Abstract. The summertime low-oxygen conditions in the Pearl River Estuary (PRE) have experienced a significant expansion in spatial extent associated with notable deoxygenation in recent decades. Nevertheless, there is still a lack of quantitative understanding of the long-term trends and interannual variabilities in oxygen conditions in the PRE as well as the driving factors, which was comprehensively investigated in this study using monthly observations in the eastern PRE during 1994-2018. To evaluate the changes in scope and intensity of oxygen conditions, an indicator (defined as the Low-oxygen Index, LOI) that integrates several metrics related to low-oxygen conditions was introduced through the principal component analysis (PCA). Moreover, primary physical and biogeochemical factors controlling the interannual variabilities and long-term trends in oxygen conditions were discerned, and their relative contributions were quantified by the multiple regression analysis. Results showed that the regression models explained over 60% of the interannual variations in LOI. Both the wind speeds and concentrations of dissolved inorganic nitrogen (DIN) played a significant role in determining the interannual variations (by 39% and 49%, respectively) and long-term trends (by 39% and 56%, respectively) in LOI. Due to the increasing nutrient loads and alterations in physical conditions (e.g. the long-term decreasing trend in wind speeds), coastal eutrophication was exaggerated and massive marine-sourced organic matter was subsequently produced, thereby resulting in an expansion of intensified low-oxygen conditions. It has also driven a shift in the dominant source of organic matter from terrestrial inputs to in situ primary production, which has probably led to an earlier onset of hypoxia in summer. In summary, the eastern PRE has undergone considerable deterioration of low-oxygen conditions in the context of substantial changes in anthropogenic eutrophication and external physical factors.

30 Estuary

1. Introduction

Dissolved oxygen (DO) plays a vital role in maintaining the good functioning of aquatic ecosystems. Hypoxia ($DO < 2$ mg/L) could lead to a marked reduction in habitat for aquatic creature (Ludsin et al., 2009) and imposes detrimental effects on ecosystem community structure and energy flow (Diaz and Rosenberg, 2008). In recent decades, long-term exacerbation on hypoxia in terms of its spatial extent and intensity has been documented in estuaries and coastal waters worldwide, including the Baltic Sea (Conley et al., 2011; Meier et al., 2019), the northern Gulf of Mexico (Obenour et al., 2013; Laurent and Fennel, 2019), Chesapeake Bay (Li et al., 2016; Ni et al., 2020), the Yangtze River Estuary (Zhu et al., 2011; Zhang et al., 2021), and the Pearl River Estuary (Li et al., 2020; Hu et al., 2021). In addition, changes in the phenology of hypoxia were also reported. For example, in Chesapeake Bay, hypoxic volume has shown a significant increase in early summer but a slight decrease in late summer since 1985 (Murphy et al., 2011; Testa et al., 2018). Zhou (2014) also found that the timing of maximum hypoxic volume in Chesapeake Bay was advanced from late July to early July during 1985-2010.

A great number of studies have indicated that the exacerbation of hypoxia in coastal systems was closely related to human activities, such as urbanization and industrialization (Breitburg et al., 2018). Due to the anthropogenic influence, massive terrestrial organic matter and nutrients were discharged into estuaries and coastal waters, leading to intense microbial respiration (Rabalais et al., 2010). Also, excessive nutrient inputs could further stimulate the growth of phytoplankton and exacerbate eutrophication, with a dramatic increase in oxygen demand from marine-sourced organic matter (Fennel and Testa, 2018). Meanwhile, physical processes such as stratification (Rabalais et al., 1991), convergence and migration of water masses (Li et al., 2021), and upwelling (Feng et al., 2014) could regulate the spatial extent and intensity of hypoxia as well. These processes are closely linked to wind forcing and freshwater discharge (Feng et al., 2012a; Yu et al., 2015). In general, the physical and biogeochemical processes exert joint impacts on the generation and development of hypoxia, but different mechanisms may predominate in different systems due to their distinctive natural conditions (e.g. topography) and pressure from anthropogenic pollution. Ni (Ni et al., 2020) quantified the contributions of ocean warming, sea level rise, and nutrient load reduction to the long-term changes in hypoxia in Chesapeake Bay through numerical simulation experiments, suggesting that ocean warming was the dominant factor. Forrest (Forrest et al., 2011) investigated the effects of various processes on the interannual variations of hypoxia in the northern Gulf of Mexico by statistical methods and pointed out that the east-west winds and nutrient loads each accounted for a considerable contribution. While in the Yangtze River Estuary, studies showed that vertical density stratification, which was heavily influenced by a combination of freshwater inputs, various water masses, and winds, was the key factor controlling the interannual changes in hypoxia (Chi et al., 2020).

