31 **Abstract**

32 One of the major undetermined problems in evaporation (ET) retrieval using thermal infrared
33 remote sensing is the lack of a physically based ground heat flux (G) model and its integration
34 with the surface energy balance model. Here, we present a novel approach based on coupling a
35 thermal inertia (TI)-based mechanistic G model with an analytical surface energy balance model,
36 Surface Temperature Initiated Closure (STIC, version STIC1.2). The coupled model is named
37 STIC-TI and it uses noon-night (1:30 pm and am) land surface temperature (T_s), surface albedo,
38 and vegetation index from MODIS Aqua in conjunction with a clear-sky net radiation model and
39 ancillary meteorological information. SEB flux estimates from STIC-TI were evaluated with
40 respect to the *in-situ* fluxes from Eddy Covariance measurements in diverse ecosystems of
41 contrasting aridity in both northern and southern hemispheres. Sensitivity analysis revealed
42 substantial sensitivity of STIC-TI-derived fluxes due to T_s uncertainty. An evaluation of
43 noontime G (G_i) estimates showed 12-21% error across six flux tower sites in both the
44 hemispheres and a comparison between STIC-TI versus other G models also revealed the
45 substantially better performance of the former. While the instantaneous noontime net radiation
46 (R_{Ni}) and latent heat flux (LE_i) was overestimated (15% and 25%), sensible heat flux (H_i) was
47 underestimated (22%). The errors in G_i were associated with the errors in daytime T_s and
48 mismatch of footprint between the model estimates and measurements. Overestimation
49 (underestimation) of LE_i (H_i) was associated with the overestimation of net available energy (R_{Ni}
50 $- G_i$) and use of unclosed surface energy balance measurements. The deviations of STIC-TI heat
51 flux estimates from measurements were found to be restricted within -40° to 30° day view angle,
52 while no impact of night view angle was evident. Being independent of any leaf-scale
53 parameterization and having a coupled sub-model of G, STIC-TI can make a valuable
54 contribution to mapping and monitoring ecosystem water stress and evaporation using noon-
55 night thermal infrared observations from existing and future EO missions such as INSAT 4th
56 generation and TRISHNA.

59 **1 Introduction**

60 One of the outstanding challenges in evaporation (ET) estimation through surface energy balance
61 (SEB) model concerns an accurate characterization of ground heat flux in the open canopy
62 system with mixed vegetation such as savanna or in ecosystems with low mean fractional
63 vegetation cover, prevailing water stress, and strong seasonality in soil moisture. Ground heat
64 flux (G) is an intrinsic component of SEB (Sauer and Horton, 2005), affecting the net available
65 energy for ET (the equivalent water depth of latent heat flux, LE) and sensible heat flux (H). It
66 represents an energy flow path that couples surface with the atmosphere and has important
67 implications for the underlying thermal regime (Sauer and Horton, 2005). Depending on the
68 vegetation fraction and water stress, the magnitude of instantaneous G varies greatly across
69 different ecosystems. In the humid ecosystems with predominantly dense canopies and high
70 mean fractional vegetation cover, G contributes to a small proportion in the surface energy
71 balance. Dense canopy cover leads to less transmission of radiative fluxes through multiple
72 layers of canopies, which results in low warming of the soil floor. Due to persistently high soil
73 water content, humid ecosystems generally show low diurnal and seasonal variability in G. By
74 contrast, the magnitude of G is substantially large in arid and semi-arid ecosystems with sparse
75 and open canopy and soil moisture deficits. Due to prevailing feedback between the physics of
76 ground heat flux, land-atmosphere interactions and vegetation ecophysiology, evaporation
77 modelling in the complex ecosystems remained a challenging task (Wang et al., 2013; Kiptala et
78 al., 2013). This paper addresses the challenge of simultaneous estimation of G and ET by
79 combining thermal remote sensing observations with a mechanistic G model and a SEB model.

80 SEB models mainly emphasize on estimating sensible heat flux (H) by resolving the
81 aerodynamic conductance (g_A) and computes LE as a residual SEB component as follows:

$$LE = R_N - G - H \quad (1)$$

82 R_N is the net radiation. The proportion of R_N that is partitioned into G depends upon soil
83 properties like its albedo, soil moisture, soil thermal properties such as thermal conductivity and
84 heat capacity, which vary with mineral, organic and soil water fractions. SEB models use land
85 surface temperature (LST or T_S) as an important lower boundary condition for estimating H and
86 LE. Due to the extraordinarily high sensitivity of T_S to evaporative cooling and soil water

87 content variations, thermal infrared (TIR) remote sensing is extensively used in large scale
88 evaporation diagnostics (Kustas and Anderson, 2009; Mallick et al., 2014, 2015a, 2018a;
89 Cammalleri and Vogt, 2015; Anderson et al., 2012). Evaporation estimation through SEB models
90 commonly employ empirical sub-models of G in a stand-alone mode. Despite the utility of
91 mechanistic G models is demonstrated in different studies (Verhoef, 2004; Murray and Verhoef,
92 2007; Verhoef et al., 2012), no TIR-based evaporation study attempted to couple a mechanistic
93 G model with a SEB model.

94 The SEB models for ET estimation driven by remote sensing observations generally use linear
95 and non-linear relationships for estimating G and such methods generally employ R_N , T_S , albedo
96 (α_R), and NDVI (e.g., Bastiaanssen et al., 1998; Friedl, 2002; Santanello and Friedl, 2003).
97 While the inclusion of T_S and albedo serves as a proxy for soil moisture and surface
98 characteristics effects in G , inclusion of NDVI provides a scaling of $G - R_N$ ratio for different
99 fractional vegetation cover. Unfortunately, the empirical approaches do not include any
100 information of soil temperature or daily temperature amplitude. These empirical models also lack
101 the universal consensus. Setting G as a fraction of R_N does not solve the energy balance equation
102 and disregards the role of thermal inertia of the land surface (Mallick et al., 2015b). This could
103 introduce substantial uncertainty in LE estimation because G effectively couples the surface
104 energy balance with energy transfer processes in the soil thermal regime. It provides physical
105 feedback to LE through the effects of soil moisture, temperature, and conductivity (thermal and
106 hydraulic) (Sauer and Horton, 2005). Such feedbacks are most critical in the arid and semi-arid
107 ecosystems where LE is significantly constrained by the soil moisture dry-down. The limits
108 imposed on LE by the water stress consequently result in greater partitioning of the net available
109 energy (i.e., $R_N - G$) into H and G (Castelli et al., 1999).

110 When LE is reduced due to soil moisture dry-down, both G and T_S tend to show rapid intra-
111 seasonal rise. Therefore, the surface energy balance equation could be linked with mechanistic G
112 model, T_S harmonics (Verhoef, 2004), and soil moisture availability. Realizing the importance of
113 direct estimates of G in LE and invigorated by the advent of TIR remote sensing, Verhoef et al.
114 (2012) demonstrated the potential of a TI-based mechanistic model (Murray and Verhoef, 2007)
115 (MV2007 hereafter) for spatiotemporal G estimates in semi-arid ecosystems of Africa. Some
116 studies also emphasized the importance of using noontime and nighttime T_S and R_N for

117 estimating G (Mallick et al., 2015b; Bennet et al., 2008; Tsuang, 2005). The method of MV2007
118 has so far been tested in a stand-alone mode, and no remote sensing method has so far been
119 attempted to combine such a mechanistic G model (e.g., MV2007-TI model) with a SEB model
120 for coupled energy-water flux estimation and validation.

121 By integrating T_s into a combined structure of the Penman-Monteith (PM) and Shuttleworth-
122 Wallace (SW) model, an analytical SEB model was proposed by Mallick et al. (2014, 2015a,
123 2016). The model, Surface Temperature Initiated Closure (STIC), is based on finding analytical
124 solution for aerodynamic and canopy-surface conductance (g_A and g_s) where the expressions of
125 the conductances were constrained by an aggregated water stress factor. Through physically
126 linking water stress (T_s derived) with g_A and g_s , STIC established direct feedback between T_s , H
127 and LE, and simultaneously overcame the need of empirical parameterization for estimating the
128 conductances (Mallick et al., 2016, 2018a). Different versions of STIC have been extensively
129 validated in different ecological transects (Tropical rainforest to woody savanna) and aridity
130 gradients (humid to arid) (Trebs et al., 2021; Bai et al., 2021; Mallick et al., 2015a; 2016; 2018a,
131 b; Bhattarai et al., 2018, 2019). Based on the conclusions of Verhoef et al. (2012), Mallick et al.
132 (2014; 2015a,b; 2016; 2018a,b, 2022), Bhattarai et al. (2018, 2019), and Bai et al. (2021), there
133 is a need to address some of the challenges in SEB modeling, which are, (i) accurate estimation
134 of G and ET in sparse vegetation, (ii) testing the utility of coupling a TI-based G model with an
135 analytical SEB model for accurately estimating G and ET, and (iii) detailed evaluation of a
136 coupled G-SEB model at the ecosystem scale. Realizing the significance of mechanistic G model
137 (MV2007), the advantage of the analytical STIC model, and to mitigate some of the overarching
138 gaps in SEB modeling in sparsely vegetated open canopy systems, this study presents the first-
139 ever coupled implementation of MV2007 G with the most recent version of STIC (STIC1.2). We
140 name this new coupled model as STIC-TI and it requires noon-night T_s and associated remotely
141 sensed land surface variables as inputs. We performed subsequent evaluation of STIC-TI in nine
142 terrestrial ecosystems in arid, semi-arid and sub-humid climate in India, the United States of
143 America (USA) (representing northern hemisphere) and Australia (representing southern
144 hemisphere) at the eddy covariance flux tower sites. The current study addresses the following
145 research questions and objectives:

146 (i) What is the performance of STIC-TI G estimates when compared with conventionally used
147 empirical G models in ecosystems having low mean fractional vegetation cover (f_c) (≤ 0.5) and
148 having larger soil exposure to radiation for example in Savanna?

149 (ii) How do the estimates from STIC-TI LE and H fluxes compare with LE and H observations in
150 diverse terrestrial ecosystems that represent a varied range of f_c (0.25 – 0.5) covering
151 cropland, savanna, mulga vegetation (woodlands and open-forests dominated by the mulga
152 tree [*Acacia aneura*]) spread across arid, semi-arid, sub-humid, humid climates over a vast
153 range of rainfall (250 to 1730 mm), temperature (-4 to 46°C) and soil regimes?

154 (iii) What is the seasonal variability of G and evaporative fraction from STIC-TI model in a wide
155 range of ecosystems having contrasting aridity and vegetation cover?

156 It is important to mention that assessing the performance of STIC-TI LE and H with respect to
157 other SEB models is not within the scope of the present study. The prime focus of the current
158 study is to assess the sensitivity of STIC-TI, temporal variability of the retrieved SEB fluxes, and
159 cross-site validation of the individual SEB components.

160 A list of variables, their symbols and corresponding units are given in Table A1 in Appendix A.

161 **2 Study area and datasets**

162 **2.1 Study site characteristics**

163 The present study was conducted using data from nine flux tower sites (four sites in India; three
164 sites in Australia; two sites in USA) equipped with Eddy Covariance (EC) measurement systems.
165 The distribution of the flux tower sites considered for the present study are shown in Fig.1
166 below. The sites cover a wide range of climate, vegetation types, low fractional vegetation cover
167 (f_c) of around 0.5 and have contrasting aridity (Table 1). In India, a network of EC towers was
168 set up under Indo-UK INCOMPASS (INteraction of Convective Organization and Monsoon
169 Precipitation, Atmosphere, Surface and Sea) Program (Turner et al., 2019) at Jaisalmer (IND-Jai)
170 in Rajasthan state, Nawagam (IND-Naw) in Gujarat state, Samastipur (IND-Sam) in Bihar state
171 and under Newton-Bhaba programme (Morisson et al., 2019 a,b) at Dharwad (IND-Dha) in
172 Karnataka state. The flux footprint for EC towers in India varied from 500 m – 1 km (Bhat et al.,
173 2019). In the present study, about 90% of the fluxes came from an area within 500 m to 1 km

174 from the EC tower. Therefore, the relative contribution of vegetated land surface area to the
 175 fluxes is close to 90% (Schmid, 2002; Vesala et al., 2008). The remaining percentage of fluxes
 176 were originated from an area beyond the flux footprint. The mean annual f_c was found to vary
 177 from 0.25 to 0.52 with standard deviation (SD) ranging from 0.1 to 0.16.
 178 The IND-Jai site represents arid western zone over desert plains of natural grassland ecosystem.
 179 The region receives very low rainfall (100 – 300 mm) during monsoon and experiences a wide
 180 range in air temperature, high solar radiation, wind speed and high evaporative demand (Raja et
 181 al., 2015). The IND-Naw site represents semi-arid agroecosystem in the middle Gujarat
 182 agroclimatic zone of north-west India and has a pre-dominant rice-wheat cropping system. The
 183 IND-Sam site has sub-humid climate of north-west alluvial plain zone in the Indo-Gangetic Plain
 184 (IGP) situated in the eastern India and this site also follows rice-wheat crop rotation. IND-Dha
 185 represents humid sub-tropical climate of transition zone in the southern India and this site
 186 comprises of crops.

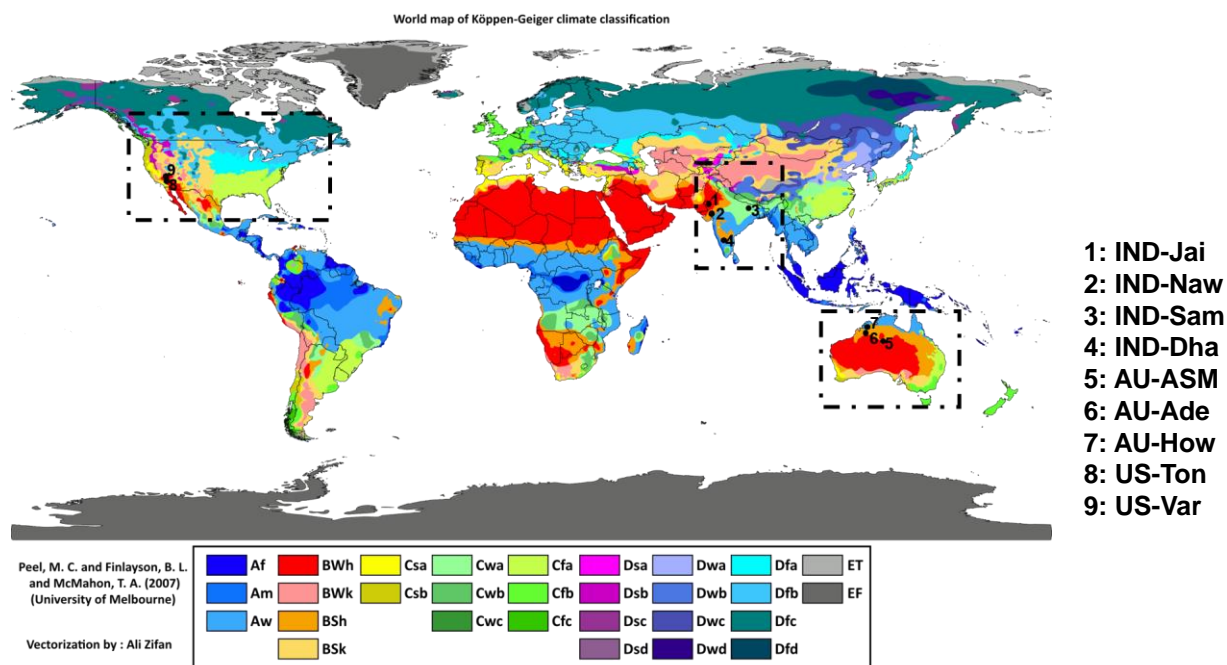

Figure 1: Locations of the flux tower sites in India, Australia and USA overlaid on climate type map. (Image Source: By Peel, M. C., Finlayson, B. L., and McMahon, T. A. (University of Melbourne) enhanced, modified, and vectorized by Ali Zifan; Hydrology and Earth System Sciences: "Updated world map of the Köppen-Geiger climate classification". 187 In USA, two EC tower sites were located at Tonzi Ranch (US-Ton) and Vaira Ranch (US-Var),
188 in the lower foothills of the Sierra Nevada Mountains. Both the EC stations are part of the
189 AMERIFLUX Management Project (<https://ameriflux.lbl.gov/>). US-Ton is classified as an oak
190 savanna woodland. While the overstorey is dominated by blue oak trees (40% of total
191 vegetation) with intermittent grey pine trees (3 treesha⁻¹), the understory species include a variety
192 of grasses and herbs. The mean annual rainfall at this site is 559 mm. US-Var is a grassland
193 dominated site and the growing season is confined to the wet season only, typically from October
194 to early May. The mean annual rainfall at this site is 559 mm. The mean annual f_c was found to
195 vary from 0.18 to 0.26 and SD of the order of 0.06 to 0.07.

196 In Australia, three EC tower sites were located at Howard Springs (AU-How), Alice Springs
197 Mulga (AU-ASM), Adelaide river (AU-Ade) in the Northern Territory as part of the OzFlux
198 network (Beringer et al., 2016) and the Terrestrial Ecosystem Research Network (TERN), which
199 is supported by the National Collaborative Infrastructure Strategy (NCRIS)
200 (<http://www.ozflux.org.au/monitoringsites/index.html>). The AU-How is situated in the Black
201 Jungle Conservation Reserve representing an open woodland savanna and the mean annual
202 rainfall is 1750 mm. The AU-ASM is located on Pine Hill cattle station near Alice Springs. The
203 woodland is characterized by mulga canopy and mean annual rainfall is 306 mm. AU-Ade
204 represents savanna with a mean annual rainfall of 1730 mm. The mean annual f_c varied from
205 0.21 to 0.48 having SD range of 0.08 - 0.17. A description of Australian flux sites is given in
206 Beringer et al. (2016). Average heights of vegetation are 1.15 m at IND-Naw, 1 m at IND-Jai,
207 1.23 m at IND-Sam, 1.5 m at IND-Dha, 6.5 m at AU-ASM, 15m at AU-How, 7 m at AU-Ade,
208 10 m at US-Ton, and ≤ 0.5 m at US-Var.

