Abstract. Growing evidence points to the dynamic role that kerogen is playing on Earth's surface in controlling atmospheric chemistry over geologic time. Although quantitative constraints on the weathering of kerogen remain loose, its changing weathering behavior modulated by the activity of glaciers suggest that this largest pool of reduced carbon on Earth may have played a key part in atmospheric CO₂ variability across recent glacial-interglacial times and beyond. This work enunciates the possibility of kerogen oxidation as a major driver of atmospheric CO₂ increase in the wake of glacial episodes. This hypothesis of centennial and millennial-timescale-relevance for this chemical weathering pathway is substantiated by several lines of independent evidence synthesized in this contribution including the timing of CO₂ increase, CO₂ isotopic composition (¹³C and ¹⁴C), seawater osmium record, kerogen oxidation kinetics, observations of kerogen reburial, and modeling results. The author hypothesizes that the deglaciation of kerogen-rich lithologies in western Canada contributed majorly to the characteristic deglacial increase in atmospheric CO₂, which reached an inflection point ≤ 300 years after the Laurentide Ice Sheet retreated into the kerogen-poor Canadian Shield. To quantitatively constrain the contribution of kerogen oxidation to CO₂ rise at glacial terminations, systematic studies on CO₂ fluxes emanating from the weathering of different lithologies, oxidation kinetics of kerogen along glacial chronosequences, and high-resolution temporal changes in the aerial extent of glacially exposed lithological units are needed.

1 Introduction

Over geologic timescales, atmospheric CO₂ is controlled by the combined effects of chemical weathering of silicates and carbonates and the organic carbon cycle (Berner, 1990; Torres et al., 2014). Organic carbon in the form of kerogen comprises around 15 million PgC, which encompasses over 99.9% of reduced carbon present on Earth. Tectonic uplift and denudation subjects 150 PgC/kyr of kerogen to weathering on Earth's surface thereby facilitating entry of this geologically ancient carbon into the atmosphere and other surficial carbon pools standing in close communication (Hedges and Oades, 1997). Upon oxidation of kerogen, O₂ is consumed and CO₂ is released to the atmosphere. In reverse, biospheric organic carbon burial in marine sediments removes carbon from the Earth's surface thereby drawing down atmospheric CO₂ and increasing O₂ over geological timescales (Galy et al., 2008). Therefore, kerogen weathering and sedimentary organic matter burial in the ocean

30 play compensational roles in governing atmospheric chemistry (Fig. 1) with kerogen oxidation considered important for atmospheric chemistry over million-year timescales (e.g., Petsch, 2014; Bolton et al., 2006).

However, the decay of kerogen on Earth's surface is incomplete, with physical erosion followed by riverine transport (Galy et al., 2015) and reburial in lacustrine and marine settings (Blattmann et al., 2018a; Blattmann et al., 2019b; Cui et al., 2016; Sparkes et al., 2020). The operation of this "simple cycle besides the more complicated common circulation of carbon",
35 enunciated by Sauramo (1938), begs the questions (i) what is the reburial efficiency of kerogen, (ii) what is the weathering efficiency of kerogen, (iii) what are their controlling factors, and (iv) what are the implications of them changing for atmospheric chemistry over geologic timescales? Here, this contribution hypothesizes a connection between kerogen oxidation and millennial/centennial-scale atmospheric CO₂ increases at glacial terminations.

2 Carbon isotopes and contradictions?

40 The amount and carbon isotopic composition of atmospheric CO₂ (Fig. 2) depend on (1) the terrestrial biospheric organic carbon pool, (2) the dissolved inorganic carbon pools residing in the surface and deep ocean, (3) exchanges between the atmosphere and the terrestrial biosphere and ocean, and (4) the export of organic matter and carbonate from the surface waters of the oceans (Sigman and Boyle, 2000). Across deglaciation, an increasingly voluminous terrestrial biosphere (Bird et al., 1994; Shackleton 1977; Shackleton et al., 1983) is inferred to have controlled an increase in the stable carbon isotopic
45 composition of dissolved inorganic carbon in ocean waters. However, this line of reasoning is complicated by various carbon pools changing in size coeval to carbon isotope fractionation as carbon rotates between these (e.g., terrestrial biosphere, pedosphere; see also discussions in Zeng (2003, 2007)). Additionally, during times of highest CO₂ increase in transitions from glacial to interglacial, negative stable carbon isotopic shifts in atmospheric CO₂ have occurred (Fig. 3; Smith et al., 1999; Schmitt et al., 2012), which is a strong indicator of respired organic carbon acting as source directly to the atmosphere (Bauska
50 et al., 2016). Additionally, the constraints imposed by radiocarbon clearly indicate there must have been a source of carbon to the atmosphere and ocean depleted or devoid of radiocarbon (Broecker and Clark 2010; Hain et al., 2014; Rafter et al., 2019; Zhao et al., 2018), thereby limiting potential contributions from a modern biospheric organic carbon source. Other studies have proposed that carbon sourced from dissolved inorganic carbon from the deep ocean was the predominant source for carbon to the atmosphere at glacial terminations (e.g., Hain et al., 2014). However, this hypothesis appears inconsistent with the negative
55 fluctuation observed in the ¹³C fingerprint of atmospheric CO₂ during this time and requires a complex overlay of processes to reconcile (Broecker and McGee, 2013). Terrestrial organic carbon comprises the sum of biospheric and surface exposed lithogenic (i.e., kerogen) forms of organic carbon, with both exhibiting similar ¹³C signatures yet modern and dead ¹⁴C signatures, respectively. As the author will argue, the ¹³C and ¹⁴C lines of evidence suggest the release of CO₂ via kerogen oxidation to the atmosphere during deglaciation, contradicting (or complementing) the commonly held notions of a strictly
60 increasing terrestrial organic carbon pool and major changes in ocean-atmosphere CO₂ exchange.