With the rapid socioeconomic development, the Pearl River Estuary (PRE) has received a large amount of pollutants and nutrients, resulting in a series of environmental problems, including eutrophication, red tide, and hypoxia (Dai et al., 2008; Li et al., 2020). Low-oxygen ($DO < 4$ mg/L) and hypoxic conditions were first observed in the eastern PRE in the 1980s (Yin et al., 2004) and have been frequently reported in the Lingdingyang Bay, Modaomen Bay, and Huangmaohai

65 Bay (Li et al., 2020; Su et al., 2017; Cui et al., 2018; Shi et al., 2019) since 2000. Previous studies have shown that hypoxia
in the PRE typically occurred in the bottom waters during summer (Yin et al., 2004), driven by strong stratification and
sediment oxygen consumption (Zhang and Li, 2010; Wang et al., 2016). Due to relatively shallow topography, short water
residence time (Rabouille et al., 2008) and short maintenance of stratification (Luo et al., 2009; Lu et al., 2018) hypoxia in
the PRE appeared to be episodic and localized (Rabouille et al., 2008). However, this long-standing point of view has been
challenged by recent observations showing the emergence of large low-oxygen and hypoxic extents. The area affected by
70 low oxygen in the bottom waters of the PRE was estimated to be around 1,000 km² in 2010 (Wen et al., 2020) and ~1,500
km² in 2015 (Li et al., 2018). With the increasing availability of observations, an apparent expansion of hypoxia with large
interannual variations has been revealed from the data during 1976-2017 (Hu et al., 2021). Nevertheless, due to the scarcity
of observations in both time and space, a clear understanding of the long-term trend and interannual changes in hypoxia in
the PRE as well as the associated drivers is still lacking, especially from a quantitative perspective.

75 In this study, we perform a quantitative analysis on the long-term oxygen changes (trend and interannual variability) by
utilizing observational data collected by the Environmental Protection Department of Hong Kong (HKEPD) in the eastern
waters of the PRE. The HKEPD monitoring program provides over 30 years of oxygen and related data at certain coastal
sites (see details in section 2.1 below), allowing us to better quantify the long-term deoxygenation in the region. Moreover,
we also aim to discern the key factors controlling the interannual variability and long-term trends in the low-oxygen
80 conditions and to quantify the relative contribution of each primary factor using multiple regression models (Murphy et al.,
2011; Forrest et al., 2011; Wang et al., 2021).

2. Materials and methods

2.1 Data sources

85 Monthly monitoring data at 10 stations (Figure 1) in the eastern PRE (113.8~114.5° E, 22.1~22.6° N) was chosen for
formal analysis. Specifically, the data in use include vertical profiles of DO, temperature, salinity, dissolved inorganic
nitrogen (DIN), and chlorophyll *a* (Chl *a*) concentrations measured in the water columns during 1994-2018 as well as total
organic carbon (TOC) and total nitrogen (TN) measured in the sediments during 1998-2018. The survey stations can be
divided into three subregions: (1) the northwestern subregion, including stations NM5 (with water depth of 20 m), NM6 (5
m), and NM8 (8 m); (2) the southern subregion, including stations SM20 (7 m), SM17 (12 m), SM18 (21 m), and SM19
90 (24m); and (3) the eastern subregion, including stations MM8 (31 m), MM13 (28 m), and MM14 (25 m). Water samples
were collected from the surface (1 m below the sea surface), middle (half of the depth at each station), and bottom (1 m
above the sediments) layers, respectively. Details on the sampling procedures and measurements were described in (Xu et al.,
2010).