218 **Table 1:** An overview of the EC flux tower site characteristics in the present study

Hemisphere	Sites	Latitude (°N), Longitude (°E)	Climate & Vegetation	Mean f_c (SD)	Soil texture	T_A range (°C)	Mean Annual P (mm)	Observation period
Northern	Jaisalmer (IND-Jai)	26.99, 71.34	Arid grassland	0.25(±0.1)	Loamy fine sand to coarse sand	8 – 40	250	2017 – 2018
	Nawagam (IND-Naw)	22.80, 72.57	Semi-arid cropland	0.41(±0.13)	Sandy loam	9 – 39	700	2017 – 2018
	Samastipur (IND-Sam)	26.00, 85.67	Humid subtropical cropland	0.52(±0.16)	Sandy loam to loam	10 – 39	1000	2017 – 2018
	Dharwad (IND-Dha)	15.50, 74.99	Tropical Savanna	0.36(±0.11)	Shallow to medium black clay and red sandy loam soils	12 – 40	650	2016 – 2018
	Tonzi ranch (US-Ton)	38.43, -120.96	Woody Savanna	0.18(±0.06)	Red sandy clay loam	0 – 40	559	2011 – 2019
	Vaira ranch (US-Var)	38.41, -120.95	Arid grassland	0.26(±0.07)	Rocky silt loam	0 – 40	559	2011 – 2019
Southern	Alice Springs Mulga (AU-ASM)	-22.28, 133.24	Semi-arid mulga	0.21(±0.09)	Loamy sand	(-4) – 40	305	2011 – 2014
	Howard Springs (AU-How)	-12.49, 131.15	Tropical savanna	0.48(±0.17)	Red kandasol	19 – 34	1700	2011 – 2014
	Adelaide River (AU-Ade)	-13.07, 131.11	Savanna	0.42(±0.08)	Yellow hydrosol, shallow, loamy sand with coarse gravel	16 – 37	1730	2007 – 2009

219 T_A : Air temperature during the observation period; P: rainfall (mm) measured using rain gauge at flux tower site during the study
 220 period. IND is for India, AU is for Australia, and US is for the United States; SD is standard deviation of annual mean f_c which is
 221 computed from NDVI as mentioned in section 3.1.

222 2.2 Datasets

223 2.2.1 Micrometeorological data at flux tower sites

224 Standardized, controlled and harmonized surface energy balance (SEB) flux and meteorological
225 data from nine EC towers were used in the present analysis. In Australia, H and LE were
226 measured through the EC systems and R_N were measured through net radiometers at varying
227 heights of 15 m (AU-Ade), 23 m (AU-How), and 11.6 m (AU-ASM), respectively. In India, the
228 EC measurement height was maintained approximately at 8 m above the surface, except at IND-
229 Dha where it was installed at a height of 4.2 m. In USA, the SEB measurements were carried out
230 at tower heights of 23 m at US-Ton and 2 m US-Var. A summary of the instrumentation is given
231 in Table A2 of Appendix A. All the flux tower sites were equipped with a range of
232 meteorological instrumentation which measured diurnal air temperature (T_A) and relative
233 humidity (R_H), four components of the net radiation (R_N , consisting of down- and up-welling
234 shortwave and long-wave radiation (SW_{\downarrow} , SW_{\uparrow} , LW_{\uparrow} and LW_{\downarrow} , respectively)) above the
235 vegetated canopy. In addition, the diurnal soil heat flux (G) and soil temperature (T_{ST}) were
236 measured at all the three Australian sites and two US sites. In India, the diurnal soil heat flux was
237 measured only at IND-Dha.

238 For the Indian sites, the raw EC measurements of the turbulent wind vectors (u , v and w , for
239 horizontal, meridional and vertical, respectively), sonic temperature (T), and CO_2 and water
240 vapor mass density were recorded at a sampling rate of 20 Hz. Raw EC data were post-processed
241 to obtain level-3 quality controlled and harmonized surface fluxes at 30-minute flux averaging
242 intervals using EddyPRO® Flux Calculation Software (LI-COR Biosciences, Lincoln, Nebraska,
243 USA) using the data handling protocol described by Bhat et al. (2019). The EC data from the
244 OzFlux sites was averaged over 30 minutes recorded by the logger and processed through levels
245 using the PyFluxPro standard software processing scripts as mentioned in Isaac et al. (2017). The
246 Level 3 (L3) used in this paper was produced using PyFluxPro (Isaac et al., 2017) employing the
247 Dynamic INtegrated Gap filling and partitioning for Ozflux (DINGO) system as described in
248 Donohue et al. (2014) and Beringer et al. (2016). The quality checked EC data at 30 minute
249 intervals for two AMERIFLUX sites US-Ton and US-Var was acquired from
250 <https://doi.org/10.17190/AMF/1245971> & <https://doi.org/10.17190/AMF/1245984>, respectively.

251 **2.2.2 Remote sensing data**

252 Optical and thermal remote sensing observations available from Moderate Resolution Imaging
 253 Spectroradiometer (MODIS) (Didan et al., 2015) on-board Aqua platform were used in the
 254 present study (Table 2) for estimating G and associated SEB fluxes. These include eight-day land
 255 surface temperature (LST or T_s) at 1:30 pm and 1:30 am, and surface emissivity (ϵ_s)
 256 (MYD11A2), daily surface albedo (α_R) (MCD43A3), 16-day NDVI (MYD13A2). The overpass
 257 times of MODIS Aqua are at 1:30 pm and 1:30 am. The 8-day average values of clear-sky T_s
 258 available from MYD11A2 data were used (Source:
 259 <https://vip.arizona.edu/documents/viplab/MYD11A2.pdf>) for all nine flux tower sites. Since
 260 MYD21A2 LST product is known to provide better accuracy (1 – 1.5 K) (Hulley et al, 2016) as
 261 compared to MYD11A2 LST over semi-arid and arid ecosystems, the former was also used in
 262 STIC-TI to compare LE and H estimates (see Table 5 in section 4.4) with the estimates of
 263 MYD11A2 LST over the arid and semi-arid sites (IND-Jai, IND-Naw, US-Ton). The noon-night
 264 pair of thermal remote sensing observations from Aqua are close to the time of occurrences of
 265 maximum and minimum soil surface temperature (see Figure 2) and are therefore ideal for soil
 266 heat flux modeling using thermal inertia. The MODIS Terra overpass times are at 11 am and 11
 267 pm and are far from the time of occurrences of minimum-maximum soil temperatures.
 268 Therefore, MODIS Aqua acquisition times were used in the present study.

269 **Table 2:** A summary of MODIS Aqua optical and thermal remote sensing products used in the
 270 present study

Data type	Product ID (version)	Variables used	Spatial resolution (m)	Temporal resolution	Purpose	Inputs to equation numbers
LST and emissivity	MYD11A2 (V006) MYD21A2	T_s (1:30 pm and am) and ϵ_s	923	8-day	For estimating R_{Ni} , G_i , LE_i , H_i	(5), (13), (C6), (C7), (B8)
Surface albedo	MCD43A3 (V006)	α_R	462	8-day composite from daily	For estimating R_{Ni}, G_i	(5), (B3)

Vegetation index	MYD13Q1 (V006)	NDVI	250	16-day	For estimating G_i	(4)
------------------	----------------	------	-----	--------	----------------------	-----

271 **3 Methodology**

272 **3.1 Coupled soil heat flux-SEB model**

273 In this paper, we modified a thermal inertia (TI) based soil heat flux (G) model using noon-night
 274 thermal remote sensing observations and thereafter coupled the TI-based G with STIC1.2. A
 275 clear-sky net radiation (R_N) model was also introduced into this coupled model and R_N
 276 estimation algorithm is described in Appendix B. The estimation of G through modifying
 277 MV2007-TI approach and its coupling with STIC1.2 is the most novel component of the
 278 modeling scheme, and it is therefore described in the main body of the paper (section 3.1.1).
 279 Such a coupling enabled the implementation of a mechanistic G model along with an analytical
 280 SEB model using optical-thermal remote sensing data. The coupled model is hereafter referred as
 281 STIC-TI.

282 **3.1.1 MV2007 soil heat flux model based on Thermal Inertia (TI)**

283 The functional form for estimating instantaneous G (G_i , hereafter) (eq. 2 below) is based on the
 284 harmonic analysis of soil surface temperature and is described in detail by Murray and Verhoef
 285 (2007) and Maltese et al. (2013).

$$G_i = \Gamma \left[(1 - 0.5f_C) \left(\sum_{n=1}^k A \sqrt{n\omega} \sin \left(n\omega t + \phi'_n + \frac{\pi}{4} - \frac{\pi\Delta t}{12} \right) \right) \right] = \Gamma J_S \quad (2)$$

286 G_i is the soil heat flux at the surface at a particular instance (Wm^{-2}), Γ is the soil thermal inertia
 287 ($\text{J m}^{-2} \text{K}^{-1} \text{s}^{-0.5}$), k is the total number of harmonics used, A is the amplitude ($^{\circ}\text{C}$) of the n^{th} soil
 288 surface temperature (T_{ST}) harmonic, ω is the angular frequency (rads^{-1}), t is the time (s), ϕ'_n is
 289 the phase shift of the n^{th} soil surface temperature harmonic (rad), J_S is the summation of harmonic
 290 terms of soil surface temperature (K), and Δt (s) is time offset between the canopy composite
 291 temperature and the below-canopy soil surface temperature. Here, we represent G_i and A as
 292 ecosystem-scale ($\leq 1\text{km}$) soil heat flux and surface soil temperature amplitude (averaged from

293 soil surface to 10 cm depth), respectively and assume it to be valid for different vegetated
294 landscape.

295 Since we have considered a single pair (noon-night corresponding to 1:30 pm and 1:30 am) of
296 MODIS aqua LST data in the present study, the phase shift (ϕ'_n) is taken as zero and number of
297 harmonics is taken as one ($k=1$) for estimating G_i . Thus equation (2) is modified as follows:

$$G_i = \Gamma \left[(1 - 0.5f_c) \left(A\sqrt{\omega} \sin \left(\omega t' + \frac{\pi}{4} - \frac{\pi \Delta t}{12} \right) \right) \right] = \Gamma J_s \quad (3)$$

298 Δt (s) is found to be 1.5 h (Murray and Verhoef, 2007). With the two boundary values (i.e., Δt
299 =1.5 h for $f_c = 1$ and $\Delta t = 0$ for $f_c = 0$), a linear approach is proposed here to describe the time
300 offset Δt as a function of vegetation fraction (f_c) (Murray and Verhoef, 2007; Maltese et al.,
301 2013). f_c was derived from NDVI on a given day or period and from the upper-lower limits of
302 annual NDVI cycle.

$$\Delta t = 1.5 f_c \quad (4)$$

303 ***3.1.1.1 Scaling function for estimating ecosystem-scale surface soil temperature amplitude (A)***

304 Estimating ecosystem-scale A involves two steps, (a) computing point-scale soil surface
305 temperature amplitude (from surface to 0.1m depth) (T_{STA} , hereafter) from the available
306 measurements of soil surface temperature, and (b) linking T_{STA} with remote sensing variables to
307 develop scaling functions for A . Point-scale soil temperature measured at different depths within
308 top 10 cm soil layer at AU-ASM, US-Ton, US-Var was averaged and considered as
309 representative surface soil temperature (0 – 10 cm). For Ind-Dha and AU-Ade, single-depth (10
310 cm) soil temperature measurement was used. Studies also showed that LST carries some signal
311 beneath the skin of the surface (Johnston et al., 2022).

312 Several studies suggested theoretical sinusoidal trajectory of soil surface and sub-surface
313 temperatures (Gao et al., 2010), where the amplitude is maximum at the surface, and it gradually
314 decreases with depth to become 37% of surface amplitude until the damping depth (Hillel, 1982).
315 However, at deeper depths, soil temperatures remain constant with time and do not show many
316 fluctuations as compared to surface or near-surface soil temperatures. This invariant soil
317 temperature is called deep soil temperature (Mihailovic et al., 1999). However, the diurnal

318 surface soil temperature measurements (within top 0.1 m depth) across different flux tower sites
 319 showed a sinusoidal-exponential behavior, i.e., sinusoidal pattern from sunrise until the
 320 afternoon and exponential pattern from afternoon through sunset to the next sunrise. An
 321 illustrative example of the theoretical and observed trajectories of surface soil temperature is
 322 shown in Fig. 2. This diurnal surface soil temperature variation has a single harmonic component
 323 (Gao et al., 2010). For computing T_{STA} , theoretical half-curve of sinusoidal pattern is assumed
 324 and was derived from measurements as exemplified in Fig 2.

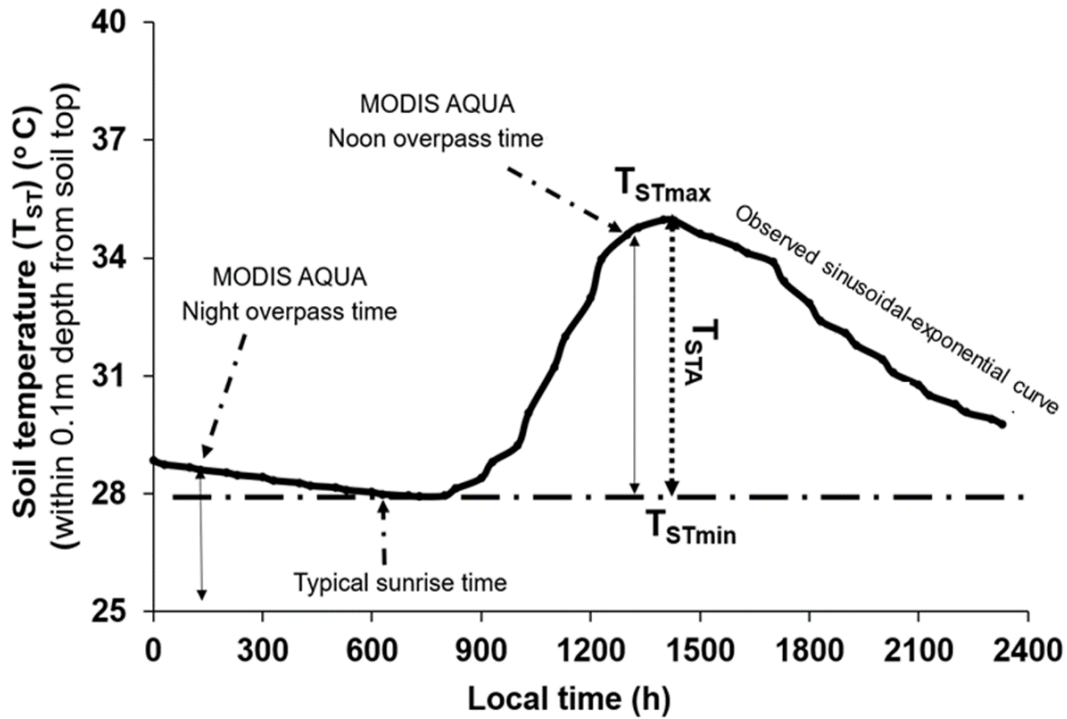

Figure 2. An illustrative example of typical diurnal variation of observed soil temperature (T_{ST}) (from surface to 0.1m depth) at OzFlux sites and timings of MODIS AQUA observations. Here, T_{STmax} and T_{STmin} are maximum and minimum point-scale observed soil surface temperatures

325
 326 It is evident from Fig. 2 that T_{STmin} represents minimum surface soil temperature occurring 1-
 327 1.5h after sunrise and T_{STmax} occurs during 12.30 – 15.00h local time. The *in-situ* measured T_{ST}
 328 on completely clear-sky days at OzFlux sites were used to extract T_{STmax} and T_{STmin} and T_{STA} was
 329 derived as $(T_{STmax} - T_{STmin})$ from the theoretical half-curve of sinusoidal pattern.

330 T_{STA} is generally influenced by several land surface characteristics such as surface temperature
 331 and surface albedo of soil-canopy complex, surface heat capacities, fractional canopy cover and

332 thermal conductivity (White, 2013). T_S and α_R are the major thermal and reflective land surface
 333 properties that have strong synergy with surface soil temperature dynamics. Hence, we have used
 334 bivariate regression analysis to develop a scaling function for estimating ecosystem-scale T_{STA}
 335 (top to 0.1m depth). The bivariate regression is based on the difference of noon (d) and night (n)
 336 T_S data and α_R (Duan et al., 2013, Li Tian et al., 2014) from MODIS Aqua. The scaling function
 337 given in eq. (5) estimates ecosystem-scale T_{STA} (symbolized as ‘A’ in equation 5) from surface to
 338 0.1 m soil depth:

$$A = B_1(T_{Sd} - T_{Sn}) + B_2(\alpha_R) + B_3 \quad (5)$$

339 Here, B_1 , B_2 , B_3 are coefficients of regression model; T_{Sd} and T_{Sn} are noon and nighttime LST,
 340 respectively. The results of this regression analysis are elaborated in section 4.1.

