAFAC components, and the number of studies with matching components reported in OpenFluor (Murphy et al., 2014).**

PARAFAC component	Ex	Em	OpenFluor reference matches (0.95)	Explanation and selected references
C1	250	446	8	Humic-like, peak A (Coble, 1996); humic-like and recalcitrant (C1) (Hansen et al., 2016)
C2	250	500	22	Terrestrial humic-like in waste water treatment impacted water, (G1) (Murphy et al., 2011); ubiquitous and recalcitrant humic (C2) (Chen et al., 2017)
C3	306	408	13	Humic-like, peak M (Coble, 1996); humic-like (C3) (Stedmon and Markager, 2005)
C4	256	444	9	Terrestrial humic-like, suggested as photo-refractory (C2) (Yamashita et al., 2010); terrestrial humic-like (C3) (Williams et al., 2013)
C5	250	382	2	Anthropogenic, microbial humic-like (C6) (Williams et al., 2016)
C6	294	352	13	Similar to tryptophan (C3) (Catalán et al., 2015); protein-like, linked to autochthonous production (C3) (Amaral et al., 2016)
C7	320	396	8	Humic-like, peak M (Coble, 1996); microbially transformed autochthonous DOM (C2) (Osburn et al., 2011)
C8	276	326	15	Protein-like, peak B(Coble, 1996); waste water treatment protein (C2) (Teymouri, 2007)