95 In addition, the monthly data of wind speeds and duration of southwesterly winds used for analysis were estimated
using the daily wind observations during 1994-2018 provided by the Waglan Island automatic weather station (Figure 1) of

the Hong Kong Observatory. It should be noted that the duration of southwestern winds was defined as the number of its occurrence in days during summer. As for the freshwater inputs from the Pearl River, the monthly data during 1994-2018 were calculated using the discharge data obtained from three major hydrological stations (i.e. Gaoyao, Shijiao, and Boluo) of the Pearl River Water Resources Commission of the Ministry of Water Resources.

100 2.2 Statistical methods

Several metrics, including the cross-sectional area and the layer thickness of low oxygen ($DO < 4$ mg/L), oxygen deficiency ($DO < 3$ mg/L) and hypoxia ($DO < 2$ mg/L) as well as the mean and minimum DO concentrations in the bottom waters, were used to depict the oxygen conditions in the region. Firstly, the observed DO profiles were interpolated by MATLAB along the three subregions with a grid resolution of 600 m (length) \times 0.3 m (depth). The total areas of DO below
105 4 mg/L, 3 mg/L, and 2 mg/L were then calculated as the cross-sectional areas of low oxygen, oxygen deficiency, and hypoxia, respectively. The associated layer thickness was defined as the averaged thickness of the grids with DO below the corresponding levels (i.e. 4 mg/L, 3 mg/L, and 2 mg/L).

In order to describe the severity of low-oxygen conditions comprehensively, we have also introduced an indicator integrating the above metrics (except the hypoxic area and thickness) through the PCA (principal component analysis)
110 technique, which can reduce the dimensionality of a dataset to make it more interpretable with minimum information loss (Cadima et al., 2016). The two metrics related to hypoxia were excluded from PCA because the occurrence of hypoxia was relatively rare and its interannual variation was not as significant as that of low oxygen and oxygen deficiency. The first component of PCA analysis explained 86.40% variance of all the input variables and was thereafter referred to as the Low-oxygen Index (LOI, Equ. 1), which was highly correlated with the cross-sectional areas (with a correlation coefficient r of
115 0.96, $p < 0.01$) and the thickness ($r = 0.96$, $p < 0.01$) of low oxygen as well as the bottom DO concentrations ($r = -0.90$, $p < 0.01$).

$$LOI = -0.40 \times DO_{\text{mean}} - 0.39 \times DO_{\text{min}} + 0.42 \times \text{Area}_4 + 0.41 \times \text{Area}_3 + 0.42 \times \text{Thickness}_4 + 0.41 \times \text{Thickness}_3$$
 (1)
where DO_{mean} and DO_{min} represent the mean and the minimum DO concentrations in the bottom waters, respectively; Area_4 (Area_3) and Thickness_4 (Thickness_3) represent the cross-sectional area and the thickness of low oxygen (oxygen deficiency),
120 respectively.

To quantify the relative contribution of each primary process to interannual variability in the oxygen conditions, the monthly averaged wind speed (WS) and freshwater discharge (flow) as well as the monthly spatial-average of bottom temperature (T) and surface DIN in the summer (June-August) were adopted to fit the LOI defined above through the multiple regression analysis. The resulting regression coefficients were then standardized by multiplying the ratio between
125 the standard deviation of each input variable (e.g. WS) and the standard deviation of LOI to evaluate their interannual contributions. In addition, the dataset was randomly split into a training dataset (70%) and a testing dataset (30%) in order to provide a more robust data fitting with estimates on the uncertainties arising from different data selections. Consequently, over 480,700 combinations of training and testing datasets were generated from this splitting process and were used to build

up a variety of regression models. Of all the established models, only those with coefficients of determination (R^2) over 0.6
130 both for the training and testing datasets were selected to quantify the impact of each input variable according to their
regression coefficients on average. Furthermore, based on the selected models (with R^2 over 0.6 for both datasets), we also
set up four sensitive experiments in which the long-term trend of each input variable was removed and only interannual
fluctuations were retained. The LOI was then re-calculated in each scenario and its change relative to the original LOI was
used to assess the impact of each variable to the long-term oxygen trend.