3 Kerogen and glaciers

Evidence accumulated in over a century of scientific studies supports that the reburial of kerogen has been more extensive during cold interludes in Earth history where glacial erosion and ice rafting dominated (Blattmann et al., 2018b). This general pattern of kerogen reburial is also observed spatially today with more efficient reburial in high latitude, glaciated than in low latitude sedimentary systems (Cui et al., 2016). This enhanced reburial efficiency strengthens the short-circuiting of the exogenous kerogen cycle keeping this ancient, reduced carbon locked away. However, under glaciofluvial conditions, the entry of kerogen-bound carbon into surficial carbon pools is promoted (Horan, 2018), with glacial meltwater releasing dissolved organic matter from kerogen, which is readily degraded and consumed by microbes (Hood et al., 2009; Schillawski and Petsch, 2008; Sharp et al., 1999). Additionally, frost shattering together with the retreat of glaciers expose finely ground, high surface area, reactive sediment, thereby accelerating oxidation and release of kerogen-bound carbon to the atmosphere (Fischer and Gaupp, 2005; Horan et al., 2017). The initially strong input of kerogen-derived CO₂ would die down as the availability of glacially ground, reactive kerogen declines into the interglacial. Enhanced degradation of kerogen in the wake of glacial episodes is consistent with observations from areas of ongoing deglaciation (Horan et al., 2017). Analogously, glaciers as agents for accelerating chemical weathering by increased sediment yield and creation of high surface area reactive substrate have also been invoked for silicate and carbonate minerals (Torres et al., 2017; Vance et al., 2009), with carbonate weathering constituting a source of CO₂ to the atmosphere when sulfuric acid is involved (Torres et al., 2014). However, kerogen oxidation, owing to its faster weathering kinetics and direct conversion to CO₂ leading to considerable losses in kerogen content over decadal timescales (Horan et al., 2017; Fischer et al., 2007), is a manifest process by which CO₂ can directly be injected into the atmosphere and intricately linked to glacial-interglacial cyclicity (Fig. 2).

In the following, quantitative arguments are presented: Of the approximately 150 PgC/kyr of kerogen reaching the Earth's surface (Hedges and Oades, 1997), 43⁺⁶¹₋₂₅ PgC/kyr is currently exported by rivers to oceans (Galy et al., 2015; Copard et al., 2007), indicating that the modern-day reburial efficiency of this carbon lies in the ballpark of 30% (10-70%). Normalized to global land area, the following average flux of carbon due to oxidation of kerogen to the atmosphere can be expected:

$$0.72^{+0.17}_{-0.41} \text{ MgC/km}^2 \text{ yr} = \frac{150 - 43^{+61}_{-25} \text{ PgC/kyr}}{149,000,000 \text{ km}^2} \quad (\text{Equation 1})$$

Reports of CO₂ fluxes from kerogen are based on disparate study sites and methods (Table 1). From this, reported CO₂ fluxes stemming from oxidation of rock disseminated forms of kerogen and across larger catchment areas under aerobic conditions span over two orders of magnitude ranging from 0.3 to 64 MgC/km²/yr. The only quantities available for catchments of ongoing deglaciation stem from the Southern Alps of New Zealand, which are one to two orders of magnitude faster than the average Earth surface (ranging between 9-50 MgC/km²/yr; Horan et al., 2017). Taking this flux range as a first order estimate, how would kerogen oxidation translate into changes in atmospheric CO₂ concentration? In Zeng's (2003) modeling work postulating soil oxidation upon retreat of overriding glaciers, the effect of continuous inputs of organic matter-derived carbon

directly to the atmosphere are calculated: 550 PgC oxidized lead to 60 PgC increase in atmospheric CO₂ (30 ppm increase).
95 Similarly, modeling by Simmons et al. (2016) also propose glacially overridden soil organic carbon oxidation upon
deglaciation and calculate 600 PgC release resulting in a 40-60 ppm increase in atmospheric CO₂ (c.f., also Ciais et al. (2012)
who calculate the deglacial oxidation of 700 PgC of an “inert” terrestrial organic carbon pool). The idea of soil oxidation is
mathematically analogous to kerogen oxidation in the hypothesis presented here. How much deglaciaded terrain would
therefore be needed to release 550-600 PgC of kerogen-derived carbon? Using Zeng’s (2003) and Simmons et al.’s (2016)
100 carbon release estimates and Horan et al.’s (2017) oxidation kinetics over a 6,000-year time window (timespan of greatest CO₂
increase over the glacial-interglacial transition) and subtracting global average baseline kerogen oxidation:

$$\text{Between 2 to 12 million km}^2 = \frac{\text{Between 550 to 600PgC}}{6000\text{yr} * ([\text{Between 9 to 50}] - 0.72_{-0.41}^{+0.17}) \text{MgC/km}^2\text{yr}} \quad (\text{Equation 2})$$