341 **3.1.1.2 Estimating Γ**

342 Γ is the key variable for estimating G_i using eq. (2). MV2007 adopted the concept of normalized
 343 thermal conductivity (Johansen, 1975) and developed a physical method to estimate Γ as
 344 follows:

$$\Gamma = e^{[\gamma'(1 - S_r^{(\gamma' - \delta)})]}(\tau_* - \tau_0) + \tau_0 \quad (6)$$

345 where τ_* and τ_0 are the thermal inertia for saturated and air-dry soil ($J m^{-2}K^{-1}s^{-0.5}$); $\tau_0 = D_1\theta^* +$
 346 D_2 ; $\tau_* = D_3 (\theta^{*-1.29})$; $\gamma' (-)$ is a parameter depending on the soil texture (Murray and Verhoef,
 347 2007; Minasny, 2007; Anderson et al., 2007); $S_r (m^3 m^{-3})$ is relative saturation and is equal to
 348 (θ/θ^*) ; δ (unitless) is the shape parameter which is dependent on the soil texture. $\theta^* (m^3 m^{-3})$ is
 349 the soil porosity (equal to the saturated soil moisture content when soil moisture suction is zero),
 350 $\theta (cm^3 cm^{-3})$ is the volumetric soil moisture and D_1 , D_2 , D_3 are coefficients which were derived
 351 from a large number of experimental data. The reported global values of D_1 , D_2 , and D_3 were
 352 taken as -1062.4, 1010.8, 788.2, respectively (Maltese et al., 2013). The value for θ^* and shape
 353 parameter for soil textures across study sites were specified according to Van Genuchten et al.
 354 (1980). The details are mentioned in Table E1 of Appendix E.

355 In the present study, the relative soil moisture saturation, $S_r(\theta/\theta^*)$ is represented in terms of an
 356 aggregated moisture availability (M) of canopy-soil complex through a linear function (eq. 12).

357 In case of zero canopy cover, M represents the soil moisture availability from surface to 0.1 m
 358 depth. In sparse and open canopy, rates of moisture availability from soil to root and root to
 359 canopy were assumed same.

360 Theoretically, M is expressed as available soil moisture fraction between field capacity (θ_{fc}) and
 361 permanent wilting (θ_{wp}) point as given in eq. (7) below.

$$M = \frac{\theta - \theta_{wp}}{\theta_{fc} - \theta_{wp}} \quad (7)$$

362 Where, θ_{fc} ($m^3 m^{-3}$) is the volumetric soil moisture at the field capacity (at a suction of 330 hPa)
 363 and θ_{wp} ($m^3 m^{-3}$) is the volumetric soil moisture at the permanent wilting point (at suction of
 364 15000 hPa) (Singh, 2007). Since θ_{fc} , θ_* , θ_{wp} are characteristic volumetric soil moisture contents
 365 corresponding to specific suctions and depends on the soil texture, dividing the numerator and
 366 denominator in eq. (7) by θ_* gives the following expression:

$$M = \frac{\frac{\theta}{\theta_*} - \frac{\theta_{wp}}{\theta_*}}{\frac{\theta_{fc}}{\theta_*} - \frac{\theta_{wp}}{\theta_*}} \quad (8)$$

367 Due to their dependence on soil texture, the ratios (θ_{fc}/θ_*) and (θ_{wp}/θ_*) are treated as constants.
 368 These are represented as C and C' in the later equations (eq. 9, 10, and 11). The constants, C and
 369 C' vary from 0.3 to 0.8 and from 0.1 to 0.4 (Murray and Verhoef, 2007; Minasny et al., 2011;
 370 Anderson et al., 2007), respectively over different soil textures.

$$M = \frac{\frac{\theta}{\theta_*} - C'}{C - C'} \quad (9)$$

$$M(C - C') = \left(\frac{\theta}{\theta_*}\right) - C' \quad (10)$$

371 By replacing S_r in eq. (6) as θ/θ_* and by rearranging eq. (10), the following linear function is
 372 obtained.

$$S_r = \frac{\theta}{\theta_*} = M(C - C') + C' = M' \quad (11)$$

373 Thus, the modified equation to calculate Γ is given by eq. (12) as follows:

$$\Gamma = e^{\left[\gamma' \left(1 - M^{\gamma' - \delta}\right)\right]} (\tau_* - \tau_0) + \tau_0 \quad (12)$$

374 By substituting the values obtained from eq. (4), (5) and (12) into eq. (3), we obtained the
 375 instantaneous ecosystem-scale G_i corresponding to MODIS Aqua noontime overpass. The
 376 intrinsic link between G_i estimates through MV2007-TI and SEB scheme in STIC1.2 is made
 377 through M , where the computation of M follows the procedure as described in Mallick et al.
 378 (2016, 2018a, b) and Bhattarai et al. (2018). (description in Appendix C).

379 **3.1.1.3 Estimating M**

380 In STIC1.2, an aggregated moisture availability (M) of canopy-soil complex is expressed as the
 381 ratio of the ‘vapor pressure difference’ between the aerodynamic roughness height of the canopy
 382 (i.e., source/sink height) and air to the ‘vapor pressure deficit’ between aerodynamic roughness
 383 height to the atmosphere:

$$M = \frac{(e_0 - e_A)}{(e_0^* - e_A)} = \frac{(e_0 - e_A)}{\kappa(e_s^* - e_A)} = \frac{s_1(T_{0D} - T_D)}{\kappa s_2(T_S - T_D)} \quad (13)$$

384 Where e_0 and e_0^* are the actual and saturation vapor pressure at the source/sink height; e_A is the
 385 atmospheric vapor pressure; e_s^* is the saturation vapor pressure at the surface; T_{0D} is dew point
 386 temperature at the source/sink height; T_S is the LST; T_D is the air dew point temperature; s_1 and
 387 s_2 are the psychrometric slopes of the saturation vapor pressure and temperature between ($T_{0D} -$
 388 T_D) versus $(e_0 - e_A)$ and $(T_S - T_D)$ versus $(e_s^* - e_A)$ relationship; and κ is the ratio between $(e_0^* -$
 389 $e_A)$ and $(e_s^* - e_A)$. To solve the eq. (13), estimation of T_{0D} is necessary. An initial estimate of T_{0D}
 390 [$T_{0D} = [(e_s^* - e_A) - s_3 T_S + s_1 T_D] / (s_1 - s_3)$] and M were obtained following Venturini et al. (2008)
 391 where s_1 and s_3 were approximated in T_D and T_S , respectively. However, eq. (13) cannot be
 392 directly solved because there are two unknowns in one equation. However, since T_{0D} also
 393 depends on LE (Mallick et al., 2016, 2018a), an iterative updation of T_{0D} (and M) was carried out
 394 by expressing T_{0D} as a function of LE [$T_{0D} = T_D + (\gamma LE / \rho c_p g_{AS1})$] which is described in detail by
 395 Mallick et al. (2016, 2018a) and Bhattarai et al. (2018). In the numerical iteration, s_1 was not
 396 updated to avoid numerical instability and it was expressed as a function of T_D .

397 **3.1.2 STIC-TI: Coupling modified MV2007-TI and STIC 1.2**

398 The initiation of the coupling between MV2007-TI and STIC1.2 was executed through linking
399 G_i estimates from the modified MV2007-TI with M estimates from STIC1.2. Having the initial
400 estimates of M (through eq. 13), an initial estimation of G_i was made from eq. (2) where S_f in eq.
401 11 was replaced with the initial estimates of M' . From the initial estimates of G_i (eq. 2) and R_{Ni}
402 (equations in Appendix B), initial estimates of LE_i and H_i were obtained through the PMEB
403 equation. Analytical expressions of the conductances for estimating H and LE through the PMEB
404 equation were obtained by solving the state equations as described in the Appendix. The process
405 was then iterated by updating T_{0D} [$T_{0D} = T_D + (\gamma LE / \rho c_p g_{AS1})$] and M in every time step (as
406 mentioned in Mallick et al., 2016, 2018a), and re-estimating G_i (using eq. 3), net available
407 energy ($R_{Ni} - G_i$), conductances, LE_i and H_i , until stable estimates of LE_i were obtained. The
408 conceptual block diagram and algorithm flow of STIC-TI is shown in Fig. 3a and Fig 3b,
409 respectively.

410

411

412

413

414

415

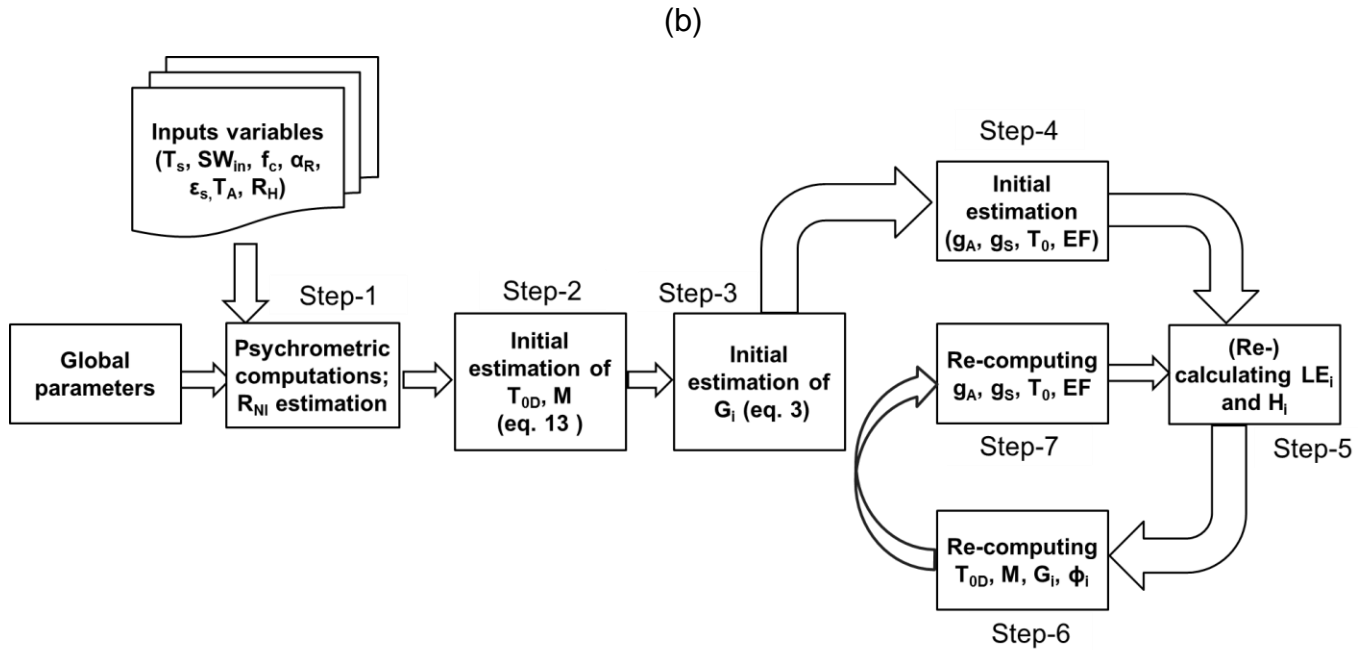

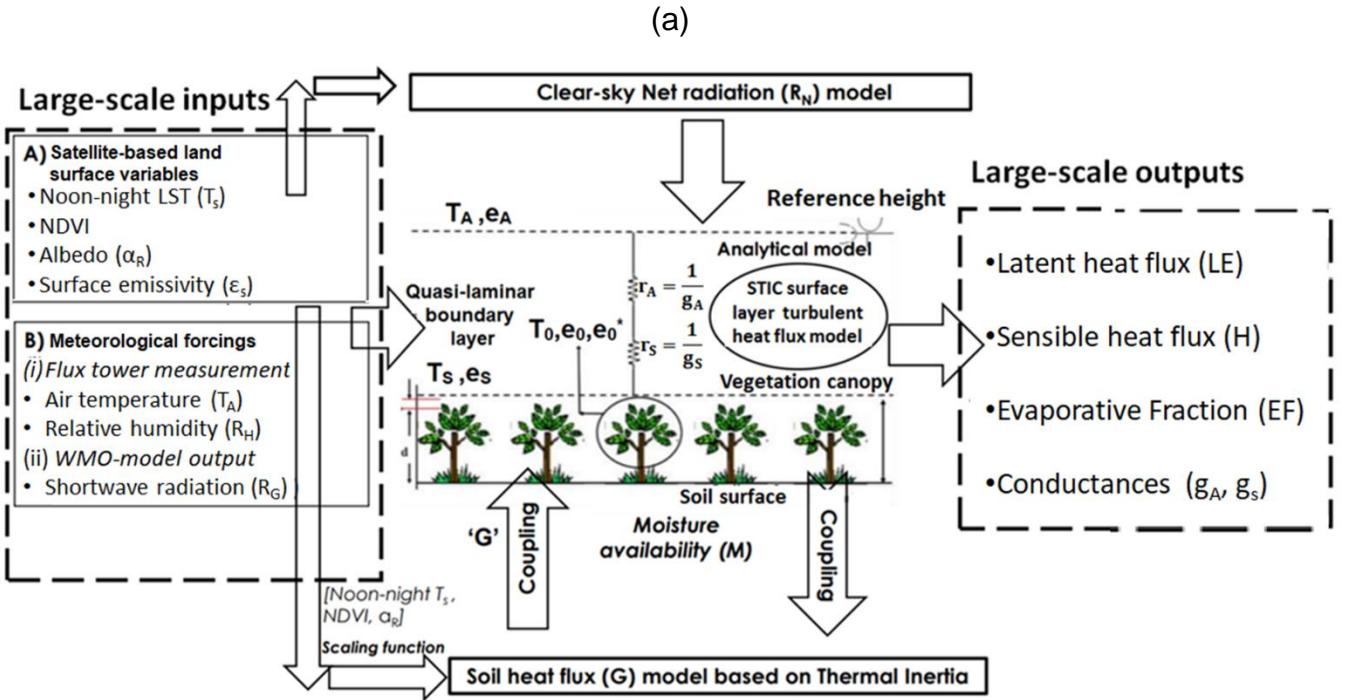

Figure 3: (a) Conceptual diagram of STIC-TI model showing different input variables and model outputs, (b) Algorithmic flow for estimating G and associated SEB fluxes through STIC-TI.

416 Examples of iterative stabilization of G_i and LE_i for Indian, Australian and US ecosystems of
 417 India are shown in Fig. 4. The iterative stabilization of G_i and LE_i was obtained between 8-25
 418 iterations for all sites.

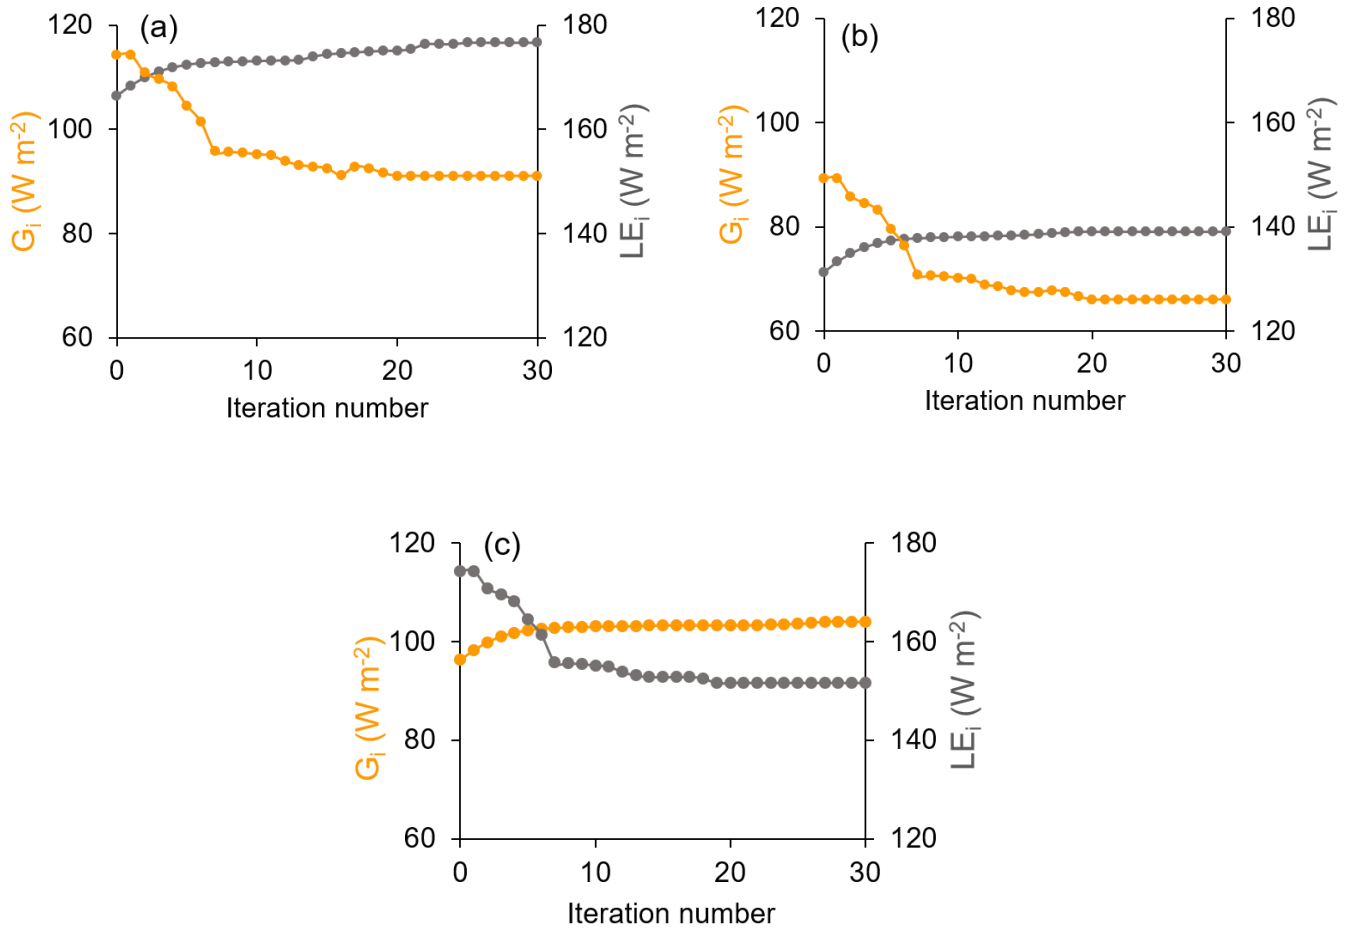

Figure 4: Illustrative examples of iterative stabilization of STIC-TI G_i (yellow marker line) and LE_i (grey marker line) in (a) IND-Jai, (b) AU-ASM, (c) US-Ton

419
 420 The noteworthy features of STIC-TI are: (1) estimating G by modifying the mechanistic
 421 MV2007-TI model using noon and midnight T_s information from thermal remote sensing
 422 observations available through polar orbiting satellite platform (e.g. MODIS Aqua), (2) coupling
 423 the mechanistic MV2007-TI G model with STIC1.2 to simultaneously estimate surface moisture
 424 availability (M), G , and SEB fluxes, (3) introducing water stress information in G (through M) to
 425 better constrain the aerodynamic and canopy-surface conductances as well as the SEB fluxes,

426 and (4) derivation of amplitude of ecosystem-scale surface soil temperature (from top soil to 0.1
427 m soil depth).