135 3. Result

3.1 Seasonal and interannual variabilities in water quality variables in the eastern Pearl River Estuary

3.1.1 Hydrological and eutrophication parameters

Significant seasonal variations could be found for the hydrologic settings (Figure 2). In winter (December-February),
temperature generally exhibited low levels, with climatological mean values of 18.62 °C and 18.54 °C during 1994-2018 in
140 the surface (Figure 2a) and the bottom waters (Figure 2b), respectively; salinity reached high values due to the invasion of
shelf saline waters, with means of 32.05 PSU at the surface (Figure 2c) and 32.44 PSU at the bottom (Figure 2d). Small
differences of temperature and salinity between the surface and the bottom layers in winter indicated that the water column
was well mixed (with mean vertical density differences of 0.33 kg/m³; Figure 2e). By comparison, temperature and salinity
in summer (June-August) showed larger vertical gradients and interannual variability. The summertime temperature varied
145 by 28.21±1.19 °C (i.e. climatological mean±one standard deviation) at the surface, which was markedly higher than that at
the bottom (24.93±2.14 °C). As affected by massive freshwater inputs from the Pearl River, salinity in summer was much
lower than that in winter and displayed pronounced vertical differences with 22.86±7.53 PSU at the surface and 30.90±5.26
PSU at the bottom, respectively. Consequently, strong water stratification prevailed in summer, where the vertical density
differences ($\Delta\rho$) varied by 7.26±4.54 kg/m³ (Figure 2e).

DIN and Chl *a* are two important parameters related to eutrophication and they both showed remarkable changes over
time (Figure 3a-d). In winter, the concentrations of DIN and Chl *a* were generally low, with climatological means of 0.19
mg/L (surface) and 0.16 mg/L (bottom) for DIN and means of 2.45 µg/L (surface) and 2.04 µg/L (bottom) for Chl *a*. While
in summer, DIN and Chl *a* reached comparatively high levels with significant interannual variability. Overall, the DIN
content varied by 0.56±0.50 mg/L at the surface (Figure 3a), which was higher than that at the bottom (0.28±0.34 mg/L; Figure
155 3b). Chl *a* also showed considerable vertical differences with 8.56±9.30 µg/L at the surface (Figure 3c) and 2.46±4.13 µg/L
at the bottom (Figure 3d).

In terms of spatial distributions, distinct differences were observed for the hydrological and eutrophication parameters
among the three subregions investigated. Due to the profound influence of river discharges, temperature/salinity in the
northwestern subregion (NM5-NM8, closer to the river outlets) was noticeably higher/lower when compared to the other two

160 (Figure 2 a-d), varying by 28.61 ± 1.09 °C/ 14.63 ± 6.23 PSU at the surface in summer. Meanwhile, the DIN concentration in
the northwestern subregion was the highest (Figure 3 a-b), reaching up to 1.17 ± 0.40 mg/L at the surface. On the contrary, the
eastern subregion (MM8-MM14), which was farthest to the river outlets and more heavily affected by the shelf water, had
the lowest temperature (27.85 ± 1.27 °C), highest salinity (29.22 ± 3.10 PSU) and lowest DIN concentration (0.14 ± 0.13 mg/L)
in the surface waters. As for Chl *a* (Figure 3c-d), the highest level appeared in the southern subregion (SM17-SM20, with
165 10.19 ± 8.86 µg/L at the surface in summer), while the lowest one was found at the northwestern subregion (with 6.82 ± 10.67
µg/L at the surface).