105 In the most conservative estimate, 12 million km² of deglaciaded terrain containing sedimentary and metasedimentary rocks
and their debris (glacial flour accumulated over millennia of glaciation) would cover the source. In comparison, Canada covers
approximately 10 million km², which was mostly covered by the Laurentide Ice Sheet during the Last Glacial Maximum. With
this, a plausible scenario for releasing kerogen-derived CO₂ to the atmosphere that could account for a 30-60 ppm rise during
the glacial-interglacial transition encompassing an area equal to or less than the terrestrial extent of the Laurentide Ice Sheet
110 is identified. Similar to the oxidation fluxes reported from deglaciating catchments (Horan et al., 2017) are those reported for
the in-situ weathering of massive outcrop formations of marls and shales (e.g., Soulet et al., 2018; Littke et al., 1991; see Table
1). Kerogen oxidation fluxes appear higher for catchments showing larger glacial coverage (Horan et al., 2017) suggesting that
the relative contribution of freshly exposed and ground bedrock is highest for these areas and that kerogen oxidation fluxes
progress over the course of deglaciation. The CO₂ flux emanating from kerogen oxidation in soils formed from glacial till
115 (Keller and Bacon, 1998) suggests that oxidation fluxes greater by an order of magnitude than the global average can be
sustained for millennia past deglaciation. However, a systematic chronosequence understanding is currently lacking that allows
conclusions to be drawn as a variety of factors (e.g., lithology, initial kerogen content, grain size) exert control over kerogen
oxidation (c.f., Fischer and Gaupp, 2005; Bolton et al., 2006). The bedrock and river sediments of the Southern Alps are
relatively lean in kerogen (Copard et al., 2007; Horan et al., 2017). Therefore, for catchments exhibiting glacially ground
120 kerogen-rich lithologies, larger oxidation fluxes can be expected from such deglaciaded landscapes (see next section).
Long-term accelerated decline in the radiocarbon concentration of atmospheric CO₂ parallel to an overall increase in CO₂
amount occurred since the Last Glacial Maximum (Reimer et al., 2013; Roth and Joos, 2013). Consistent with such a dilutional
process, kerogen oxidation releases radiocarbon-dead CO₂ to the atmosphere. During the time period of greatest CO₂ increase
from 17.5 until 11.5 kyr before present, the rate of decline in the concentration of ¹⁴C in atmospheric CO₂ is greatest and
125 averages about 35 ‰/kyr (Fig. 3; c.f., Broecker and Barker (2007)). With the release of 500 PgC (radiocarbon-dead) to the
atmosphere over deglaciation, a drop in 100 to 200 ‰ Δ¹⁴C of atmospheric CO₂ can be expected (see calculations by Zeng,

2007; c.f., Sarntheim et al. (2013) who propose a comparable release yet argue for an oceanic mechanism). Kerogen oxidation would also release isotopically light carbon to the atmosphere, which is also consistent with the atmospheric record (Fig. 3; Bauska et al., 2016). Finally, driven by orbital forcing (Hays et al., 1976), the response in atmospheric CO₂ faithfully echoing increasing global temperatures and diminishing glaciated terrain (Sigman and Boyle, 2000; Stips et al., 2016) goes hand in hand with continuous aerial exposure and enhanced oxidation of finely ground, reactive kerogen (Fig. 2).