428 **3.1.3 Generation of remote sensing inputs**

429 Two of the key variables in SEB modeling are T_s and ϵ_s . These two variables were retrieved at
430 923m spatial resolution from MODIS Aqua noon-night TIR observations (MYD11A2) in bands
431 11.03 μm and 12.02 μm using a generalized split-window algorithm (Wan et al., 2015). For
432 optimal retrieval, tractable sub-ranges of atmospheric column water vapor and lower boundary
433 air surface temperature were used. Land surface emissivity was estimated from land cover types
434 and anisotropy factors. The MYD21A2 LST product was generated using Temperature-
435 Emissivity Separation (TES) algorithm (Hulley et al, 2016) and improved water vapor scaling
436 method to remove the atmospheric effects. Albedo was estimated from MODIS (MCD43A2
437 Version 6.0) Bidirectional Reflectance Distribution Function and Albedo (BRDF/Albedo) daily
438 dataset (Schaaf et al., 2002)) at 462 m spatial resolution. Actual albedo is a value which is
439 interpolated between white-sky and black-sky albedo as a function of fractional diffuse skylight
440 (which is a function of aerosol optical depth). NDVI was obtained from level 3 MODIS
441 vegetation indices product (MYD13Q1, version 6.1), which are generated every 16-day at 250
442 meter (m) spatial resolution. All the input remote sensing variables mentioned in table 2 were
443 resampled to spatial resolution of MYD11A2 product (923 m).

444 **3.2 Sensitivity and statistical analysis**

445 The accuracy of STIC-TI heavily depends on the accuracy of T_s , NDVI, and α_R due to the dual
446 role of T_s in estimating M and G_i , the role of NDVI in G_i , and the combined role of T_s and α_R in
447 estimating R_{Ni} . Therefore, one-dimensional sensitivity analysis was conducted to assess the
448 impacts of uncertainty in T_s , NDVI and α_R on G_i , H_i and LE_i . The sensitivity was assessed by
449 varying noon-time T_s by ± 0.5 K, ± 1.0 K and ± 1.5 K (keeping nighttime T_s constant so that
450 amplitude can vary automatically); varying NDVI by ± 0.05 ; ± 0.10 , ± 0.15 ; and varying albedo by
451 ± 0.02 , ± 0.05 , ± 0.10 , respectively. SEB fluxes were computed by using T_s , NDVI, and α_R for
452 three different periods of the year in all the eight ecosystems. Sensitivity analyses were
453 conducted by increasing and decreasing systematically T_s , NDVI, α_R from its central value while
454 keeping the other variables and parameters constant. This procedure was selected because the

455 fluxes and intermediate outputs of the STIC-TI model reflect an integrated effect due to
 456 uncertainty in T_S . In the first run, SEB fluxes were computed using *in-situ* T_S measurements
 457 obtained from the flux tower outgoing longwave radiation measurements. Then T_S was increased
 458 and decreased at constant interval and a new set of fluxes were estimated. In the similar way, α_R
 459 and NDVI were increased and decreased at constant intervals and new set of fluxes were
 460 computed. The sensitivity of STIC-TI was assessed by the equation 14.

$$\text{Sensitivity} = \frac{E_{i0} - E_{iM}}{O_i} * 100 \quad (14)$$

461 E_{i0} is the estimated (original) model output and E_{iM} is the estimated (modified) output obtained
 462 by changing the variable whose sensitivity is to be tested. O_i is actual measurements. Apart from
 463 the sensitivity analysis, the following set of statistical metrics were used to assess model
 464 performances.

$$R^2 = \left(\frac{\sum_{i=1}^n (E_i - \bar{E}) (O_i - \bar{O})}{\sqrt{\sum_{i=1}^n (E_i - \bar{E})^2} \sqrt{\sum_{i=1}^n (O_i - \bar{O})^2}} \right)^2 \quad (15)$$

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^n (E_i - O_i)^2}{n}} \quad (16)$$

$$\text{BIAS} = \frac{\sum_{i=1}^n (E_i - O_i)}{n} \quad (17)$$

$$\text{MAPD} = \frac{100}{n} \sum_{i=1}^n \left| \frac{E_i - O_i}{O_i} \right| \quad (18)$$

$$\text{KGE} = 1 - \sqrt{(r - 1)^2 + \left(\frac{\sigma_E}{\sigma_o} - 1 \right)^2 + \left(\frac{\bar{E}}{\bar{O}} - 1 \right)^2} \quad (19)$$

465 Where R^2 is the coefficient of determination, RMSE is root-mean-square error, BIAS is the mean
 466 bias, MAPD is the mean absolute percent deviation, KGE is Kling-Gupta efficiency, n is the total
 467 number of data pairs, the bar indicates mean value of the measured variable and model estimates
 468 of the same variable. E_i and O_i are the model estimated and measured SEB fluxes, r is
 469 the Pearson's correlation coefficient and \bar{O} is the average of measured values and \bar{E} is the

470 average of estimated values and σ_o is standard deviation of observation values and σ_E is the
471 standard deviation of estimated values. The KGE has been widely used for calibration and
472 evaluation hydrological models in recent years and it combines the three components of Nash-
473 Sutcliffe efficiency (NSE) of model errors (i.e., correlation, bias, ratio of variances or
474 coefficients of variation) in a more balanced way. But it has not been widely used for analyzing
475 the ET model performances. $KGE = 1$ indicates perfect agreement between modeled estimates
476 and observations. The performance of a model is considered ‘poor’ for KGE between 0 and 0.5
477 and models with negative KGE values is considered ‘not satisfactory’.

478 **4 Results**

479 **4.1 Ecosystem- scale surface soil temperature amplitude (A)**

480 The scaling functions developed to estimate ecosystem-scale (1km) surface soil temperature
481 amplitude (A) from point-scale T_{STA} were used to estimate G_i . However, before the development
482 of the scaling functions, analysis was carried out to investigate the relationship of soil
483 temperature amplitude between the two different spatial scales. The scatterplot (Fig. 5a) of noon-
484 night LST difference (ΔT_s) versus T_{STA} for different albedo classes showed a linear increase in
485 ΔT_s with increasing T_{STA} . However, some divergence of data points within the cluster were also
486 noticed which could be associated with different albedo (α_R) levels. Bivariate linear function was
487 fitted between T_{STA} as predictand (Y) versus ΔT_s ($T_{sd} - T_{sn}$) and α_R as predictors (X1 and X2,
488 respectively). The function was found to be $Y = 0.59X1 - 51.3X2 + 8.66$ by combining the data
489 of nine ecosystems ($r = 0.86$). The coefficients in the above expressions correspond to B1 (0.59),
490 B2 (51.3), B3 (8.66) of eq. 5 in section 3.1.1.1. The estimated amplitude from this ecosystem-
491 scale predictors and scaling functions was treated as ecosystem-scale surface soil temperature
492 amplitude (A).

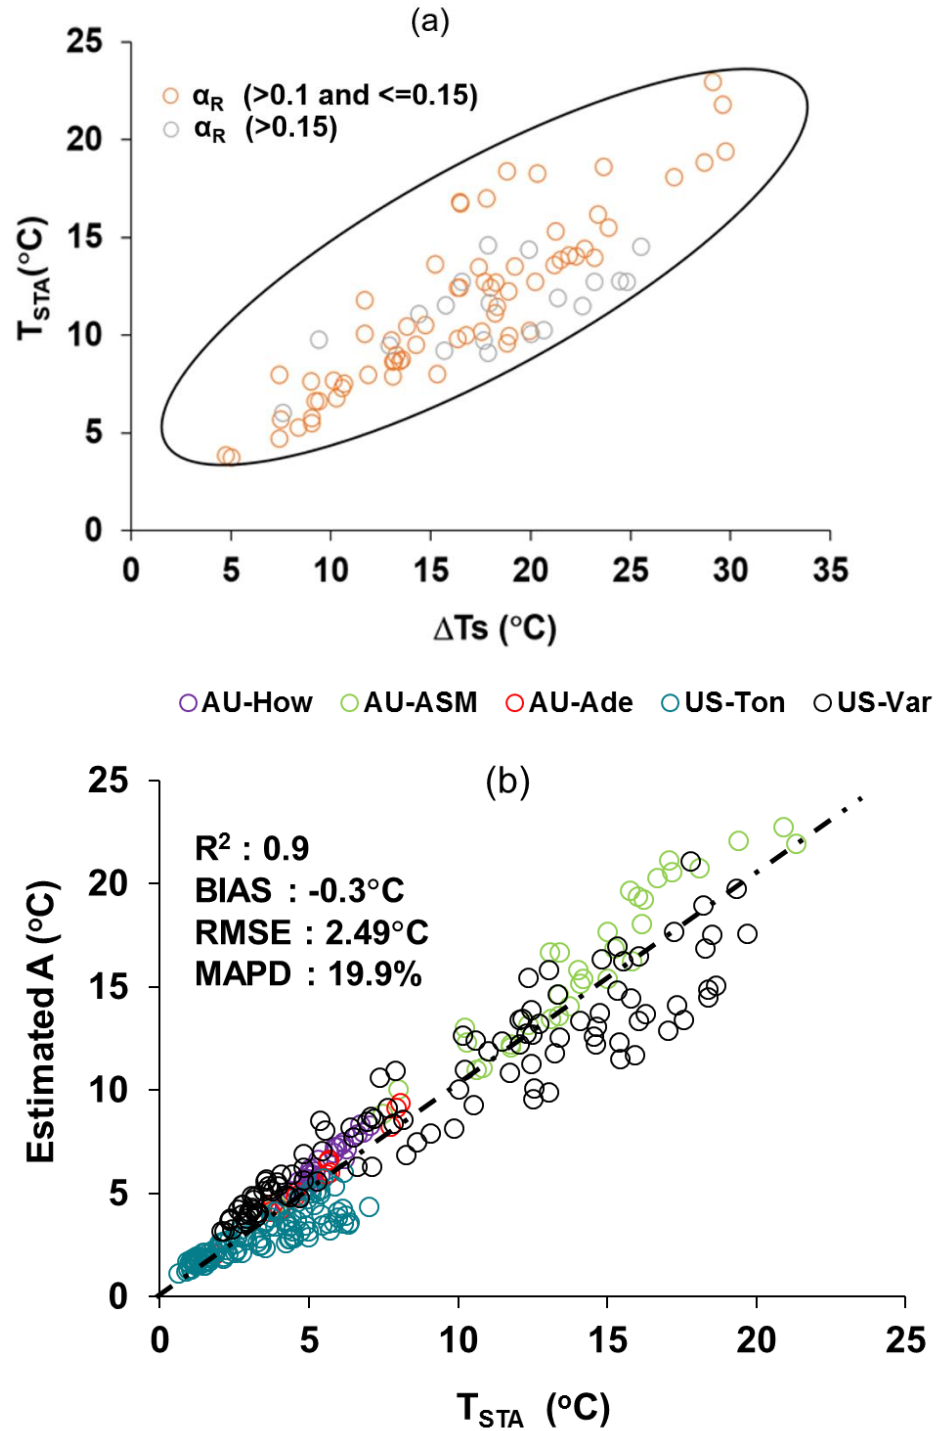

Figure 5. (a) Two-dimensional scatterplots between (ΔT_s) versus T_{STA} at different α_R levels over different ecosystems. Here T_{STA} in y-axis is the observed soil temperature amplitude that is used to develop the scaling function and delta ΔT_s is noon-night LST difference of MODIS AQUA; (b) Validation of ecosystem-scale estimates of A from the above functions over different sites.

493 Validation of ecosystem-scale estimates of A from the above functions over different sites is
494 shown in Fig. 5b with respect to T_{STA} for the independent datasets. The estimated A was found to
495 have MAPD of 19.9%, negative bias, and $R^2 = 0.90$ over different ecosystems. The temporal
496 variation of estimated A and T_{STA} is shown in Fig D1 in Appendix D. Further analysis was
497 carried out to investigate the bias in A at three fractional vegetation cover (f_c) slabs ($f_c < 0.3$;
498 $0.3 \leq f_c \leq 0.5$; $f_c > 0.5$) representing bare soil (slab 1), 30 – 50% canopy cover (slab 2) and more
499 than 50% canopy cover (slab 3), respectively. While negative bias was noted for slab 1 and slab
500 3 (-0.54°C and -0.83°C), the bias was positive (0.49°C) in the intermediate f_c which represents
501 sparse and patchy canopy cover. The signals of surface albedo, emissivity and temperatures of
502 soil surface and canopy are relatively pure in slab1 and slab 3 as compared to slab 2, where the
503 surface signal carries more heterogeneity. Given T_{STA} is computed from the in-situ
504 measurements, it is likely to carry more heterogeneity in slab 2 as compared to the other two
505 slabs. The land surface emissivity in MYD11A2 was estimated from land cover types and
506 anisotropy factor, which have differential impacts on T_{ST} and T_S leading to such opposite bias in
507 slab 2 as compared to slab 1 and slab 3.

508 **4.2 Sensitivity analysis of STIC-TI G_i , LE_i and H_i to land surface variables**

509 **4.2.1 Sensitivity of G_i to land surface variables**

510 The average sensitivity of G_i to three land surface variables (T_S , NDVI, α_R) by combining the
511 estimates of wet and dry periods is shown in Fig. 6. G_i was found to be substantially sensitive to
512 T_S with error magnitude ranging from 2 – 18% due to T_S uncertainties of $\pm 0.5 - 2.5$ K (Fig. 6a),
513 with greater sensitivity to T_S during the summer season as compared to other seasons. The
514 median sensitivity of G_i due to $\pm 5 - 10\%$ uncertainty in α_R varied from 5 to 12% in all the
515 ecosystems (Fig. 6b). The uncertainties in NDVI revealed 2 to 15% error in G_i estimates (Fig.
516 6c), and no significant difference in the mean sensitivity due to NDVI uncertainties was noted
517 between the ecosystems. The sensitivity of G_i decreased with increasing values of NDVI.

518 **4.2.2 Sensitivity of LE_i and H_i to land surface variables**

519 Both LE_i and H_i were sensitive to T_S to the order of 2 – 29% (LE_i) and 5 – 35% (H_i) for T_S
520 uncertainty of $\pm 0.5 - 2.5$ K from its mean values (Table 3). Interestingly, LE_i was more sensitive
521 to T_S uncertainties as compared to H_i in the rainfed ecosystems. The highest mean sensitivity of

522 LE_i to T_S was found in arid (IND-Jai: 2 – 28%), semi-arid (AU-ASM: 5 – 21%), tropical savanna
 523 (IND-Dha: 3 – 26%), savanna (US-Ton: 4-29%) and arid (US-Var: 3-26%) ecosystems. The
 524 mean sensitivity of H_i to T_S was maximum in sub-humid (IND-Sam: 2 – 32%), semi-arid (IND-
 525 Naw: 2 – 28%), savanna (AU-Ade: 8 – 17%) (Table 3). A greater sensitivity of the SEB fluxes
 526 due to α_R uncertainties was found than due to NDVI. The median sensitivity of LE_i and H_i due to
 527 10% uncertainty from mean α_R varied within 2 – 16% in all the ecosystems (Table 3). By
 528 contrast, errors in the two SEB fluxes were substantially low (2 – 13%) due to $\pm 0.05 - 0.15$
 529 uncertainty from mean NDVI (Table 3).