3.1.2 Dissolved oxygen and low-oxygen conditions

With respect to DO, it exhibited significant seasonal and interannual variations in both layers (Figure 3e-f). The DO
content maintained at higher levels during winter (with 7.07 ± 0.99 mg/L and 7.27 ± 0.87 mg/L in the surface and the bottom
170 waters over 1994-2018, respectively) and dropped to a level of 6.91 ± 1.71 mg/L at the surface and 4.42 ± 1.37 mg/L at the
bottom in summer. Statistic results showed that low-oxygen events mainly appeared in the bottom waters of summer, which
had much higher occurrences of DO < 4 mg/L and DO < 2 mg/L compared to other seasons and other layers (with the
occurrences mostly less than 10%; Appendix figure A1). In addition, the summertime DO minimum at the bottom (Figure 4a)
varied by 2.28 ± 0.89 mg/L, further indicating the water quality deterioration with severe oxygen deficits in the eastern PRE.
175 Among the three subregions, the northwestern and the southern ones had relatively lower bottom DO levels (with 4.56 ± 1.56
mg/L and 4.14 ± 1.45 mg/L, respectively) and considerably higher occurrences of low-oxygen conditions (with 38.76% and
49.32%, respectively) compared to the eastern subregion (with DO of 4.68 ± 0.93 mg/L and occurrence of 17.24%; Appendix
figure A1).

In addition to the DO levels, we also investigated the interannual changes in the summertime low-oxygen conditions in
180 terms of areal extents (vertical profiles), thickness, and the LOI as defined in section 2.2 (Figure 4). Significant interannual
fluctuations were found for all these metrics; for example, the area and thickness affected by low oxygen varied by $(3.35 \pm$
 $2.38) \times 10^5$ m² and 5.66 ± 4.01 m, respectively, while those for oxygen deficiency were $(7.13 \pm 8.37) \times 10^4$ m² and $1.20 \pm$
 1.41 m. Low-oxygen and hypoxic conditions were more severe in the years such as 2007, 2011, and 2017, as indicated by
the high LOI values. In particular, the year 2011 had the largest low-oxygen area ($\sim 7.66 \times 10^5$ m²) and the lowest DO
185 concentration (~ 0.40 mg/L) over the past 25 years, thus possessing the highest LOI; it could be observed that the low-oxygen
waters almost occupied the entire middle-to-bottom layers across all the sites during this period (Appendix figure A2). On
the other hand, hypoxic conditions were absent in some years (e.g. 2004, 2006, and 2018), where the water column resided
in a comparatively well-oxygenated status (Appendix figure A2); the corresponding LOI in these hypoxia-relief years fell to
large negative values (Figure 4d).

190 3.2 Long-term trends of low-oxygen conditions in the eastern Pearl River Estuary

Despite the large DO fluctuations by years, a clear deoxygenation trend could be observed in summer over the past 25 years, showing a long-term decline in the DO content associated with increases in the areas and occurrences affected by low oxygen (Figure 4). More specifically, before 2000 the spatially-averaged DO concentrations in the bottom waters exceeded 4 mg/L and low-oxygen conditions were seldom observed (Figure 4a), while the DO minimums were all above 2 mg/L (i.e. no hypoxic events occurred). However, since 2000 the occurrences of low oxygen and hypoxia have become more frequent, with a significant growth in the LOI and its related metrics, confirming the exacerbation of low-oxygen conditions in the eastern PRE.