4 A Canadian tale. And what about microbes?

Controlled to a first order by lithology, kerogen exposed on Earth's surface is distributed unevenly, with kerogen-rich surface lithologies extending along much of western Canada (see Fig. 2 in Copard et al., 2007). These areas experienced dramatic deglaciation across the 17.5-11.5 ka timeframe (Fig. 4; Dyke, 2004; Dalton et al., 2020). In addition to the widespread occurrence and high abundance of rock disseminated forms of kerogen, there are also notable surficial occurrences of hydrocarbon-rich lithologies including coal and oil sands within the deglaciated terrains of western Canada. Within Alberta province, Andriashek and Pawlowicz (2002) report the widespread occurrence of reworked shale and bitumen in Quaternary till stemming from Cretaceous shales the oil sands, with unoxidized and oxidized forms present, and the latter enhanced by aerial exposure along paleosurfaces. Today, bituminous erratic boulders are found strewn around the region across tens of thousands of square kilometers (Rutherford, 1928; Andriashek, 2018). As Andriashek (2018) points out, Rutherford (1928) states: "There are perhaps many more occurrences of bituminous sand within the glacial deposits of Alberta, but since they weather comparatively readily and become covered with soil, they are not likely to be detected unless by accident, ...". This observation of rapid weathering of bitumen indicates that today's occurrences in glacial tills represent the tip of the iceberg of what once was present. CO₂ respiration from bituminous materials based on laboratory incubations reveal fluxes that are markedly higher in comparison to oxidation of rock disseminated forms of kerogen (see Table 1). Chang and Berner (1998, 1999) report subaquatic bituminous coal oxidation (calculated >300 MgC/km²/yr) releasing CO₂ greater by 1-2 orders of magnitude than values reported from oxidation of rock disseminated kerogen and 3 orders of magnitude greater than for the average Earth's surface. Microbes likely play key roles in assimilating and releasing this ancient organic carbon as CO₂ to the atmosphere (ZoBell, 1946; Hemingway et al., 2018) with microbial communities on the surface colonizing oil sand-derived bitumen under both summer and winter conditions (Wyndham and Costerton, 1981; Wong et al., 2015). Biodegradation is accelerated during summer months where subaerially exposed outcrops of oil sands reach 60°C (Wong et al., 2015). Microbial degradation experiments of bitumen (Ait-Langomazino et al., 1991) reveal an even greater CO₂ release when extrapolated to natural systems (e.g., oil sands, see Table 1) exceeding 18 MgC/km²/day, over one hundred times greater than the highest CO₂ flux released by rock disseminated kerogen oxidation. Other laboratory-based studies (e.g., Uribe-Alvarez et al., 2011) studying oxidative decay of hydrocarbon fractions also suggest similarly astronomical fluxes when scaled to natural systems, which however only monitor over time periods of weeks. Such observations likely overestimate long-term natural fluxes over multiple years and decades, while the fluxes by Chang and Berner (1998, 1999) likely represent an underestimation due to

sample storage for several years prior to analysis and the absence of microbial activity under their experimental conditions.
160 Additionally, comparable quantities of kerogen-derived CO₂ can also release under anaerobic conditions, which may become relevant under warming glaciers (e.g., Bertassoli Jr. et al., 2016; Rogieri Pelissari et al., 2021; see also Sharp et al., 1999; Sharp and Tranter, 2017). Therefore, it is unclear how much such potential super carbon source terrains supply a disproportionate quantity of radiocarbon dead CO₂ to the atmosphere over glacial-interglacial transitions.

By 11.5 ka before present, the pronounced rise in atmospheric CO₂ had subsided. By this time, the Laurentide Ice Sheet
165 retreated beyond the easternmost reaches of the Western Canadian Sedimentary Basin and was now exposing bedrock from the relatively kerogen-poor, highly metamorphosed Canadian Shield (Fig. 4; Dalton et al., 2020). The timing of the inflection point in the rise of CO₂ occurs ≤ 300 after the entire western edge of the Laurentide Ice Sheet moves fully into the Canadian Shield suggesting abating decay of kerogen and relaxation of the landscape. By this time, the rate of soil organic carbon sequestration in these paraglacial landscapes begins to pick up substantially (Harden et al., 1992). Lithologies of the
170 Fennoscandian Shield and most of its adjacent landmasses (deglaciated eastern and southern sectors of the Fennoscandian Ice Shield; see Stroeven et al., 2016 and Copard et al., 2007) also contain relatively low kerogen contents, therefore limiting the contributions of atmospheric CO₂ rise in the wake of Fennoscandian Ice Sheet retreat. Glacially ground graphite shed from these highly metamorphosed rocks behaves chemically recalcitrant and is mostly redeposited (Sauramo, 1938; Sparkes et al., 2020).

175 In the bigger picture, during Earth's recent glacial episodes, the Laurentide Ice Sheet represents the aerially most extensive part of the cryosphere that waxed and waned across the continents (Batchelor et al., 2019) and in conjunction with its lithological underpinning (Copard et al., 2007) likely played the largest role in releasing kerogen-derived CO₂ to the atmosphere upon glacial retreat. However, estimates on CO₂ fluxes emanating from bedrock show a wide range (Table 1) and considerable uncertainty resides in our current state of knowledge: Dedicated biogeochemical weathering studies are lacking
180 which provide carbon fluxes emanating from bedrock-derived kerogen under relevant environmental conditions and timescales. Chronosequence studies of kerogen oxidation rates in deglaciated terrains are needed to provide constraints on time-integrated CO₂ release to the atmosphere. Such information in conjunction with high-resolution spatiotemporal changes in land ice extent together with lithology of bedrock and glacial till can theoretically quantitatively disentangle the contribution of kerogen-derived CO₂ to the atmosphere during glacial-interglacial transitions.