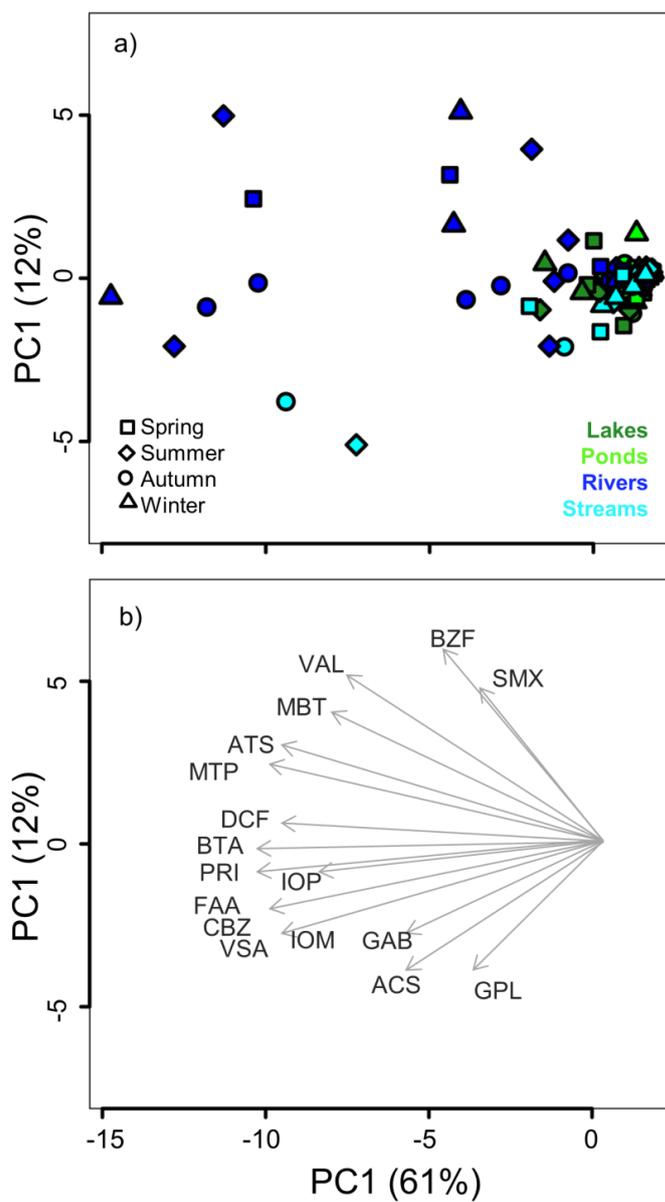

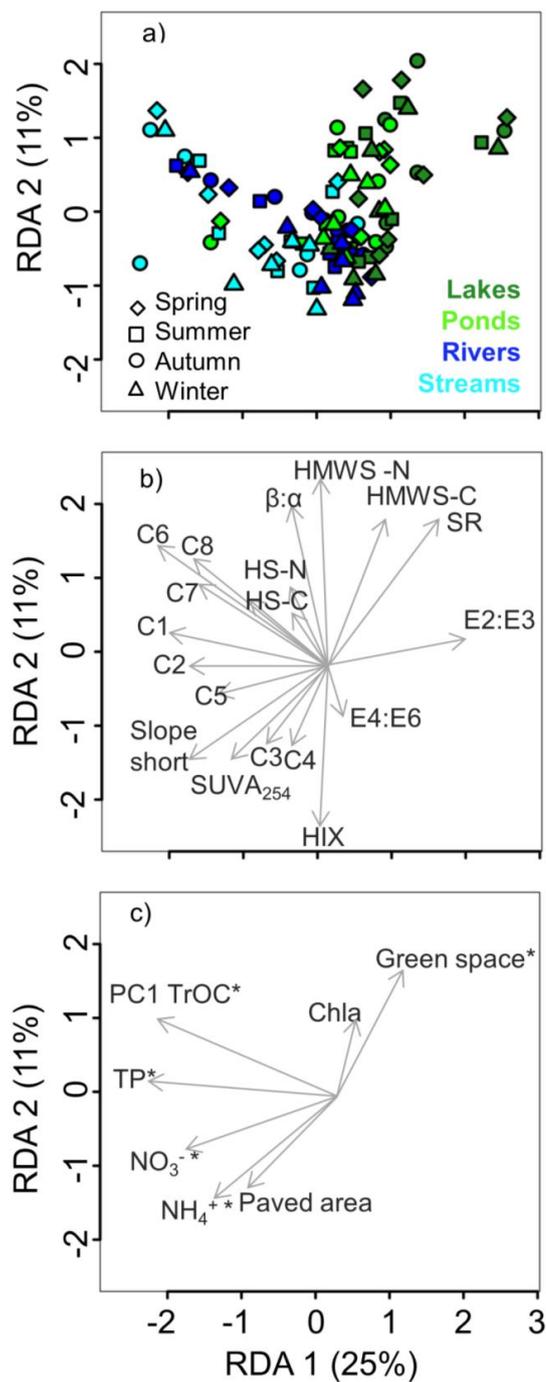

Figure B1 Principal Component Analysis (PCA) of urban sampling sites (a) and Trace Organic Compounds (TrOCs) (b). Extreme site S5 was included in the analysis but is not presented in the biplot to better visualize variability among the other sites. Abbreviations of the TrOCs (B) are explained in Table B1.

480

Appendix C includes figures that complement the statistical analysis

485 **Figure C1 Redundancy Analysis (RDA) of urban sampling sites (a) visited 4 times over one year, the DOM characteristics included in the analysis (b) and the predictor variables (c), the last marked by an asterisk (*) when significant. DOM characteristics include (i) absorbance and fluorescence indexes (E2:E3, molecular size, E4:E6, indicator of humification, SR, slope ratio, β : α , freshness index, slope short, SUVA₂₅₄ and HIX, humification index), (ii) PARAFAC components (C1 to C8), and (iii) fractions derived from size exclusion chromatography (HS, humic-like substances; HMWS, high-molecular weight non-humic substances; and LMWS, low-molecular weight substances).**

490 *Supplement.* The supplement related to this article is available online.

Author contributions. All authors contributed to designing the study. CR and SH collected the data. CR did the optical analysis and the PARAFAC modelling, GS carried out the FT-ICR-MS analysis. CR and GS conducted the statistical analysis. CR led the manuscript writing, jointly with GS. All authors discussed results and edited the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

495 *Data availability.* The data will be available at a suitable repository at <https://www.re3data.org/>.

Acknowledgments. We thank A. Köhler at the Senate Berlin (SenUVK) for water quality data, authorities and private land owners for providing access to the study sites, C.N. Stratmann for obtaining permissions, U. Mallok for nutrient analyses, C. Schmalsch for the LCOCD analysis, S. Krockner and T. Fuss for the DOC analysis and T. Goldhammer for advice with chemical analyses. C.N. Stratmann, Meinhold, I. Ajamil, G. Idoate, L. Thuile-Bistarelli, A. Sultan, R. Schulte, E. Tupper, T. Fuss, R. del Campo, A. Wieland, and M. Bethke for field assistance. G. Aschermann and A. Putschew kindly enabled TrOC analyses. Access to FT-ICR-MS and associated expertise was generously provided by T. Dittmar during a stay of G. Singer at University Oldenburg that was funded by Hanse-Wissenschaftskolleg Delmenhorst. Thank you also to K. Pypkins for support with GIS and to B. Kleinschmit for advice in sampling strategy and data analysis. This project was funded by the German Research Foundation (DFG) through the Research Training
500
505 Group ‘Urban Water Interfaces’ (UWI; GRK 2032).