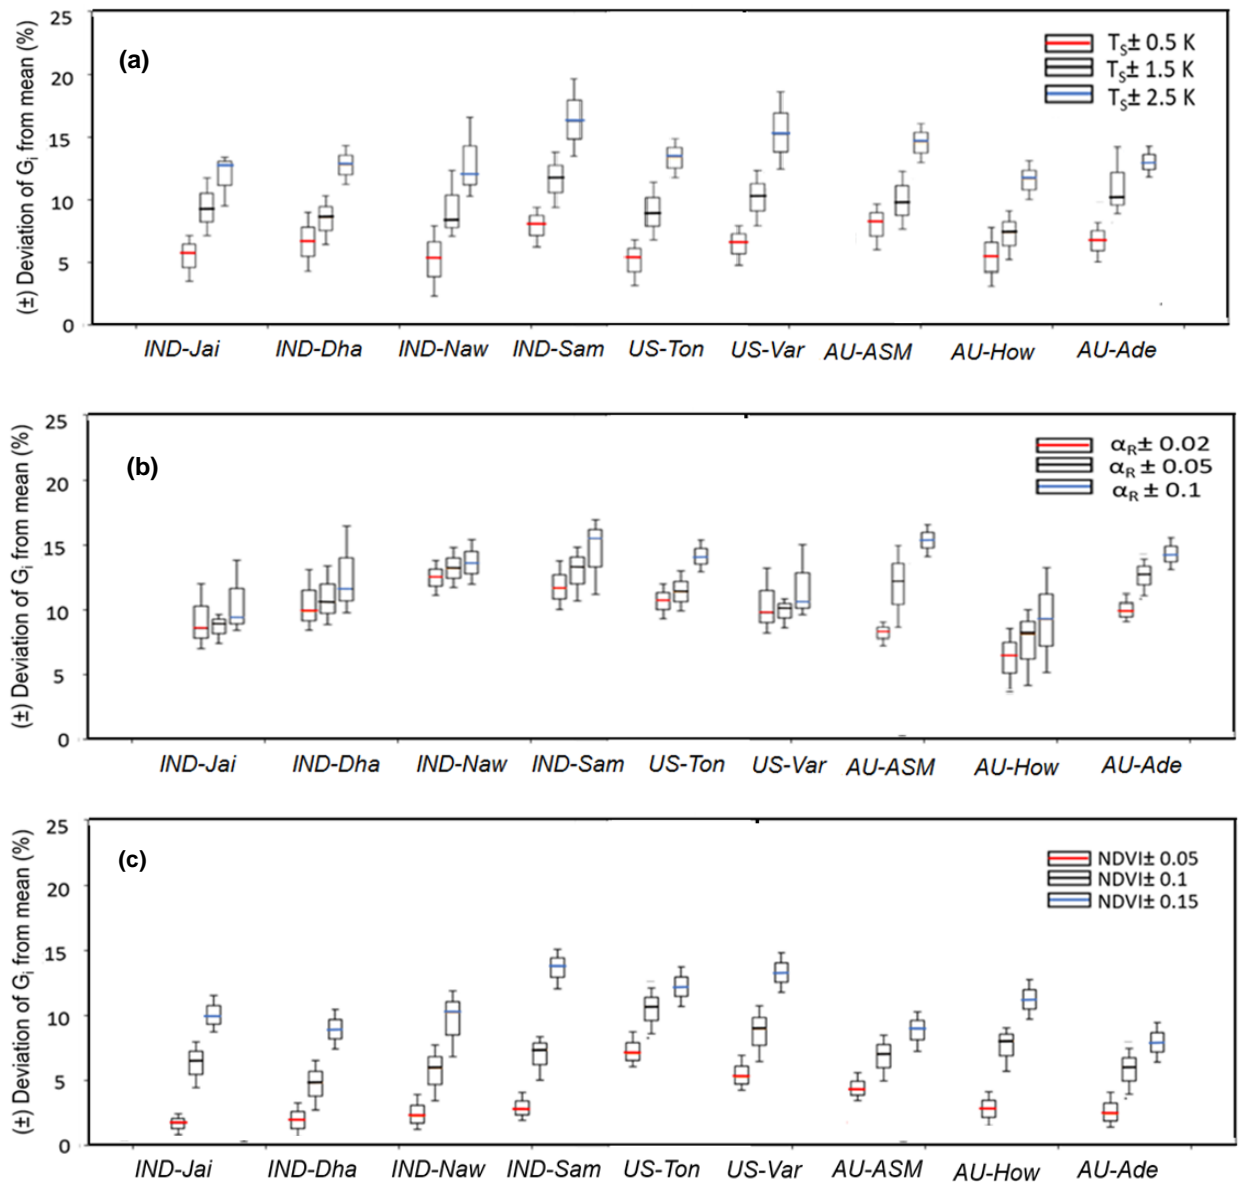

Figure 6: Sensitivity of STIC-TI G_i due to uncertainties in T_S (a), α_R (b), and NDVI (c) for eight

flux tower sites in India and Australia. The uncertainties were introduced by taking the mean values of these variables during three different periods (summer, rainy and winter) of a year. Mean uncertainties of the three periods are presented in the figure.

530 **Table 3:** Sensitivity (in percent) of LE_i and H_i due to T_s , NDVI, and α_R uncertainties

Study sites	Sensitivity of LE_i and H_i to T_s , NDVI and α_R (percent change)					
	T_s uncertainty ($\pm 0.5 - 2.5 K$)		α_R uncertainty ($\pm 5 - 10\%$)		NDVI uncertainty ($\pm 0.05 - 0.15$)	
	LE_i	H_i	LE_i	H_i	LE_i	H_i
IND-Jai	2-28	1-6	3-14	2-13	2-8	2-6
IND-Dha	3-26	2-8	2-12	3-12	3-10	3-9
IND-Naw	1-20	2-28	2-10	3-10	2-7	2-6

531

532 4.3 Comparative evaluation of STIC-TI and contemporary G_i models

533 The performances of STIC-TI and existing G_i models were evaluated and compared with respect
534 to *in-situ* G_i measurements. The existing models reported by Moran et al. (1989), Bastiaanssen et
535 al. (1998), Su (2002), and Boegh et al. (2004) have been considered for comparing with TI-based
536 model. These four existing models are referred here as MOR89, BAS98, SU02 and BO04,
537 respectively. While the models MOR89, SU02 and BO04 are based on linear regression between
538 G versus NDVI, BAS98 is based on multivariate regression of G with NDVI, LST and α_R . The
539 performance of the STIC-TI was substantially better as compared to MOR89, SU02 and BO04
540 with respect to MAPD (19%), RMSE (22 Wm^{-2}) and coefficient of determination ($R^2 = 0.8$)
541 when compared with *in-situ* measurements over one Indian, three Australian and two US flux

542 tower sites (Table 4) and also comparable with BAS98 G_i model. The validation plot of retrieved
 543 noontime G_i from STIC-TI is shown in Fig. 7.

Figure 7: Validation of noontime (1:30 pm) G_i estimates with respect to in-situ measurements in different ecosystems. The regression between the two sources of G_i is G_i (STIC-TI) = 0.90 G_i (tower) -0.10.

544 **Table 4:** A comparison of error statistics of G_i estimates from STIC-TI and existing G_i models
 545 over different ecosystems

G models	R^2	RMSE (W m^{-2})	MAPD (%)	KGE
STIC-TI	0.80	22	19	0.74
MOR89	0.70	31	29	0.46
BAS98	0.80	20	18	0.61
SU02	0.80	30	26	0.54
BO04	0.70	35	29	0.48

546 The RMSE varied from 9 to 20 W m^{-2} with MAPD ranging from 12 to 21% across individual
 547 flux tower sites. High magnitude of G_i was predicted in the arid and semi-arid systems (120 –

548 240 W m⁻²) as compared to the humid systems (20 – 90 W m⁻²), which was in close
 549 correspondence with the observations. The model also captured the range of G_i that are generally
 550 found in different biomes (20 – 140 W m⁻² for grasslands, 20 – 90 W m⁻² for cropland) (Purdy et
 551 al., 2016). Due to the paucity of G_i measurements, direct validation of G_i was only possible for
 552 32 days (concurrent to MODIS overpass) at the IND-Dha site. Overall, STIC-TI tends to provide
 553 reasonable G estimates for the terrestrial ecosystems having soil temperature amplitude above
 554 5°C.

555 4.4 Evaluation of STIC-TI LE_i, H_i, and EF

556 The modeled versus measured LE_i and H_i showed good agreement in all the nine ecosystems
 557 with RMSE in LE_i and H_i estimates using MYD11 LST product to the order of 29 – 62 W m⁻²
 558 and 26 – 61 W m⁻², MAPD of 9 – 31% and 20 – 36%, BIAS of -29 to 38 W m⁻² and -44 to 32 W
 559 m⁻² (Fig. 8a, b; Table 5) and high R² of 0.8.

Figure 8: (a) Validation of STIC-TI LE_i estimates with respect to *in-situ* measurements in different ecosystems; (b) Validation of STIC-TI H_i estimates with respect to *in-situ* measurements in different ecosystems.

560

561 **Table 5:** Error statistics of STIC-TI LE_i and H_i estimates with respect to EC measurements in
 562 different ecosystems of India, US, and Australia using MYD11A2 LST product for all nine sites
 563 and using MYD21A2 LST product for three semi-arid and arid sites. The statistics obtained by
 564 using MYD21A2LST are shown in the parentheses.

Sites	STIC-TI (LE_i and H_i)									
	R ²		BIAS ($W\ m^{-2}$)		RMSE ($W\ m^{-2}$)		MAPD (%)		KGE	
	LE_i	H_i	LE_i	H_i	LE_i	H_i	LE_i	H_i	LE_i	H_i
IND-Jai	0.90 (0.91)	0.90 (0.92)	-21 (-16)	12 (9)	57 (45)	27 (21)	31 (24)	22 (19)	0.80 (0.82)	0.76 (0.79)
IND-Naw	0.90 (0.92)	0.80 (0.85)	19 (12)	-26 (-16)	44 (37)	51 (46)	17 (16)	28 (25)	0.92 (0.92)	0.71 (0.73)
IND-Dha	0.90	0.90	38	-44	43	35	27	25	0.71	0.64
IND-Sam	0.90	0.80	12	-10	32	61	9	27	0.95	0.70
US-Ton	0.90 (0.91)	0.90 (0.92)	-29 (-18)	-32 (-21)	53 (45)	34 (27)	25 (22)	17 (15)	0.85 (0.87)	0.91 (0.93)
US-Var	0.90	0.80	-19	-28	49	39	27	20	0.82	0.89
AU-ASM	0.90 (0.93)	0.90 (0.91)	-3 (6)	22 (16)	46 (37)	26 (18)	29 (24)	20 (17)	0.94 (0.95)	0.83 (0.85)
AU-How	0.90	0.90	16	-25	42	27	17	21	0.89	0.85
AU-Ade	0.90	0.90	21	15	29	53	28	36	0.77	0.80

565

566 Arid ecosystems in India (IND-Jai), US (Ton and Var) and semi-arid ecosystem in Australia
567 (AU-ASM) revealed relatively high MAPD (31%, 25%, 27%, and 28%) (Table 5). In general,
568 STIC-TI was able to produce the dominant convective heat fluxes with respect to the EC
569 measurements as evident through low RMSE for H_i and high RMSE for LE_i in the IND-Jai, US-
570 Ton, US-Var, and AU-Ade where LE_i is inherently low except few rainy days. A uniform
571 distribution of data points around 1:1 validation line (Fig. 8a) indicated overall low BIAS in LE_i
572 estimates. However, modeled H_i was consistently lower than the observations (negative BIAS) in
573 the tropical savanna (IND-Dha and AU-How) and semi-arid (IND-Naw) ecosystems [(-44) – (-
574 25) $W\ m^{-2}$ and -26 $W\ m^{-2}$] while a consistent positive BIAS was observed in the AU-ASM
575 (semi-arid) and AU-Ade (savanna), US-Var (arid) (Fig. 8b; Table 5). This consequently led to
576 overall low negative BIAS (-10 $W\ m^{-2}$), relatively low R^2 in H_i ($R^2 = 0.8$) as compared to the
577 errors in LE_i (BIAS = 15 $W\ m^{-2}$, $R^2 = 0.9$). The regression between the modeled and tower
578 measurements of LE_i is $LE_i(\text{STIC-TI}) = 0.98LE_i(\text{tower}) - 0.266$. The regression between the
579 modeled and tower measurements of H_i is $H_i(\text{STIC-TI}) = 0.93H_i(\text{tower}) + 4.90$. The KGE
580 statistics varied in the range of 0.71 – 0.95 for LE_i and in the range of 0.64 – 0.91 for H_i ,
581 respectively across all nine flux tower sites, thus revealed reasonably high efficiency of the
582 model to capture the magnitude and variability of SEB fluxes.

583 The effects of day-night view angle of MODIS Aqua on STIC-TI were further investigated,
 584 where the percent deviations in LE_i , H_i and G_i with respect to measurements were analysed in
 585 response to the day and night view angle distributed over 12 angular bins within $\pm 50^\circ$ at 10°
 586 interval. Number of occurrences of deviations in each bin of day view angle are plotted in Figure
 587 F (Refer Appendix F), which showed similar near normal distribution of the three fluxes with G_i
 588 deviation having less peak occurrence as compared to the other two. This is due to a smaller
 589 number of available datasets used in case of G_i . It has been found that 90% of deviations occur
 590 within -40° to 30° day view angle thus showing some impact of day view angle on the modeled
 591 fluxes. The night view angle variation apparently had no impact on the modelled fluxes.

Figure 9: Relationship between KGE of STIC-TI (G_i and LE_i) with $\Delta T_s / f_c$ in different terrestrial ecosystems.

592 Further investigation was made on whether KGE for STIC-TI G_i and LE_i follow any systematic
 593 pattern and the ratio ΔT_s and f_c was used as proxy for surface heterogeneity and dryness. The
 594 plot of KGE of G_i and LE_i with this ratio is shown in Fig. 9. KGE- G_i was found to show a
 595 systematic decrease with increase in ΔT_s - f_c ratio up to 40, after which it remained unchanged
 596 with increase in the ratio. Although KGE of LE_i also decreased (20% reduction) with increase in
 597 ΔT_s - f_c ratio, KGE- LE_i was found to increase beyond ΔT_s - f_c 40. This revealed that the model

598 efficiency remained high (>0.8) within certain dryness limits (ΔT_s -fc ratio <20 and >50) and the
 599 efficiency reduced moderately (within $0.7 - 0.8$) for intermediate dryness. Interestingly, the use
 600 of MYD21A2 LST in STIC-TI showed improvements (see the parentheses in different columns
 601 in Table 5) in LE_i and H_i error statistics as compared to using MYD11A2 LST in terms of higher
 602 R^2 and KGE, and lower RMSE in LE_i (3-8% less) and H_i (2-3% less) for semi-arid and arid sites
 603 such as IND-Jai, IND-Naw and US-Ton.

604 An independent evaluation of multi-temporal heat fluxes over two US flux sites for the years
 605 2016-2018 is shown in Fig. 10 and Fig 11. STIC-TI G_i estimates with MYD11A2 LST product
 606 showed close match with *in-situ* measurements with respect to intra and inter-annual variability
 607 in G_i followed by LE_i and H_i . This further demonstrates the merit of the coupled model for
 608 reproducing ecosystem-scale G_i estimates especially for shorter and open canopies.

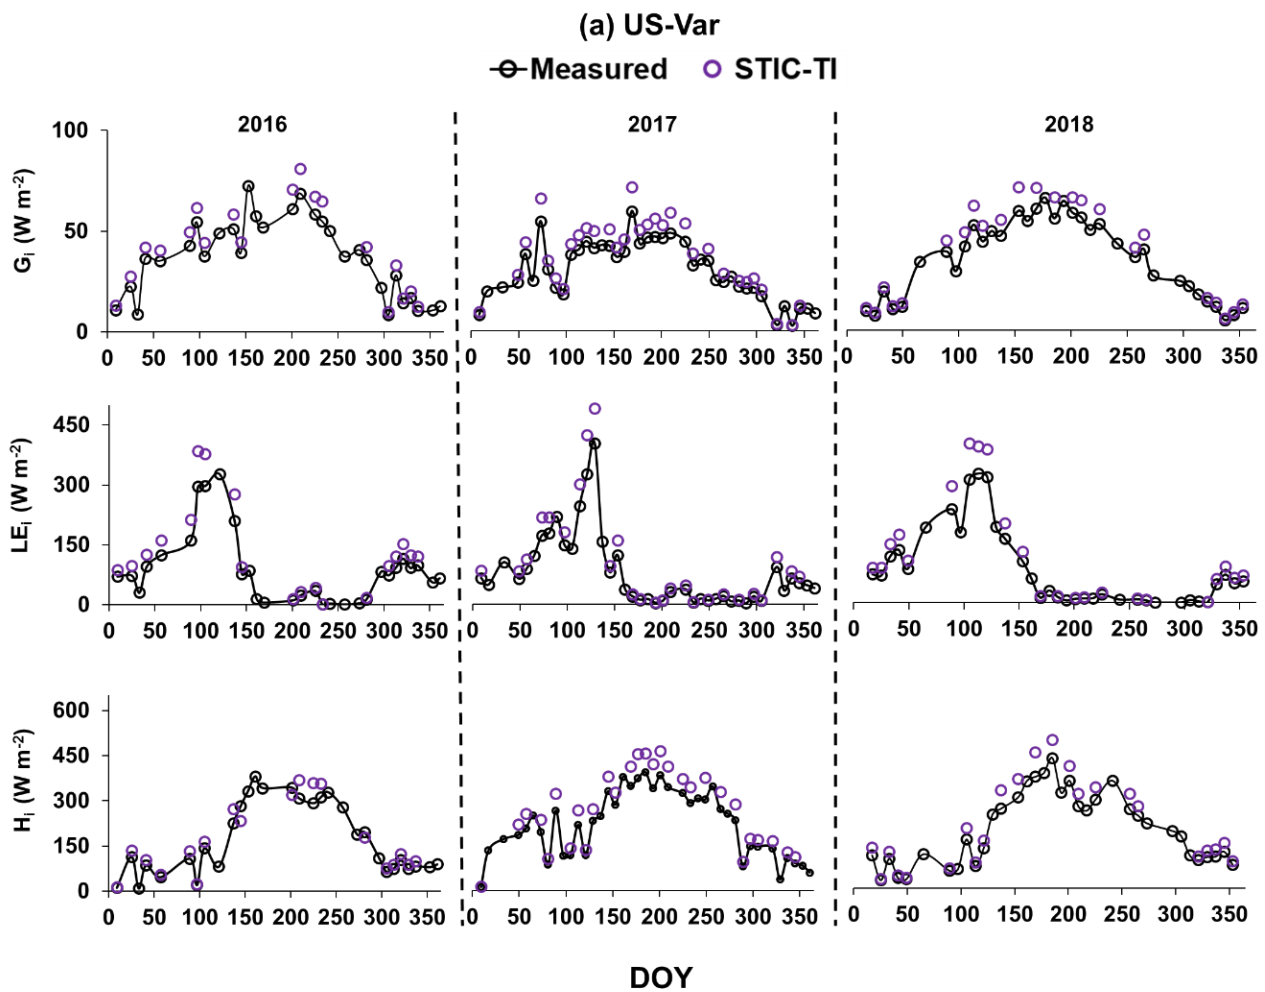

Figure 10: Illustrative examples of temporal evolution of STIC-TI derived fluxes using MYD11A2 LST product versus observed SEB fluxes for three consecutive years from 2016 to 2018 in a grassland ecosystem in United States (e.g., US-Var).