185 **5 Tackling geologic deep time**

While modern day kerogen weathering and reburial efficiencies are only loosely constrained, even less is known about how they varied back in geologic time. Overarching controls on these processes include the mode of erosion and transport ranging from glacial to glaciofluvial to fluvial, remineralization intensity, controlled by continental margin type and geomorphology, and the intrinsic reactivity of the kerogen present locally (Blair and Aller, 2012; Blattmann et al., 2018b). Also important is
190 bedrock lithology and regolith composition which have been hypothesized to exert feedback on temporal patterns of glacial-

interglacial cyclicality (e.g., Roy et al., 2004; Zeng, 2007). For the Paleocene-Eocene Thermal Maximum, an extreme greenhouse episode, evidence increasingly points towards enhanced remineralization and leaching of kerogen (Boucein and Stein, 2009; Lyons et al., 2019), possibly enhanced by the activity of microbes (Hemingway et al., 2018; Petsch et al., 2001), thereby increasing the flux of carbon entering actively circulating pools on Earth's surface. Across Earth's history over 10⁹-
195 year timescales, kerogen reburial efficiency presumably varied as a function of atmospheric O₂ content, with lower O₂ contents tied to higher reburial efficiency (Daines et al., 2017). Kerogen is surmised to have acted as a major source of carbon to the atmosphere and as an "antioxidant" during the early rise of atmospheric O₂ (Daines et al., 2017; Kump et al., 2011). Across multiple glacial-interglacial cycles, enhanced kerogen oxidation would also be consistent with declining atmospheric O₂ over 10⁶ yr timescales (Stolper et al., 2016).

200 In order to understand atmospheric chemistry through geologic time, in addition to comprehensively budgeting the effect of mineral chemical weathering (Blattmann et al., 2019a; Horan et al., 2019; Hilton et al., 2014), changing reburial efficiency of sedimentary kerogen needs to be evaluated. Direct quantification of kerogen found reburied in sediments is often associated with considerable uncertainty owing to uncertainties in organic matter source apportionment (e.g., Lin et al., 2020; Blattmann et al., 2019b) and geospatial variability (e.g., Blattmann et al., 2018a; Cui et al., 2016). While radiocarbon was paramount for
205 establishing the importance of and quantifying kerogen reburial in the Recent (Blattmann et al., 2018b), the utility of radiocarbon quickly diminishes for strata preceding the Last Glacial Maximum owing to its radioactive decay. However, associated with kerogen are a promising suite of trace elements and their respective isotope signatures including, among others, rhenium (Hilton et al., 2014; Horan et al., 2017), osmium (Georg et al., 2013; Ravizza and Esser, 1993), and iodine (Moran et al., 1998), that can be exploited to trace sedimentary kerogen and its degradation. In the case of osmium, seawater records
210 reveal isotopic shifts at the beginning of interglacials attributable to the oxidation of kerogen (Georg et al., 2013; compare discussions in Peucker-Ehrenbrink and Ravizza, 2020), consistent with the presented hypothesis. More research constraining the exogenous kerogen cycle by quantification of reburied kerogen inputs (e.g., iodine isotopes, organic petrology) and kerogen oxidation recorded by chemical weathering proxies (e.g., osmium isotopes) is needed to put the presented hypothesis to the test.

215 **6 Synthesis and outlook**

In a nutshell, the presented hypothesis proposes the following: Less than 300 years after the Laurentide Ice Sheet retreated east past the easternmost edges of the kerogen-rich Western Canadian Sedimentary Basin, atmospheric CO₂ levels stabilized and its rate of ¹⁴C decline subsided (Figs. 3 and 4). This inflection point is mirrored in the surficial lithologies of the Canadian Shield, which exposed comparatively minor amounts of reactive kerogen to the elements upon further deglaciation. Within the
220 context of the presented hypothesis, the coincidence of global trends in atmospheric chemistry with spatiotemporal patterns of freshly exposed deglaciated terrain impregnated with oxidizable and biodegradable kerogen and bituminous materials suggest that a burst(s) of respired CO₂ contributed to the characteristic deglacial rebound in atmospheric CO₂. As soon as glacially

ground shales and bituminous materials either exhausted their labile kerogen content and/or became buried by soil and vegetation taking hold of the deglaciated landscape, classically considered processes (land-ocean exchange, biospheric uptake, etc.) reassumed dominant control on fluctuations of atmospheric chemistry. As a corollary of this hypothesis: CO₂ rise within the envelope of glacial-interglacial cyclicity would primarily have responded as a slave to orbitally controlled glacial retreat across kerogen impregnated landscapes as a result of global temperature increase. CO₂ rise may therefore lead or lag global temperature depending on the spatiotemporal patterns of glacial retreat exposing glacially ground, kerogen-impregnated or even bituminous parent material.

225

230 Various mechanisms for explaining CO₂ increases at glacial interglacial transitions have been proposed (e.g., Martin, 1990; Broecker and Peng, 1993; Rapp, 2019). However, as a cogwheel operating under manifold feedbacks in the greater Earth system (Sigman and Boyle, 2000), continuous glacial retreat and oxidation of finely ground kerogen provides a hypothesis consistent with a CO₂ increase in the wake of glacial episodes. This dilution of radiocarbon-dead CO₂ in the atmosphere may well have been complemented by other terrestrial sources such as subglacial paleosol oxidation (Zeng, 2007; Simmons et al.,