To further quantify the intensity of long-term deoxygenation in summer, linear regressions were performed for the DO contents in different layers and in different subregions and also for the areal extents of low-oxygen conditions during 1994-2018 (Figure 5). As shown, apparent declining trends were found for the DO series both at the surface (although not significant, Figure 5a) and the bottom (Figure 5b). For the bottom waters, the averaged DO concentrations displayed a decreasing pattern with a rate of 0.03 mg/L per year (equivalent to approximately 0.7% of the climatological DO mean at the bottom), while the DO minimums showed a more significant decline with a rate of 0.08 mg/L per year (~3.5% of the climatological mean of the bottom DO minimums). It was also noted that the intensity of deoxygenation varied between subregions (Figure 5c-h). As for the bottom DO content, the most significant decrease was found in the eastern subregion (with a deoxygenation rate of 0.05 mg/L per year, Figure 5h), while the most significant decline in the DO minimum appeared in the southern subregion (with a rate of 0.08 mg/L per year, Figure 5f). Likewise, significant increasing trends were also found for the areas of low oxygen and oxygen deficiency (Figure 5i-j), showing an annual growth rate at 1.95×10^4 m² and 4.75×10^3 m², respectively. Regarding the changes in LOI, it had a growth rate of 0.20 per year, which corresponds to an increasing rate of 1.99×10^4 m² in the low-oxygen area and a declining rate of 0.07 mg/L in the DO minimum.

Furthermore, the long-term oxygen changes varied between different months of the summer season as well (Figure 6). It could be seen that the decreasing magnitude of the averaged DO concentration was close to each other for all the summer months, while the decline in the DO minimum was most pronounced in July (with a decreasing rate of 0.10 mg/L per year, Figure 6c), followed by that in August (0.06 mg/L per year, Figure 6e). In fact, the long-term changes in the DO minimum had different patterns in July and August. As for July, the DO minimum generally showed a consecutive decrease over the past 25 years (Figure 6d). While in August, the DO minimum experienced a rapid decline with a rate of 0.14 mg/L per year during 1994-2011, which was higher than that in July during the same period (0.11 mg/L per year), but subsequently undertook a recovery from the hypoxic conditions since 2012 (Figure 6f). Along with such distinctive intra-seasonal patterns, an interesting phenomenon was also noticed: hypoxic events were present mostly in August prior to 2012 (e.g. in 2007 and 2010-2011; no hypoxia was found in July during the same period) but only in July instead since 2012 (e.g. in 2014 and 2016-2017), as shown in Figure 6. This finding implied a potential shift in the onset of hypoxia generation from August to July, i.e. an earlier timing for the arrival of the summertime hypoxia. Accordingly, distinct changes were found for the areas affected

by hypoxia in the two periods around 2012. The hypoxic area estimated in July increased from zero during 1994-2011 to $(5.42 \pm 8.77) \times 10^3 \text{ m}^2$ during 2012-2018, whereas the hypoxic area in August decreased from $(0.89 \pm 2.82) \times 10^4 \text{ m}^2$ to zero.

225 4. Discussion

4.1 Primary factors controlling the interannual variabilities in low-oxygen conditions

As shown above, significant interannual variabilities were observed in the spatial extent (e.g. cross-sectional area) and intensity of oxygen conditions (e.g. the mean bottom DO concentrations). Such variabilities were largely influenced by multiple physical and biogeochemical factors, including wind forcing, freshwater discharge, water temperature and nutrient
230 loads. These processes jointly act to affect density stratification (Yu et al., 2015), water residence time (Li et al., 2021) and temporal and spatial distributions of eutrophication parameters (Cui et al., 2018). As described in section 2.2, four important influential factors (i.e. WS, flow, T, and DIN) were used to predict the interannual variations in LOI by the multiple regression models, in which there have been 56,010 cases (~12% of the total, Figure 7) with $R^2 > 0.6$ both in the training dataset (mean R^2 of 0.64) and the testing dataset (mean R^2 of 0.70). The standardized coefficients (mean \pm standard deviation)
235 for these well-performing regression cases were given as follows:

$$\text{LOI} = - (0.39 \pm 0.12) \times \text{WS} - (0.14 \pm 0.12) \times \text{flow} - (0.11 \pm 0.08) \times \text{T} + (0.49 \pm 0.12) \times \text{DIN} \quad (2)$$