Figure 11: Illustrative examples of temporal evolution of STIC-TI derived fluxes using MYD11A2 LST product versus observed SEB fluxes for three consecutive years from 2016 to 2018 in a woody savanna ecosystem in the United States (e.g., US-Ton).

609 The temporal behavior of STIC-TI and observed evaporative fraction (EF) (ratio of LE and $R_N -$
 610 G) (Fig. 12) along with observed monthly rainfall (P) distinctly captured the substantial temporal
 611 variability in EF during the dry-to-wet transition in the Indian study sites, which also
 612 corresponded to low (high) θ and P. In IND-Naw and IND-Sam, a marked rise (>0.4) in STIC-TI
 613 EF was noted during day-of-the-year (DOY) 25 to 75 where wheat is grown under assured
 614 irrigation. The impact of irrigation is thus captured by the substantial increase in EF in the
 615 absence of P. In contrast, the rainfed grassland system (IND-Jai) showed peak EF (~ 0.8), which
 616 corresponded to south-west monsoon rainfall during June to September and a progressive decline

617 in EF during the dry down period in October to April corresponding to post south-west monsoon
 618 phase. Some intermittent spikes in EF were also noted during dry-down phase in both STIC-TI
 619 and observations. The intermittent EF spikes during the soil moisture dry down phase could be
 620 due to enhanced LE through moisture advection from the surrounding vegetation causing an
 621 enhancement of evaporation than expected. This is known as the ‘clothesline effect’ which
 622 frequently occurs in semi-arid and arid ecosystems. In addition to IND-Jai, the response of both
 623 modeled and measured EF to wet and dry spells was also noted during south-west monsoon
 624 period at all other flux tower sites of India.

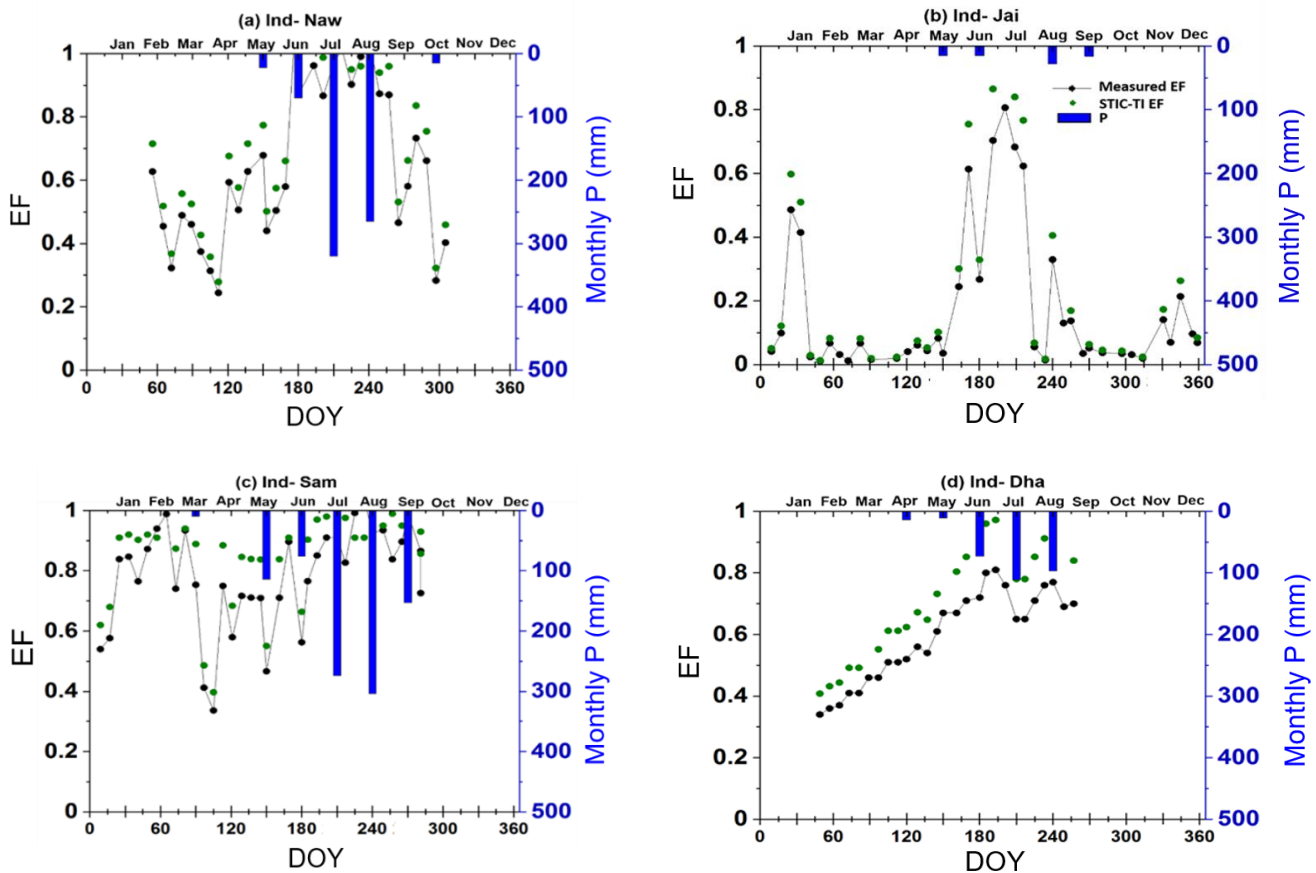

Figure 12: Illustrative examples of temporal variation of STIC-TI derived EF using MYD11A2 LST product with respect to measured EF and P in (a) IND-Naw, (b) IND-Jai, (c) IND-Sam, and (d) IND-Dha

625 The temporal behavior of EF from STIC-TI using MYD11A2 LST product and EC
 626 measurements along with measured θ and P at the OzFlux and AmeriFlux sites also revealed
 627 (Fig. 13) close correspondence of STIC-TI with EC observations. Low EF (0.05 – 0.40) during
 628 the dry season around DOY 100 – 250 and high EF (>0.4) during the wet season (DOY 1 – 120

629 and 300 to 360) in AU-ASM, US-Ton and US-Var was observed. The analysis showed that
 630 STIC-TI EF can capture the annual variability of observed EF and its responses across different
 631 ecosystems during wet and dry seasons. The plots of STIC-TI EF versus measured θ (in the inset
 632 of Fig. 13) revealed triangular scatter close to right-angled triangle with positive slope of
 633 hypotenuse in three ecosystems AU-ASM, US-Var and US-Ton. This showed that in the water-
 634 controlled ecosystems, where distinct wet-dry seasons exist, the positive EF- θ relationship is an
 635 outcome of the soil moisture controls on transpiration during the dry season.

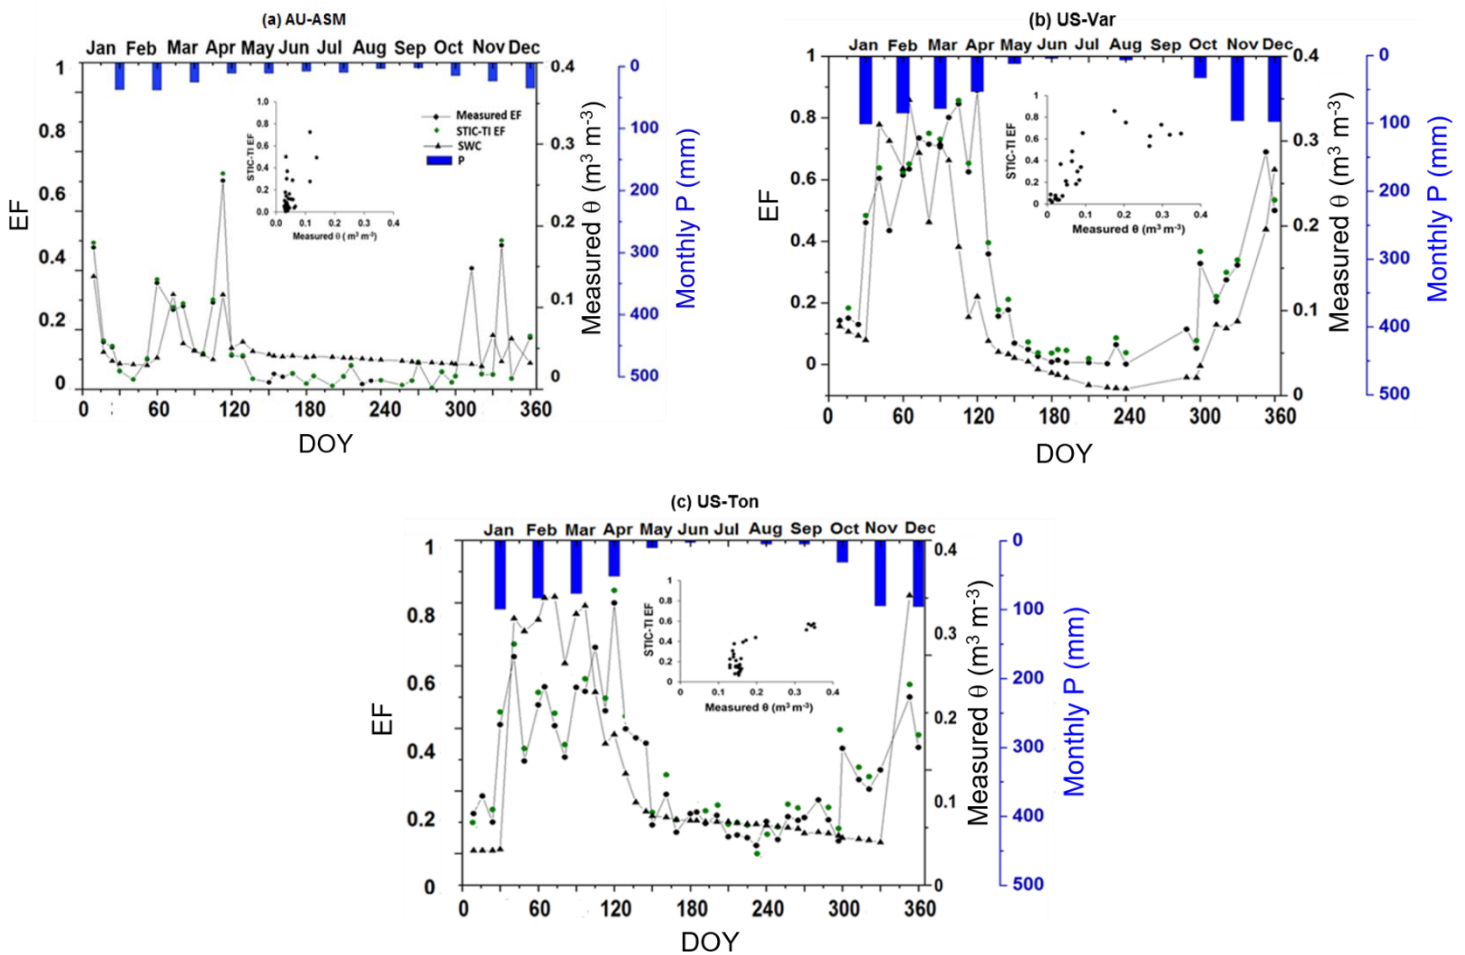

Figure 13: Comparison of temporal variation of STIC-TI derived EF using MYD11A2 LST with respect to measured EF, θ and Pin (a) AU-ASM, (b) US-Var, (c) US-Ton. The scatterplots in the inset shows the relationship between STIC-TI EF with respect to measured θ .

636 **5 Discussion**

637 **5.1 Interaction of flux and internal SEB metrics**

638 From section 4.1 we found relatively reduced sensitivity of G_i to T_s uncertainties. In any given
639 condition, if an over(under) estimation of M due to noontime T_s uncertainties (through eq. 13)
640 leads to an over(under) estimation of Γ , the effects of such over(under) estimation of Γ (due to
641 noontime T_s uncertainties) tend to be compensated by under(over) estimation of amplitude A (in
642 eq. 5), ultimately leading to a reduction of the sensitivity of G_i to T_s . While the scatter between G
643 versus A for a wide range of Γ (Fig. 14a) revealed large scatter with increasing amplitude under
644 the dry conditions (low Γ), the scatter between Γ versus T_s for different M (Fig. 14b) revealed
645 exponential reduction of Γ with increasing T_s and dryness, and almost no significant change in Γ
646 with increasing T_s at a constantly high dryness ($M < 0.25$). Thus, the confounding effects of Γ , A ,
647 and M through eq. 3, 5, 12 and 13 led to a reduction of sensitivity of G to T_s , as exemplified in
648 Fig. 14.

Figure 14: Response plots among parameters of TI-based G_i model, such as (a) G_i versus Amplitude (A) for varying Γ , and (b) Noon-time T_s versus Γ with varying M .

649

650 Concerning LE_i and H_i , dual uncertainties could be propagated in both the fluxes through
651 daytime T_s (through M and G_i), leading to high sensitivity of these two SEB fluxes due to T_s
652 perturbations. The relatively high sensitivity of LE_i to T_s (as compared to H_i) in the non-
653 irrigated ecosystems could be due to partial compensation of g_A/g_s in both numerator and
654 denominator of the PMEB equation for H (eq. C7 of Appendix C). A recent study (Fig.10 in
655 Mallick et al., 2018a) showed high sensitivity of g_s due to T_s (1% change in T_s led to 5.2–
656 7.5% change in g_s) as compared to g_A sensitivity to T_s (1% change in T_s led to 1.6–2%

657 change in g_A), suggesting that errors in g_S due to T_S uncertainty tend to be larger than errors in
658 g_A . Partial cancellation of the conductance errors in the numerator of eq. (C7 of Appendix C)
659 might have resulted in compensation of H_i errors in the water-limited ecosystems. In this
660 environment, the variability of LE_i is mainly dominated by g_A/g_S , which makes LE_i highly
661 sensitive due to T_S uncertainties. Combined uncertainty due to g_A/g_S in the denominator and
662 g_A in the numerator of eq. (C6 of Appendix C) resulted into greater sensitivity in LE_i to T_S in
663 the arid and tropical savannah ecosystems (Mallick et al., 2015, 2018a; Winter & Eltahir,
664 2010). The very low sensitivity of LE_i and H_i due to uncertainties in NDVI is because NDVI
665 was not used in the conductance parameterizations and effects due to NDVI in STIC-TI was
666 only propagated through G_i . The sensitivity of LE_i and H_i to albedo was mainly due to the
667 dependence of net radiation (R_{Ni}) on albedo, and any resultant uncertainty in R_{Ni} (due to
668 albedo) tends to be reflected in the sensitivity of LE_i and H_i to albedo.

669 **5.2 Possible sources of errors in SEB flux evaluation**

670 In STIC-TI, underestimation and overestimation errors in G_i in different ecosystems (Fig. 7)
671 could originate due to the errors in MYD11A2 LST product. A host of studies previously
672 reported that the standard deviations of errors in retrieved emissivity in bands 31 and 32 are
673 0.009, and the maximum error in retrieved T_S of MOD11A1 LST falls within 2-3 K, which is
674 mainly due to the errors in surface emissivity correction (Duan et al., 2017; Wan, 2014; Lei et
675 al., 2018). In the present analysis, we found an overestimation error of MODIS T_S in the range of
676 0.5 – 1.5 K when compared with *in-situ* infrared temperature measurements at the tropical
677 savanna site. As mentioned in section 3.1, a positive (negative) bias in T_S would tend to an
678 overestimation (underestimation) of amplitude (A) in eq. (5); underestimation (overestimation)
679 of M in eq. (13), and consequent underestimation (overestimation) of Γ (eq. 12) and G_i ,
680 respectively. Furthermore, the standard deviation of NDVI surrounding the tower sites varied
681 from 0.01 – 0.05 when compared to the ground measurements, which could be another source of
682 error in the STIC-TI model. In addition, NDVI saturates at $LAI > 3$. However, STIC-TI provides
683 direct estimates of ecosystem G and is independent of R_N .

684 Despite the comparable accuracy of current G estimates with the G model of Bastiaanssen et al
685 (1998), the foundation of STIC-TI lies in the use of soil moisture characteristics with varying soil
686 textural types which are known to influence the soil heat conductance and thereby G . Thus, the

687 control of soil moisture on evaporation is explicitly included in STIC-TI as opposed to the semi-
688 empirical G function of Bastiaanssen et al (1998). The higher accuracies of TI-based thermal
689 diffusion model as compared to R_N -based empirical G models were also reported by Purdy et al.
690 (2016) at daily or longer time scales in cropland, grassland. All these G model estimates many a
691 times differ from in situ measurements because of the no accounting of leaf litter presence or
692 layer on soil floor in the remote sensing-based G-model.