235 2016), permafrost-bound organic carbon oxidation (Tesi et al., 2016; Winterfeld et al., 2018; Köhler et al., 2014; Ciais et al., 2012), and by (time-delayed) volcanic emissions due to unloading of the lithosphere (Roth and Joos, 2012). In addition to studies of weathering in glacial forefields and source-to-sink tracing of sedimentary kerogen, several lines of geochemical evidence including atmospheric carbon isotopic composition (¹³C and ¹⁴C), which have thus far received contorted, partial explanations (Broecker and Clark, 2010; Schmitt et al., 2012; Broecker and McGee, 2013), glacial-interglacial changes in ¹⁴C

240 of dissolved inorganic carbon in seawater (Rafter et al., 2019, c.f., discussions therein), seawater osmium isotope changes, and long-term atmospheric O₂ content, conceptually go hand-in-hand with an opening of the exogenous kerogen cycle modulated by glacial activity. While geomagnetic variability and ocean ventilation together struggle to fully explain observed changes in atmospheric radiocarbon (Broecker and Barker, 2007; Cheng et al., 2018), the dilution of atmospheric CO₂ by accelerated ancient terrestrial organic carbon oxidation at glacial terminations, in conjunction with other mechanisms including

245 atmosphere-ocean gas exchange (e.g., Sigman et al., 2010; Marcott et al., 2014; Menviel et al., 2018; Martin, 1990; Sarntheim et al., 2013) appears as a simple and plausible explanation. In addition to kerogen oxidation at glacial terminations, the presented hypothesis carries other important implications, including the closure of the exogenous kerogen cycle during glacial periods (Fig. 2) potentially contributing to relatively high atmospheric ¹⁴C signatures, a problem highlighted by Dinauer et al. (2020), as a reduced ¹⁴C-free CO₂ flux would reduce the dilution of the atmosphere's cosmogenic ¹⁴C. Overall, increased

250 reburial efficiency of kerogen can account for several tens of PgC over millennial timescales entirely bypassing actively circulating carbon pools on Earth's surface (Fig. 1). In contrast, increased oxidation efficiency of kerogen in the wake of glacial episodes that have built up stores of finely ground reactive substrate and expose fresh weathering profiles can account for several hundreds of PgC over millennial timescales released into actively circulating pools. Owing to increased bedrock exhumation over the Ice Ages (Herman et al., 2013; Herman et al., 2015) the dynamism of the exogenous kerogen cycle may

255 have been intensified, with greater fluxes of detrital kerogen reburied in ocean sediments during glacial episodes and enhanced supplies of ground kerogen exposed to the elements in their wake.

While basic controls on kerogen reburial efficiency have emerged, its quantitative impact on atmospheric chemistry through geologic time remains conjectural. Mathematically analogous modeling results (Zeng, 2003; Simmons et al., 2016) suggest that kerogen oxidation could account for 30–60 ppm rise in atmospheric CO₂ over the course of the last deglaciation. However, there is a lack of data on kerogen weathering to provide sufficient quantitative constraint for testing this hypothesis. To work towards such a test, investigating kinetics of kerogen oxidation along glacial chronosequences with contrasting lithologies would provide numerical input for Earth system models. Such information in conjunction with spatiotemporal changes in land ice extent (e.g., Dalton et al., 2020; Stroeven et al., 2016) integrating over areal changes of glacially exposed lithological units (c.f., Copard et al., 2007) would constrain the quantitative impact of the exogenous kerogen cycle on atmospheric chemistry over glacial-interglacial cycles. Additionally, the role of super carbon source terrains (e.g., surficial oil sands and coal) deserve special attention as biogeochemical weathering and associated CO₂ fluxes emanating from such areas conceivably contribute disproportionately, particularly upon deglaciation. Overall, the spatiotemporal deglaciation of contrasting source terrains across North America with the coeval progression of atmospheric chemistry provide strong incentive to explore the potential role of the exogenous kerogen cycle on glacial-interglacial patterns. From a greenhouse perspective, further study of pivotal episodes such as the Paleocene-Eocene Thermal Maximum under this lens may provide an outlook for geological processes relevant today. In the context of our warming world, once critical thresholds are breached (Steffen et al., 2018), enhanced opening of the exogenous kerogen cycle may entrain the Earth system onto a new trajectory influencing the carbon cycle and climate for millennia to come.

Acknowledgments

This work greatly benefitted from the input of two anonymous reviewers. The author is thankful for discussions with Timothy Eglinton, Dominik Letsch, Maarten Lupker, Jesper Suhrhoff, Valier Galy, and Robert Hilton. This work was supported by funding from JAMSTEC.