As denoted by the regression coefficients, wind forcing has exerted a significant impact on the interannual changes in LOI, with a relative contribution of $39\% \pm 12\%$ to the LOI variability explained. Its importance could also be evidenced by the significant negative correlation between WS and LOI ($r = -0.67$, $p < 0.01$, Figure 8), suggesting that calm winds were
240 beneficial to low-oxygen conditions. In most cases, strong winds could break down stratification in the water column (Rabalais et al., 1991; Feng et al., 2012b), which was conducive to water mixing and atmospheric reoxygenation (Rabalais et al., 1991). However, the weak correlation between WS and Δp (Figure 8) indicated that the wind forcing may control hypoxia through other alternative mechanisms. Actually, weak winds in combination with flow convergence induced by wind-driven circulation could contribute to long water residence time and nutrient accumulation in the eastern PRE and thus
245 favored the phytoplankton blooms (Li et al., 2021). This could be supported by the significant negative correlation between WS and Chl *a* ($r = -0.62$, $p < 0.01$). With respect to the DIN content, it played a vital role in determining the interannual variabilities of the oxygen conditions, with a contribution up to $49\% \pm 12\%$. It has been widely recognized that eutrophication stimulated by anthropogenic nutrient inputs could provide a large quantity of depositing detritus and subsequently led to substantial oxygen depletion and occurrence of low-oxygen events (Rabalais et al., 2010; Fennel and Testa, 2018), as
250 confirmed by the significant positive correlation between DIN and LOI ($r = 0.65$, $p < 0.01$) in the present study. Collectively, DIN and WS were identified as the two key factors controlling the interannual changes in low-oxygen conditions.

Compared to WS and DIN, the freshwater discharges (flow) had a much smaller contribution ($\sim 14\% \pm 12\%$) to the variations in LOI. Generally speaking, large freshwater inputs tend to enhance the intensity of water stratification and facilitate the generation of hypoxia (Rabalais et al., 1991). However, we found a negative correlation between flow and LOI

255 (r = -0.45, p < 0.05, Figure 8), implying that the effect of freshwater discharges on low-oxygen conditions might involve
more complex mechanisms and act through indirect pathways; for example, the weakened discharge could prolong the
residence time of nutrients and thereby stimulate local productions of organic matter (Li et al., 2021), which ultimately
promoted oxygen depletion. Similarly, the contribution of water temperature (T) to the LOI changes was not significant
either, as revealed by its weak correlation with LOI as well. Overall, the role of temperature and freshwater discharges in
260 regulating the interannual oxygen variability in the eastern PRE appeared to be secondary.

4.2 Drivers of the long-term deoxygenation trend

The data over the past 25 years showed that the eastern PRE has experienced a notable long-term oxygen decline,
especially for the DO minimum in the bottom waters. Based on the observed deoxygenation rate, the bottom DO minimum
was expected to decrease by approximately 15%-70% in 5-20 years (reaching a level of 0.4-1.6 mg/L) compared to the
265 climatological mean of 1994-2018. The impacts of influential factors on the long-term deoxygenation trend were then
evaluated using the regression models mentioned in section 4.1 and quantified by the relative changes of LOI in the sensitive
experiments (see details in section 2.2) compared to the original one. It was noted that WS exhibited a decreasing trend of
0.03 m/s per year (p < 0.05, Figure 9a) over the past 25 years, while DIN showed an increase with a rate of 0.01 mg/L per
year (p < 0.01, Figure 9e). The growth in DIN and decline in WS have led to a 56%±10% and 39%±14% increase in LOI
270 (Table 4), respectively, indicating that DIN and WS were the main driving factors for the long-term deoxygenation. On the
other hand, significant long-term trends were also found for the freshwater discharges (with a decreasing rate of 4.19×10^2
m³/s per year, Figure 9b) and water temperature (with an increasing rate of 0.06 °C per year, Figure 9d), but their impacts
were relatively small, resulting in a 16%±14% increase and 11%±9% decrease in LOI, respectively.