693 The overestimation (underestimation) of $LE_i(H_i)$ is also due to the effects of spatial resolution of
694 different input variables on these two SEB fluxes and conducted statistical evaluation with
695 respect to the measured SEB fluxes. Eswar et al. (2017) demonstrated the need for spatial
696 disaggregation models for monitoring LE_i at field scale using contextual models by
697 disaggregation of evaporative fraction (Λ) and downwelling shortwave radiation ratio (R_G).
698 Using different disaggregation models, they estimated LE_i at 250m spatial resolution and
699 reported RMSE of $30 - 32 \text{ W m}^{-2}$ as compared to LE_i obtained at 1000m spatial resolution with
700 RMSE of $40 - 70 \text{ W m}^{-2}$ over different sites in India. Anderson et al. (2007) reviewed different
701 validation experiments conducted in diverse agricultural landscapes (Anderson et al., 2004, 2005;
702 Norman et al., 2003) and reported RMSE in LE_i in the range of $35 - 40 \text{ W m}^{-2}$ (15%) at 30 - 120
703 m disaggregated spatial resolution. Current analysis also brought out the need for noon-night
704 thermal imaging with spatial resolution finer than 1000m to adequately capture the magnitude
705 and variability of LE_i in the terrestrial ecosystems especially agroecosystems where average field
706 sizes are less ($< 0.5 \text{ ha}$) and fragmented such as in India and other sub-continent.

707 As seen in Fig. 8a and Table 5, there is a gross overestimation of LE_i with respect to the tower
708 observations when MYD11A2 LST was used. The consistent positive BIAS in STIC-TI LE_i in
709 five out of nine sites is presumably due to the overestimation of R_{Ni} (Figure B1 of Appendix B)
710 and underestimation of G_i . Figure 7 shows overestimation of G_i for three OzFlux sites and US
711 sites and underestimation of G_i for Indian site with $G_i(\text{STIC-TI}) = 0.90 G_i(\text{tower}) - 0.10$ and
712 overestimation of R_{Ni} at the ecosystem-scale, with $R_{Ni}(\text{STIC-TI}) = 0.78R_{Ni}(\text{tower}) + 58.92$
713 (Appendix-B2). This means a systematic overestimation of the net available energy ($R_{Ni} - G_i$)
714 will be obvious in cases where STIC-TI shows underestimation of G_i , which consequently leads
715 to an overestimation of retrieved LE_i . It may be also noted that the use of MYD21A2 LST led to
716 relatively better accuracy in LE_i (3-8%) and H_i (2-3%) as compared to using MYD11A2 LST in
717 semi-arid and arid ecosystems. The higher retrieval accuracy of MYD21A2 LST using TES

718 (Temperature-Emissivity Separation) algorithm over MYD11A2 LST that uses split-window
719 algorithm (Wan et al, 2015) is the main reason for obtaining higher accuracy in LE_i and H_i
720 estimates.

721 **5.3 Effects of SEB closure**

722 Given there is a widespread lack of SEB closure ($H + LE \neq R_N - G$) or residual energy balance,
723 knowledge of the impact of different vegetation types and climatic variables on SEB ‘non-
724 closure’ is essential. A recent study by Dare-Idowu et al. (2021) covering 8 growing seasons and
725 3 crops (maize, wheat, and rapeseed) in two sites of south-western France showed that the
726 systematic effect of each site on SEB closure was stronger than the influence of crop type and
727 stage. Same study revealed a greater percentage of SEB closure under unstable atmospheric
728 conditions and in the prevailing wind directions, and sensible heat advection accounted for more
729 than half of the imbalance at both the sites.

730 In our study, using unclosed SEB observations for Indian sites in the absence of *in-situ* G_i
731 observations also added to the consistent positive BIAS in the statistical evaluation of LE_i . A
732 ubiquitous lack of energy balance closure to the order of 10 – 20% worldwide at most of the EC
733 sites is reported in different literatures (Stoy et al., 2013; Wilson et al., 2002), which implies a
734 systematic underestimation (overestimation) of LE_i (EC tower) (and/or H_i (EC tower)).
735 Accommodating an average 15% imbalance in LE_i (EC tower) would tend to diminish the
736 positive BIAS in STIC-TI. Therefore, the pooled gain (0.98) and positive BIAS between the
737 STIC-TI and tower LE_i is determined by the overestimation of $(R_{Ni} - G_i)$, combined with the
738 underestimation of measured LE_i from the EC towers. An underestimation of H_i (negative BIAS)
739 is associated with two reasons; (a) ignoring the two-sided aerodynamic conductance of the leaves
740 (Jarvis and McNaughton, 1986; Monteith and Unsworth, 2013; Schymanski et al., 2017), which
741 could lead to substantial underestimation of H_i , and (b) due to the complementary nature of the
742 PMEB equation, if LE_i is overestimated, H_i will be underestimated. In addition, frequent micro-
743 advection fluxes alter measured in situ H and LE fluxes. But these advection conditions are not
744 explicitly accounted in the current STIC-TI model. At the EC tower sites, the fraction of residual
745 energy balance to R_N can be quantified with respect to vegetation/crop growth characteristics or
746 biophysical properties. However, where G observations are lacking such as in many Indian EC

747 tower sites, the TI-based G model can be used to fill up the missing G observations to quantify
748 residual energy balance and to correct the SEB non-closure.

749 **6 Summary and conclusions**

750 This study addressed one of the outstanding challenges in simultaneous retrieval of ground heat
751 flux (G) and evaporation (ET) in open canopy, water-controlled and radiation-controlled
752 ecosystems. It demonstrated coupling of a thermal inertia (TI)-based mechanistic G model with a
753 surface energy balance (SEB) model (Surface Temperature Initiated Closure, STIC) using
754 satellite-based land surface temperature (T_s) and associated biophysical variables and has
755 minimal independence on *in-situ* measurements. The model is called STIC-TI, and this is the
756 first ever implementation of a coupled G-SEB model which also does not require any empirical
757 function for inferring the aerodynamic (g_A) and canopy-surface (g_S) conductance. The estimation
758 of g_A and g_S in STIC-TI is independent of any parameterization of surface roughness and
759 atmospheric stability and does not involve any look-up table for biome or plant functional
760 attributes. By linking T_s with thermal inertia (Γ) and surface moisture availability (M), STIC-TI
761 derives G through the harmonics equation between G and Γ , and subsequently coupled G with
762 the SEB fluxes. Independent validation of STIC-TI using measured flux data from nine terrestrial
763 ecosystems in arid, semi-arid and sub-humid climate in India, USA (representing northern
764 hemisphere) and Australia (representing southern hemisphere) led us to the following
765 conclusions:

- 766 (i) The retrieved G and associated SEB fluxes through STIC-TI were reasonably sensitive to
767 uncertainties in T_s and vegetation index. However, a compensation effect was evident due to
768 the partial cancellation of overestimated TI and underestimated A in the harmonics equation
769 of G. Both, latent and sensible heat fluxes (LE and H), were extremely sensitive to T_s
770 uncertainties, with maximum sensitivity of LE (H) to T_s found in arid and semi-arid (sub-
771 humid) ecosystems.
- 772 (ii) G estimates through STIC-TI performed better as compared to most of the contemporary
773 empirical G models, with lower MAPD and higher correlation coefficient with respect to *in-*
774 *situ* measurements. The most notable advantages of STIC-TI are, (a) it provides direct
775 estimates of G and is not dependent on net radiation estimates, (b) the ecosystem-scale

776 surface soil temperature amplitude used in G model can advance our understanding on
777 associated terrestrial ecosystem processes.

778 (iii) Underestimation of G in some ecosystems was primarily attributed to the inherent bias in
779 MODIS T_s product, NDVI saturation at higher LAI (>3) in conjunction with the spatial
780 scale mismatch between single MODIS pixel and the footprint of G measurements. The
781 consequent overestimation (underestimation) of LE (H) in some ecosystems was associated
782 with the overestimation of net available energy, use of ‘unclosed’ SEB observation in LE
783 and H validation, the spatial scale discrepancy between MODIS pixel versus eddy
784 covariance measurement footprint, the complementary nature of the Penman Monteith
785 Energy Balance equation (for H), and possibly due to ignoring the two-sided aerodynamic
786 conductance by the leaves (for H), respectively.

787 (iv) While the MODIS Aqua day view angle within -40° to 30° showed moderate impact on the
788 deviations in the modeled heat fluxes, the night view angle had no impact on the flux
789 deviations.

790 The requirement of few input variables in STIC-TI generates promise for surface-atmosphere
791 exchange studies using readily available data from the current generation remote sensing
792 satellites (e.g., MODIS, INSAT) that have noon-night TIR observations. STIC-TI can be
793 potentially used for distributed ET mapping using current and future 4th generation Indian
794 Geostationary satellite observations from INSAT as well as future high spatial resolution (~
795 60m) TIR observations with 3-day revisit from polar orbiting platform (Lagouarde et al., 2018,
796 2019) through the planned Indo-French space-borne mission, TRISHNA (Thermal infrared
797 Imaging Satellite for High-resolution Natural Resource Assessment). This simple approach will
798 also help in catering the need for a reliable, space-time continuous ET datasets in data-poor
799 regions like Indian sub-tropics, South-East Asia, and other parts of the world from thermal
800 remote sensing observation.

801 **Author contributions**

802 KM and BKB conceptualized the idea; DD conducted STIC-TI model coding, simulations and
803 data analysis in consultation with KM and BKB; DD and BKB wrote the first version of the
804 manuscript with KM writing the introduction, discussions and conclusions; all authors

805 contributed to discussions, editing and corrections; BKB and KM jointly finalized the
806 manuscript.

807 **Acknowledgement**

808 The authors gratefully acknowledge Ministry of Earth Sciences (MoES), Govt. of India and
809 National Environmental Research Council for providing necessary support through Indo-UK
810 INCOMPASS programme (NE/L013819/1, NE/L013843/1, NE/L01386X/1, NE/P003117/1).
811 BKB acknowledges Deputy Director, EPSA, SAC-ISRO and Director, SAC-ISRO for providing
812 necessary support to participate and contribute to Indo-UK INCOMPASS programme. DD
813 acknowledges Prof. P.D. Lele and Head from Department of Physics, Electronics and Space
814 Sciences, Gujarat University Ahmedabad and for providing the necessary support to carry out
815 this work. KM was supported through the International Mobility fellowship of Luxembourg
816 National Research Fund (FNR) (INTER/MOBILITY/2020/14521920/MONASTIC). KCN is
817 supported by the Jet Propulsion Laboratory, California Institute of Technology, under contract
818 with the National Aeronautics and Space Administration and Government sponsorship is
819 acknowledged. DDB acknowledges support from NASA Ecostress project and the US
820 Department of Energy, Office of Science which supports the AmeriFlux project

821 **Data and code availability**

822 Harmonized time series datasets over the study grids are available in
823 <https://doi.org/10.5281/zenodo.5806501>. The model code is available to the first author upon
824 reasonable request.

1118 **Appendix A**

1119 **Table A1: A list of symbols, their descriptions and units used in the present study**

Attributes	Symbol	Description
Temperature	T_A	Air temperature ($^{\circ}\text{C}$)
	T_{Max}	Maximum air temperature ($^{\circ}\text{C}$)
	T_{Min}	Minimum air temperature ($^{\circ}\text{C}$)
	T_D	Air dew-point temperature ($^{\circ}\text{C}$)
	T_{STA}	point-scale soil temperature amplitude
	ΔT_s	noon-night LST difference ($^{\circ}\text{C}$)
	T_{ST}	Soil temperature ($^{\circ}\text{C}$)

	T_S	Land surface temperature (LST) ($^{\circ}\text{C}$)
Humidity, vapor pressures	R_H	Relative humidity (%)
	e_A	Atmospheric vapor pressure at the level of T_A measurement (hPa)
	e_A^*	Saturation vapor pressure at the level of T_A measurement (hPa)
	e_S^*	Saturation vapor pressure at surface (hPa)
	D_A	Atmospheric vapor pressure deficit at the level of T_A measurement (hPa)
Radiation	R_G	Downwelling shortwave radiation (or global radiation) (W m^{-2})
	R_R	Upwelling or reflected shortwave radiation (W m^{-2})
	$R_{L\downarrow}$	Downwelling longwave radiation (W m^{-2})
	$R_{L\uparrow}$	Upwelling longwave radiation (W m^{-2})
	τ_{sw}	Atmospheric transmissivity for shortwave radiation (unitless)
	α_R	Broadband shortwave surface albedo (unitless)
SEB components	LE_i	Latent heat flux (W m^{-2}); subscript 'i' signifies 'instantaneous'
	H_i	Sensible heat flux (W m^{-2}); subscript 'i' signifies 'instantaneous'
	G_i	Ground heat flux (W m^{-2}); subscript 'i' signifies 'instantaneous'
	R_{N_i}	Net radiation (W m^{-2}); subscript 'i' signifies 'instantaneous'
	ϕ	Net available energy (W m^{-2}); i.e., $R_N - G$
	A	Ecosystem-scale surface soil temperature amplitude($^{\circ}\text{C}$)
	T_{Sd}	Daytime T_S ($^{\circ}\text{C}$)
	T_{Sn}	Nighttime T_S ($^{\circ}\text{C}$)
	ω	Angular frequency (rad s^{-1})
	ϕ'_n	Phase shift of the n^{th} soil surface temperature harmonic (rad)
	Δ	Shape parameter (unitless)
	S_r	Relative soil moisture saturation ($\text{m}^3 \text{m}^{-3}$)

MV2007 model	f_s	Sand fraction (unitless)
	θ_{fc}	Soil water content at field capacity ($m^3 m^{-3}$)
	θ_{wp}	Soil water content at permanent wilting point ($m^3 m^{-3}$)
	θ^*	Soil porosity ($cm^3 cm^{-3}$)
	J_s	Summation of harmonic terms of soil surface temperature (K)
	γ'	Soil textural parameter (unitless)
	Γ	Soil thermal inertia ($J K^{-1} m^{-2} s^{-0.5}$)
	τ_0	Thermal inertia of air-dry soil ($J K^{-1} m^{-2} s^{-0.5}$)
	τ^*	Thermal inertia of saturated soil ($J K^{-1} m^{-2} s^{-0.5}$)
	t'	Time of satellite overpass (seconds)
	Δt	Time offset between the canopy composite temperature and the below-canopy soil surface temperature (seconds)
	κ	Total number of harmonics used (unitless)
	f_c	Vegetation fraction (unitless)
	θ	Volumetric soil moisture ($cm cm^{-3}$)
Clear-sky R_{Ni} model	R_{ns}	Net shortwave radiation ($W m^{-2}$)
	R_{nl}	Net long wave radiation ($W m^{-2}$)
	G_{sc}	Solar constant ($1367 W m^{-2}$)
	β_e	Sun elevation angle ($^\circ$).
	ε_s	Infrared surface emissivity (unitless)
	ε_a	Atmospheric emissivity (unitless)
	E	Eccentricity correction factor due to variation in Sun-Earth distance (unitless)
	M	Aggregated moisture availability (0-1)

STIC-TI model	g_A	Aerodynamic conductance ($m s^{-1}$)
	g_s	Canopy-surface conductance ($m s^{-1}$)
	T_0	Aerodynamic temperature (or source/sink height temperature) ($^{\circ}C$)
	T_{0D}	Dewpoint temperature at the source/sink height ($^{\circ}C$)
	Λ	Evaporative fraction (unit less)
	e_0	Vapor pressure at the source/sink height (hPa)
	e_0^*	Saturation vapor pressure at the source/sink height (hPa)
	D_0	Vapor pressure deficit at source/sink height (hPa)
	s_1	Psychrometric slope of vapor pressure and temperature between ($T_{0D} - T_D$) versus ($e_0 - e_A$) ($h Pa K^{-1}$)
	s_2	Psychrometric slope of vapor pressure and temperature between ($T_S - T_D$) versus ($e_s^* - e_A$) ($h Pa K^{-1}$)
	s_3	Psychrometric slope of vapor pressure and temperature between ($T_{0D} - T_D$) versus ($e_s^* - e_A$).
	κ	Ratio between ($e_0^* - e_A$) and ($e_s^* - e_A$) (unitless)
	s	Slope of saturation vapor pressure vs. temperature curve ($h Pa K^{-1}$)
	α	Priestley-Taylor coefficient (unitless)
Ancillary meteorological variables	U	Wind speed at 8 m height ($m s^{-1}$)
	u^*	Friction velocity ($m s^{-1}$)
Constants	P	Precipitation ($mm d^{-1}$)
	γ	Psychrometric constant ($h Pa k^{-1}$)
	c_p	Specific heat capacity of air at constant pressure ($MJ kg^{-1} K^{-1}$)
	ρ	Density of air ($Kg m^{-3}$)

	σ	Stefan–Boltzmann constant ($5.67 \times 10^{-8} \text{ Wm}^{-2}\text{K}^{-4}$)
--	----------	--

1120

1121

1122 **Table A2:** Summary of instruments used, height or depth and period of measurements, measured
 1123 variables at nine EC flux tower sites

Type of primary instruments used for in situ data recording at flux tower sites	Measurement Height/ Depth (m) at different sites	Measured variables
Net radiometer	<ul style="list-style-type: none"> • 3m (IND-Naw, IND-Jai, IND-Sam) • 15m (AU-Ade) • 12.2m (AU-ASM) • 23m (AU-How) 2m (US-Ton, US-Var) 	Four radiation flux components: shortwave incoming (R_G) and outgoing (R_R); longwave incoming ($R_{L\downarrow}$) and outgoing ($R_{L\uparrow}$)
EC assembly with IRGA (Infrared Gas Analyzer), three-dimensional sonic anemometer, TC probe	<ul style="list-style-type: none"> • 8m (IND-Naw; IND-Jai; IND-Sam) • 4.5m (IND-Dha) • 15m (AU-Ade) • 11.6m (AU-ASM) • 23m (AU-How) • 2m (US-Ton, US-Var) 	High response wind vectors (u , v and w), sonic temperature, and CO_2 - water vapor mass at 10/20 Hz frequency
Humidity and temperature probe	<ul style="list-style-type: none"> • 8m (IND-Naw, IND-Jai, IND-Sam) • 4.5m (IND-Dha) • 15m (AU-Ade), 11.6m (AU-ASM) • 23m (AU-How), 70m (AU-How) • 2m (US-Ton, US-Var) 	T_A and R_H
Soil temperature probe	<ul style="list-style-type: none"> • -0.1m (IND-Dha) • -0.15m (AU-Ade) • (-0.02, -0.06m) (AU-ASM) • -0.08m (AU-How) • -0.02m, -0.04m, -0.08m, and -0.16m (US-Ton, US-Var) 	T_{ST}
Soil heat flux plates	<ul style="list-style-type: none"> • Ground, 0.1 m (IND-Dha) • Ground, -0.15 m (AU-Ade) • Ground, -0.08 m (AU-ASM) • Ground, -0.15 m (AU-How) • -0.01m (US-Ton, US-Var) 	Soil heat flux (G)

1124 **Appendix B**

1125 **B1: Clear-sky instantaneous net radiation (R_{Ni}) model**

1126 Net radiation (R_N) is defined as the difference between the incoming and outgoing radiation
1127 fluxes, which includes both longwave and shortwave radiation at the surface of earth.