Competing interests

	7-13	Rhenium-based estimate integrating over catchment and riverine in-situ weathering.	Hilton et al., (2014)
Shale (Posidonia, Germany)	11-16	Onsite kerogen oxidation based on Holocene scenario described in reference using mass loss of kerogen and estimated erosion rates. Weathering depth of 5 m and organic carbon to organic matter conversion factor of 1.5 assumed.	Littke et al., (1991)
Southern Alps, New Zealand	9-50	Rhenium-based estimate integrating over catchment and riverine in-situ weathering. Oxidation fluxes reported for 4 catchments with minimum and maximum reported here.	Horan et al., (2017)
Tar sandstone (Brazil)	~54	Laboratory-based experiments over 1 year duration under water saturated and anoxic conditions at 20°C. Results scaled with density taken as 2000 kg/m ³ and 1 m weathering depth.	Rogieri Pelissari et al., (2021)
Shale (Jurassic marl, France)	61-64	Field-based observations spanning over minutes to up to 101 days using zeolite traps.	Soulet et al., (2018)
Bituminous coal	320-530	Laboratory-based subaquatic oxidation experiments at 24°C for air-saturated water over 179-442 days duration. Carbon release calculated assuming 30-50% of oxygen reacts to form CO ₂ , an average specific surface area of coal of 1 m ² /g, average density of 1400 kg/m ³ , and 1 m weathering depth.	Chang and Berner (1998, 1999)
Shale (Brazil)	80-1050	Laboratory-based experiments over 75 days duration under water saturated, dark, and anoxic conditions at 25°C. Results scaled with density taken as 2200 kg/m ³ and 1 m weathering depth.	Bertassoli Jr. et al., (2016)
Oil sands (Bitumen)	6800-13000	Laboratory-based experiments of 100 days duration for biodegradation of bitumen with different microbial cultures. Results scaled to oil sands with density taken as 2000 kg/m ³ with 10% bitumen content, and 1 m weathering depth.	Ait-Langomazino et al., (1991)

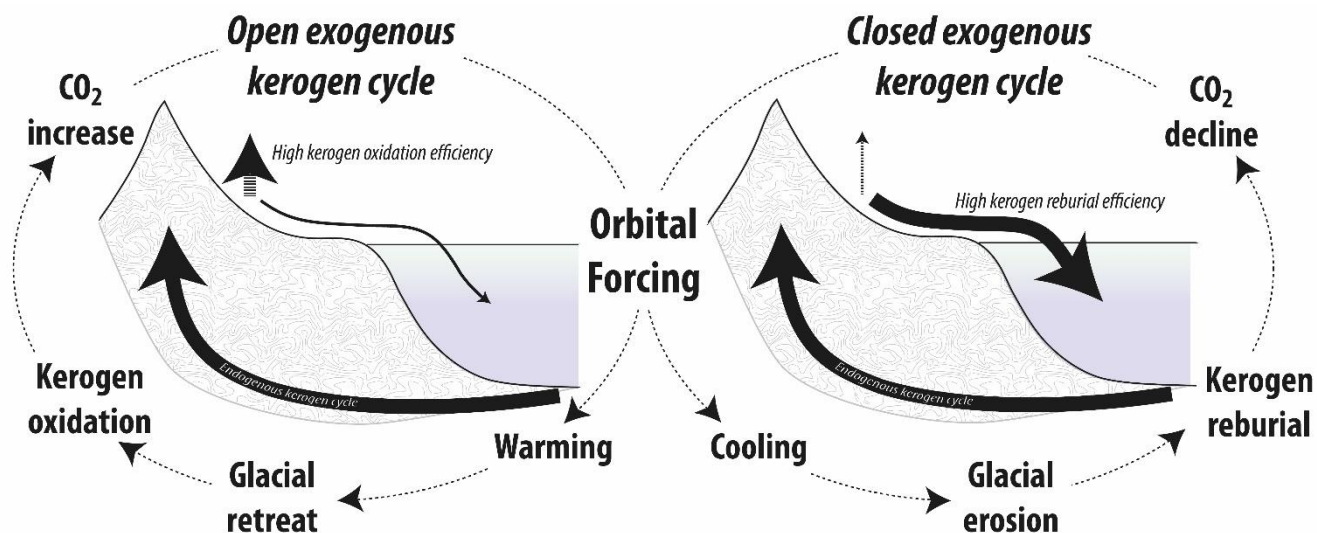

Figure 1: Organic carbon cycle with the flow of kerogen (black solid lines) and the flow of biospheric carbon (green solid lines) showing both the fixation of atmospheric CO₂ by terrestrial and marine primary productivity. The combined flux of reworked kerogen and biospheric carbon into ocean sediments constitutes total organic carbon burial entering the endogenous kerogen pool (Galy et al., 2015; Hedges and Oades, 1997).