Despite the different influences of the factors mentioned above, they were likely to impose synergetic impacts on the
275 low-oxygen conditions by aggravating eutrophication as discussed earlier; it could be observed that the long-term growth in
Chl *a* (with a rate of 0.15 µg/L per year, Figure 9 f) matched well with the increase in LOI. Specifically, the significant
increase in phytoplankton biomass was primarily due to the combined effects of more stable water-column condition and
longer residence time facilitated by the weaken wind forcing and river discharges, higher nutrient levels, and lower water
turbidity (Figure 9g) in recent years. Consequently, the elevated organic matter through phytoplankton primary production
280 would lead to strong oxygen consumption, thereby contributing to an expansion of low-oxygen conditions in terms of areal
extent and intensity.

Moreover, with massive algal fragments provided by primary production, the composition of organic matter in the
eastern PRE has probably changed and would cause substantial changes in the timing of hypoxia generation. As noted in
section 3.2, the onset of hypoxia was observed to shift from August to July around 2012. To explore this issue, we first used
285 the ratio of TOC to TN measured in the sediments to estimate the main source of organic matter, with values of 14-30
pointing to a terrestrial source and values of 4-10 indicating a marine source from in-situ production (Bordovskiy, 1965;
Meyers and Ishiwatari, 1993). It is clear that the TOC:TN showed a significant decreasing trend and was mostly below 10

since 2012 (Figure 9h). This implied a shift in the dominant source of organic matter from terrestrial inputs to local production (marine-sourced). As such, oxygen consumption became faster because the marine-sourced organic matter was fresher and more active (Raymond and Bauer, 2001) and therefore the time required to reach hypoxia would be shortened. Furthermore, changes in the physical conditions provided sufficient time for more thorough decomposition of organic matter in July, which left less organic matter for August and thus weakened the deoxygenation therein.

5. Conclusion

We have comprehensively investigated the spatiotemporal characteristics of DO and various related water quality variables in the eastern PRE and found that low-oxygen conditions occurred mostly in the bottom waters of summer, with significant interannual variability and an apparent deoxygenation trend over the past 25 years. As quantified by statistic methods, the increasing DIN levels and the decreasing wind speeds, both of which would eventually lead to the intensification of eutrophication, contributed most to the interannual variations and long-term trend in LOI. Therefore, more marine-sourced organic matter was produced by the elevated primary production, leading to an exacerbation in low-oxygen conditions with larger areal extents as well as a potential earlier onset of the summertime hypoxia. By comparison, the freshwater inputs and water temperature had relatively small impacts on the long-term changes in LOI. To sum up, this study has shown that oxygen conditions in the eastern PRE have been deteriorating under the interactions of altered physical forcing (e.g. winds) and aggravated eutrophication and it would develop into a severe hypoxic state within the next two decades. Lastly, given the significant intra-seasonal variability in low-oxygen conditions during summer, it is of great importance to conduct more cruise surveys to collect estuary-wide observations on a longer time scale in order to fully capture the generation and development of hypoxia and to confirm the change in the timing of its arrival.

Data availability. The marine water quality and the sediment data during 1994-2018 from the HKEPD are available at <https://www.epd.gov.hk/epd/epic/english/epichome.html>, while the daily wind observation data from Waglan Island automatic weather station are available at <https://www.hko.gov.hk/sc/cis/climat.htm>. Daily discharge data of hydrological stations (i.e. Gaoyao, Shijiao, and Boluo) can be collected at <http://www.zswsj.com/cms/webfile/waterInfo/index.html>.

Author contributions. Under the conceptualization of JH, ZC completed the data analysis and graphic visualization. This work was supervised by JH and SL. ZC wrote the paper with contributions from all co-authors and all co-authors contributed to the review and editing of manuscript, especially for JH and BW.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We would like to express gratitude to the Environmental Protection Department of Hong Kong, the
320 Waglan Island automatic weather station of the Hong Kong Observatory and the Pearl River Water Resources Commission
of the Ministry of Water Resources for sharing the monitoring data.

Financial support. This work was supported by the Joint Research Fund of the National Natural Science Foundation of China
and Guangdong Province (U1901209).