1128 Terrestrial R_N has four components: downwelling and upwelling shortwave radiation (R_G and
1129 R_R), downwelling and upwelling longwave radiation ($R_{L\downarrow}$ and $R_{L\uparrow}$), respectively.

$$R_N = (R_G - R_R) + (R_{L\downarrow} - R_{L\uparrow}) \quad (B1)$$

1130 Out of these four terms mentioned in eq.(B1), R_G and $R_{L\downarrow}$ are dependent on various factors such
1131 as geographic location, season, cloudiness, aerosol loading, atmospheric water vapor content and
1132 less on surface properties. On the other hand, the upwelling radiations in eq. (B1) strongly
1133 depends on the surface properties such as surface reflectance and emittance, land surface
1134 temperature, and soil water content (Zerefos and Bais, 2013).

1135 Instantaneous net radiation (R_{Ni}) can be derived using eq. B2 as follows (Mallick et al., 2007):

$$R_{Ni} = R_{ns} - R_{nl} \quad (B2)$$

$$R_{ns} = (1 - \alpha_R) R_G \quad (B3)$$

$$R_{nl} = R_{L\downarrow} - R_{L\uparrow} \quad (B4)$$

1136 Where, R_{ns} is net shortwave radiation ($W m^{-2}$), R_{nl} is net longwave radiation ($W m^{-2}$).and α_R is
1137 the broadband surface albedo shortwave spectrum.

1138 A WMO (World Meteorological Organization) shortwave radiation model (Cano et al.,1986)
1139 calibrated over Indian conditions (Mallick et al., 2007, 2009) was used to compute R_G using the
1140 following equation:

$$R_G = \tau_{sw} G_{sc} E (\sin\beta_e)^{1.15} \quad (B5)$$

1141 Where, τ_{sw} is the is the global clear sky transmissivity for the shortwave radiation (0.7), G_{sc} is the
 1142 solar constant (1367 Wm^{-2}), ϵ is the eccentricity correction factor due to variation in Sun-Earth
 1143 distance and β_e is the sun elevation in degrees.

1144 $R_{L\downarrow}$ at any instance was calculated as follows:

$$R_{L\downarrow} = \epsilon_a \sigma (273.14 + T_A)^4 \quad (\text{B6})$$

1145 Where, σ is the Stefan–Boltzmann constant ($5.67 \times 10^{-8} \text{ Wm}^{-2}\text{K}^{-4}$); T_A is the air temperature ($^{\circ}\text{C}$);
 1146 ϵ_a is the atmospheric emissivity.

1147 Atmospheric emissivity (ϵ_a) was computed using the following equation (Bastiaanssen et
 1148 al.,1998):

$$\epsilon_a = 0.85 - \ln \tau_{sw}^{0.09} \quad (\text{B7})$$

1149 $R_{L\uparrow}$ at any particular instance was calculated as follows:

$$R_{L\uparrow} = \epsilon_s \sigma (273.14 + T_s)^4 \quad (\text{B8})$$

1150 Where, ϵ_s is the surface emissivity in thermal infrared (8 – 14 μm) spectrum and T_s is the land
 1151 surface temperature ($^{\circ}\text{C}$).

1152 **B2: Evaluation of STIC-TI R_{Ni}**

1153 Comparison of the clear-sky R_{Ni} estimates with respect to *in situ* measurements revealed RMSE
 1154 in R_{Ni} to the order of $27 - 72 \text{ W m}^{-2}$, MAPD 8 –24%, BIAS (-67) – 50 W m^{-2} , and R^2 varying
 1155 from 0.62– 0.90 across all the sites (Fig. B2, Table B2). Among the nine sites, a consistent
 1156 underestimation of R_{Ni} was noted in IND-Dha, US-Ton, and US-Var (with BIAS of -23 W m^{-2} , -
 1157 61 W m^{-2} and -67 W m^{-2}), whereas substantial overestimation of R_{Ni} was found in IND-Sam,
 1158 IND-Naw, and AU-ASM with a BIAS of 50 W m^{-2} , 37 W m^{-2} and 43 W m^{-2} , respectively (Table
 1159 B2).

Figure B2: Validation of STIC-TI derived R_{Ni} estimates with respect to *in situ* measurements in different ecosystems. The regression equation between modeled versus in-situ R_{Ni} is, R_{Ni} (STIC-TI) = $0.78R_{Ni}$ (tower) + 58.92.

1160 **Table B2:** Performance evaluation statistics of clear-sky R_{Ni} estimates in nine different
1161 agroecosystems

Sites	Error statistics of clear-sky R_{Ni} model estimates			
	R^2	BIAS ($W m^{-2}$)	RMSE ($W m^{-2}$)	MAPD (%)
IND-Jai	0.81	-9	32	8
IND-Naw	0.81	37	56	12
IND-Dha	0.81	-23	42	9
IND-Sam	0.64	50	67	15
US-Ton	0.68	-61	69	21
US-Var	0.62	-67	72	24
Au-How	0.87	7	27	15
AU-ASM	0.88	43	50	14
AU-Ade	0.90	11	27	16

1162 **Appendix C**

1163 **C1: Estimating SEB fluxes using STIC1.2 analytical model and thermal remote sensing**
1164 **data**

1165 STIC1.2 (Mallick et al., 2014, 2015a,b, 2016, 2018a) is a one-dimensional physically based SEB
1166 model and is based on the integration of satellite LST observations into the Penman–Monteith
1167 Energy Balance (PMEB) equation (Monteith, 1965). In STIC1.2, the vegetation–substrate
1168 complex is considered as a single slab. Therefore, the aerodynamic conductances from individual
1169 air-canopy and canopy-substrate components is regarded as an ‘effective’ aerodynamic
1170 conductance (g_A), and surface conductances from individual canopy (stomatal) and substrate
1171 complexes is regarded as an ‘effective’ canopy-surface conductance (g_S) which simultaneously
1172 regulate the exchanges of sensible and latent heat fluxes (H and LE) between surface and
1173 atmosphere. One of the fundamental assumptions in STIC1.2 is the first order dependence of
1174 these two critical conductances on M through T_s . Such an assumption enabled an integration of
1175 satellite LST in the PMEB model (Mallick et al., 2016). The common expression for LE and H
1176 according to the PMEB equation is as follows:

$$LE = \frac{s\phi + \rho c_P g_A D_A}{s + \gamma \left(1 + \frac{g_A}{g_S}\right)} \quad (C6)$$

$$H = \frac{\gamma\phi \left(1 + \frac{g_A}{g_S}\right) - \rho c_P g_A D_A}{s + \gamma \left(1 + \frac{g_A}{g_S}\right)} \quad (C7)$$

1177 In the above equations, the two biophysical conductances (g_A and g_S) are unknown and the
1178 STIC1.2 methodology is based on finding analytical solutions for the two unknown
1179 conductances to directly estimate LE (Mallick et al., 2016, 2018a). The need for such analytical
1180 estimation of these conductances is motivated by the fact that g_A and g_S can neither be measured
1181 at the canopy nor at larger spatial scales, and there is no universally agreed appropriate model of
1182 g_A and g_S that currently exists (Matheny et al., 2014; van Dijk et al., 2015). By integrating T_s
1183 with standard SEB theory and vegetation biophysical principles, STIC1.2 formulates multiple

1184 state equations in order to eliminate the need to use the empirical parameterizations of the g_A and
1185 g_S and also to bypass the scaling uncertainties of the leaf-scale conductance functions to
1186 represent the canopy-scale attributes. The state equations for the conductances are expressed as a
1187 function of those variables that are mostly available as remote sensing observations and weather
1188 forecasting models. In the state equations, a direct connection to T_S is established by estimating
1189 M as a function of T_S . The information of M is subsequently used in the state equations of
1190 conductances, aerodynamic variables (aerodynamic temperature, aerodynamic vapor pressure),
1191 and evaporative fraction, which is eventually propagated into their analytical solutions. M is a
1192 unitless quantity, which describes the relative wetness (or dryness) of a surface and also controls
1193 the transition from potential to actual evaporation; which implies $M \rightarrow 1$ under saturated surface
1194 conditions and $M \rightarrow 0$ under extremely dry conditions. Therefore, M is critical for providing a
1195 constraint against which the conductances are estimated. Since T_S is extremely sensitive to the
1196 surface moisture variations, it is extensively used for estimating M in a physical retrieval scheme
1197 (detail in Appendix A3 of Bhattarai et al., 2018; Mallick et al., 2016, 2018a). It is hypothesized
1198 that linking M with the conductances will simultaneously integrate the information of T_S into the
1199 PMEB model. To illustrate, we express the state equations by symbols, $sv_1 = f \{c_1, c_2, c_3, v_1, v_2,$
1200 $v_3, v_4, sv_3, sv_5\}$; $sv_2 = f \{v_4, sv_1, sv_5, sv_6\}$; $sv_3 = f \{c_3, v_3, v_4, sv_4, sv_5\}$; $sv_4 = f \{c_3, v_3, sv_1, sv_2,$
1201 $sv_7, sv_8\}$. Here, f , sv , v , and c denote the function, state variables, input variables (5 input
1202 variables; radiative and meteorological), and constants (3 constants), respectively. Here sv_1 to sv_4
1203 are g_A , g_S , aerodynamic temperature (T_0), evaporative fraction (Λ), and sv_8 is M . Given the
1204 estimates of M , net radiative energy ($R_{N i} - G_i$), T_A , R_H , the four state equations are solved
1205 simultaneously to derive analytical solutions for the four state variables and to produce a surface
1206 energy balance “closure” that is independent of empirical parameterizations for g_A , g_S , T_0 , and Λ .
1207 However, the analytical solutions to the four state equations contain three accompanying
1208 unknown state variables (effective vapor pressures at source/sink height, and Priestley-Taylor
1209 variable), and as a result there are four equations with seven unknowns. Consequently, an
1210 iterative solution was found to determine the three additional unknown variables as detailed in
1211 this section above and also described in Mallick et al. (2016, 2018a) and Bhattarai et al. (2018).
1212 The state equations of STIC are given below.

$$g_A = \frac{\phi}{\rho c_P \left[(T_0 - T_A) + \left(\frac{e_0 - e_A}{\gamma} \right) \right]} \quad (C1)$$

$$g_S = g_A \frac{(e_0 - e_A)}{(e_0^* - e_0)} \quad (C2)$$

$$T_0 = T_A + \left(\frac{e_0 - e_A}{\gamma} \right) \left(\frac{1 - \Lambda}{\Lambda} \right) \quad (C3)$$

$$\Lambda = \frac{2\alpha s}{2s + 2\gamma + \gamma \frac{g_A}{g_S} (1 + M)} \quad (C4)$$

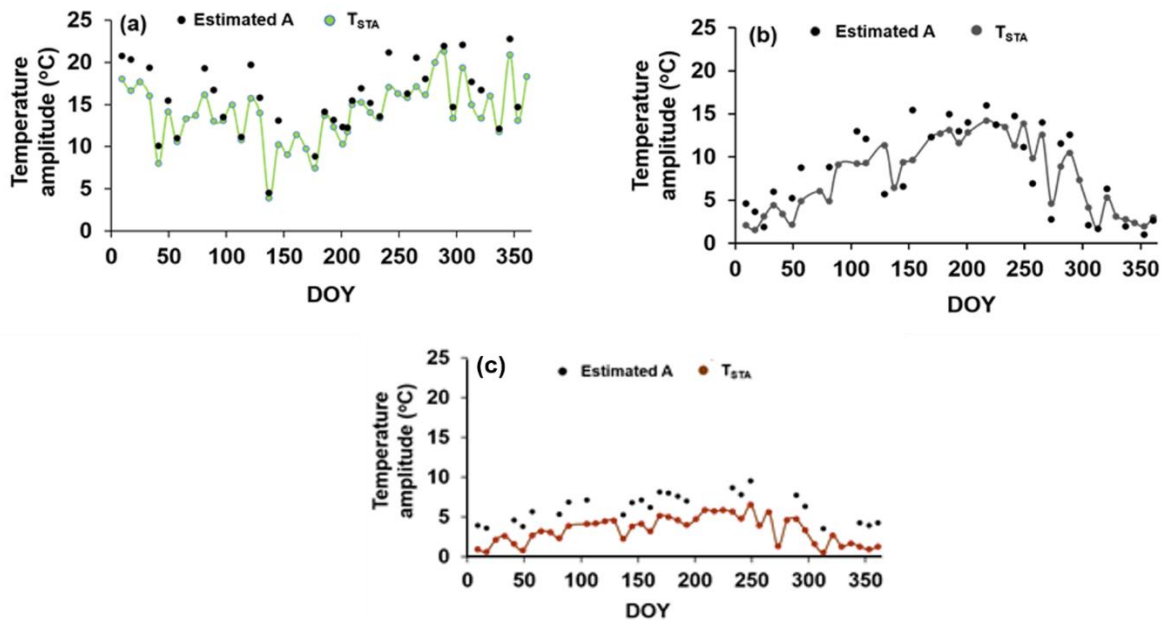

1213 Detailed derivations of these four state equations are given in Mallick et al. (2016). Given the
 1214 values of M , R_N , G , T_A , and R_H or e_A , the four state equations can be solved simultaneously to
 1215 derive analytical solutions for the four unobserved variables and to simultaneously produce a
 1216 ‘closure’ of the PMEB model that is independent of empirical parameterizations for both g_A and
 1217 g_S . However, the analytical solutions to the four state equations contain three accompanying
 1218 unknowns; e_0 (vapor pressure at the source/sink height), e_0^* (saturation vapor pressure at the
 1219 source/sink height), and Priestley-Taylor coefficient (α), and as a result there are four equations
 1220 with seven unknowns. Consequently, an iterative solution was needed to determine the three
 1221 unknown variables (as described in Appendix A2 in Mallick et al. 2016). Once the analytical
 1222 solutions of g_A and g_S are obtained, both variables are returned into eq. (13) to directly estimate
 1223 LE.

1224 In STIC-TI, an initial value of α was assigned as 1.26; initial estimates of e_0^* were obtained from
 1225 T_s through temperature-saturation vapour pressure relationship, and initial estimates of e_0 were
 1226 obtained from M as, $e_0 = e_A + M(e_0^* - e_A)$. Initial T_{0D} and M were estimated according to
 1227 Venturini et al. (2008) as described in section 3.2, and initial estimation of G was performed
 1228 from initial M using the equation sets eq. (2) – eq. (11). With the initial estimates of these
 1229 variables; first estimate of the conductances, T_0 , Λ , H , and LE were obtained. The process was
 1230 then iterated by updating e_0^* , D_0 , e_0 , T_{0D} , M , and α (using eq. A9, A10, A11, A17, A16 and A15
 1231 in Mallick et al., 2016), with the first estimates of g_S , g_A , T_0 , and LE, and re-computing G , ϕ , g_S ,
 1232 g_A , T_0 , Λ , H , and LE in the subsequent iterations with the previous estimates of e_0^* , e_0 , T_{0D} , M ,

1233 and α until the convergence of LE was achieved. Stable values of G, conductances, LE, H, T_0 ,
1234 e_0^* , e_0 , T_{0D} , M, and α were obtained within ~25 iterations. The inputs needed for computation of
1235 LE_i (eq.C6) are air temperature (T_A), land surface temperature (T_S), relative humidity (R_H), net
1236 radiation (R_{Ni}) and soil heat flux (G_i).

1237 Appendix D

1238 The temporal variation of estimated A and T_{STA} is shown in Fig. D1. The annual variations of
1239 T_{STA} in different ecosystem was found to be within the ranges of 1 - 4°C.

1240 **Figure D1:** Temporal variation of A and T_{STA} in (a) AU-ASM (2013), (b) US-Ton (2014), (c)
1241 US- Var (2014).