505

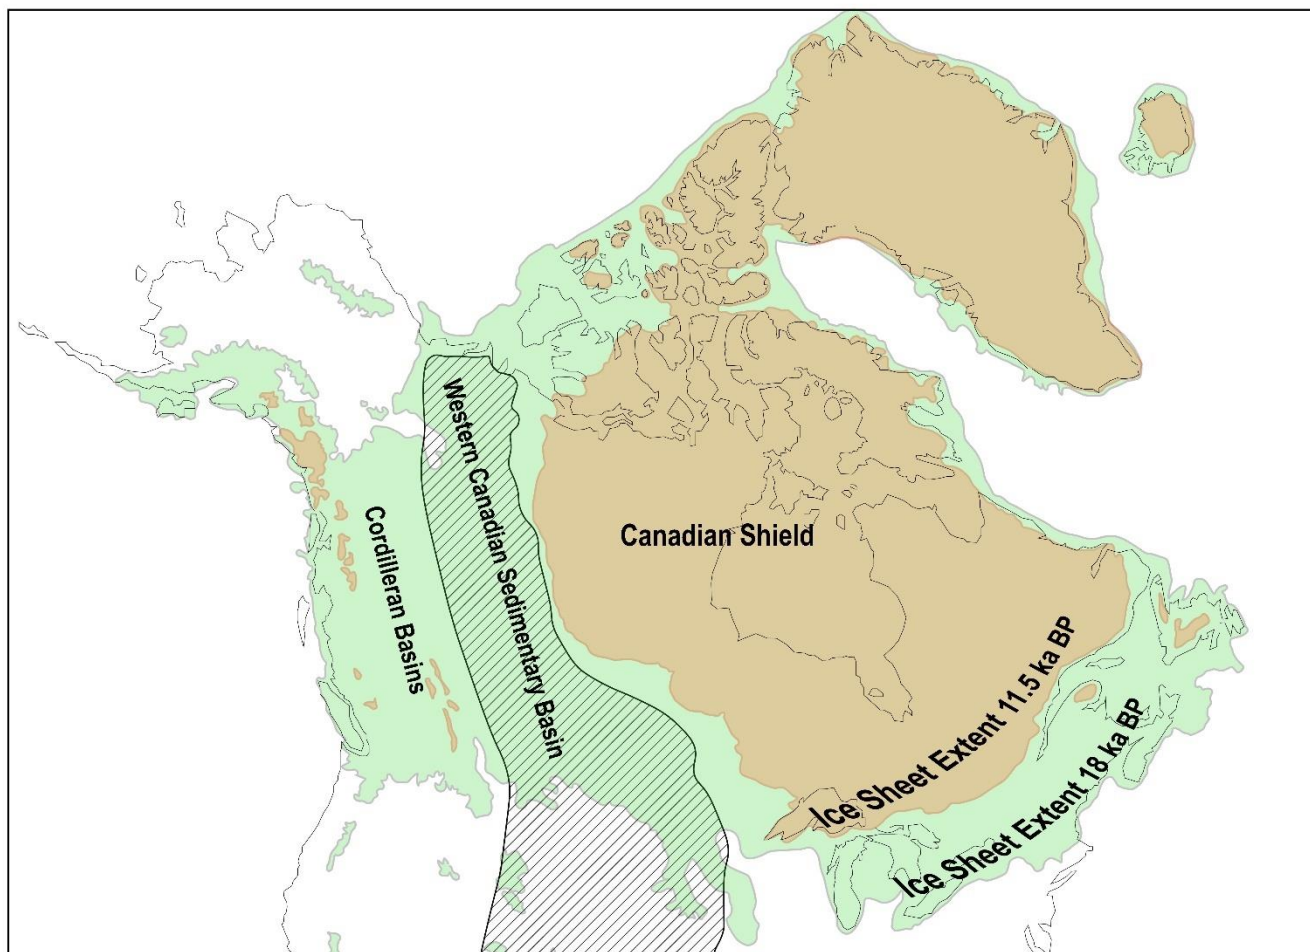

510 Figure 2: Conceptual hypothesis overview: Changes in kerogen reburial efficiency and its effect on the reentry of ancient carbon into surficial carbon pools as a function of overall climate state. During glacial times, kerogen reburial is promoted by the activity of glaciers and ice sheets with relatively little oxidation of this carbon during its transit across Earth's surface characteristic of a "closed" exogenous kerogen cycle. During glacial terminations and interglacials, the oxidation of kerogen is more efficient leading to the exhalation of this carbon to the atmosphere characteristic of an "open" exogenous kerogen cycle.

515

Figure 3: Evolution of atmospheric CO₂ and its carbon isotopic composition starting from the Last Glacial Maximum with redrawn data from Schmitt et al. (2012) and ¹⁴C data from Reimer et al. (2013). The area of the Laurentide Ice Sheet (including Greenland) is plotted after Dalton et al. (2020). The gray time envelope indicates the greatest rate of atmospheric CO₂ increase coinciding with a pronounced negative pulse in stable carbon isotopic composition and accelerated decrease in radiocarbon concentration. In addition to the hypothesized role of kerogen oxidation, the superimposed effects of ocean-air gas exchange, an increasingly voluminous terrestrial biosphere, changes in radiocarbon production in the atmosphere, etc. all contribute to the evolution of these parameters.

520

525 **Figure 4:** Laurentide Ice sheet extents bracketing the time span of most pronounced glacial-interglacial CO₂ increase (redrawn after Dalton et al., 2020). Sedimentary basins showing the Western Canadian Sedimentary Basin (hatched area, with extension of related units into the United States) and the Cordilleran Basins and Canadian Shield to the east and west, respectively (simplified after Miall and Blakey, 2019). The surficial kerogen content in the Canadian Shield is generally low, while high kerogen contents are present along the axes of the Cordilleran and Western Canadian Sedimentary Basins (see Fig. 2 in Copard et al., 2007). ≤300 years after glacial retreat extended into the Canadian Shield, the rise in atmospheric CO₂ subsided (compare with Fig. 3). Here, kerogen oxidation mainly in western Canada is hypothesized to have acted as a major source of CO₂ to the atmosphere in the wake of glacial retreat.
