16 **Abstract.** According to current experimental evidence, coral reefs could disappear within the century if CO<sub>2</sub> emissions remain  
17 unabated. However, recent discoveries of diverse and high cover reefs that already ~~thrive live~~ under extreme conditions ~~seem~~  
18 ~~to contradict these projections~~ suggest that some corals might thrive well under hot, high pCO<sub>2</sub>, and deoxygenated seawater.  
19 Volcanic CO<sub>2</sub> vents, semi-enclosed lagoons and mangrove estuaries are unique study sites where one or more ecologically  
20 relevant parameters for life in the oceans are close or even worse than currently projected for the year 2100. ~~These natural~~  
21 ~~analogues of future conditions hold new hope for the future of coral reefs and provide unique natural laboratories to explore~~  
22 ~~how reef species could keep pace with climate change. Although they do not perfectly mimic future conditions, these natural~~  
23 ~~laboratories offer unique opportunities to explore the mechanisms~~ ~~how that reef species could use to keep pace with climate~~  
24 ~~change.~~ To achieve this, it is essential to characterize their environment as a whole, and accurately consider all possible  
25 environmental factors that may differ from what is expected in the future, ~~and that may possibly altering~~ the ecosystem  
26 response.

27 ~~In~~ This study ~~we focus~~es on the semi-enclosed lagoon of Bouraké (New Caledonia, SW Pacific Ocean) where a healthy reef  
28 ecosystem thrives in warm, acidified and deoxygenated water. We used a multi-scale approach to characterize the main  
29 physical-chemical parameters and mapped the benthic community composition (i.e., corals, sponges, and macroalgae). The  
30 data revealed that most physical and chemical parameters are regulated by the tide, strongly fluctuate 3 to 4 times a day, and  
31 are entirely predictable. The seawater pH and dissolved oxygen decrease during falling tide and reach extreme low values at  
32 low tide (7.2 pH<sub>T</sub> and 1.9 mg O<sub>2</sub> L<sup>-1</sup> at Bouraké, vs 7.9 pH<sub>T</sub> and 5.5 mg O<sub>2</sub> L<sup>-1</sup> at reference reefs). Dissolved oxygen,  
33 temperature, and pH fluctuates according to the tide of up to 4.91 mg O<sub>2</sub> L<sup>-1</sup>, 6.50 °C, and 0.69 pH<sub>T</sub> units on a single day.  
34 Furthermore, the concentration of most of the chemical parameters was one- to ~~five 5~~ times higher at the Bouraké lagoon,  
35 particularly for organic and inorganic carbon and nitrogen, but also for some nutrients, notably silicates. Surprisingly, despite  
36 extreme environmental conditions and altered seawater chemical composition ~~measured at Bouraké~~, our results reveal a  
37 diverse and high cover community of macroalgae, sponges and corals accounting for 28, 11 and 66 species, respectively. Both  
38 environmental variability and nutrient imbalance might contribute to their survival under such extreme environmental  
39 conditions. We describe the natural dynamics of the Bouraké ecosystem and its relevance as a natural laboratory to investigate  
40 the benthic organism's adaptive responses to multiple ~~stressors like future climate change~~ extreme environmental conditions.

## 46 1 Introduction

47 Atmospheric carbon dioxide (CO<sub>2</sub>) has steadily increased over the industrial period (Gattuso et al., 2015), leading to ocean  
48 warming, acidification and deoxygenation. Although the extent to which these stressors will affect marine life is still debated,  
49 there is no doubt that their combination will negatively affect a range of marine organisms (e.g., Kroeker et al., 2011;  
50 Wittmann and Pörtner, 2013; Hughes et al., 2018). Coral reefs are among the most productive and biodiverse marine  
51 ecosystems on Earth, and their survival is expected to be compromised by climate change, whose impacts on reef structures  
52 and associated communities span from biodiversity loss to ecosystem change shift (e.g., Fabricius et al., 2013; Sunday et al.,  
53 2017; Agostini et al., 2018).

54 Marginal and extreme environments, where some species persist under sub-optimal environmental conditions, have become  
55 a precious tool to investigate the potential resilience of marine organisms in the face of climate change (Camp et al., 2017,  
56 2018). These sites may be used as natural ~~analogues-laboratories of future climatic conditions when-where~~ at least one or  
57 more environmental parameters naturally mimic ~~climate-change-like~~ extreme environmental conditions over a large area of  
58 the ecosystem. They provide an opportunity to simultaneously investigate changes in species responses and their ability to  
59 acclimatize and adapt to global environmental changes (Soares, 2020; Kurihara et al., 2020). Shallow-water volcanic CO<sub>2</sub>  
60 seeps, low pH springs, semi-enclosed bays, mangrove habitats, shallow sheltered-bay reefs, macrotidal environments, and  
61 low-pH upwelling areas are all potential study systems where the surrounding seawater is subject to a localized or widespread  
62 increase in either pCO<sub>2</sub>, or temperature, and eventually a decrease in dissolved oxygen (Camp et al., 2018). At these sites,  
63 ~~observations overall~~ general observations suggest ecosystem-level consequences of life-long exposure to extreme conditions,  
64 such as reduced biological diversity, especially among calcifying organisms, ~~decreasing-decreased~~ rates of coral calcification,  
65 and high rates of bioerosion (e.g., Hall-Spencer et al., 2008; Manzello et al., 2008; Fabricius et al., 2011; Crook et al., 2013;  
66 Kroeker et al., 2011; Iglesias-Prieto et al., 2014; Milazzo et al., 2014; Paytan et al., 2014). However, some natural ~~analogues~~  
67 laboratories can host ~~quite-very~~ rich reef communities. ~~These-Examples of such sites~~ have been documented in Palau (Golbuu  
68 et al., 2016; Barkley et al., 2017; Shamberger et al., 2018; (Kurihara et al., 2021)-), Papua New Guinea (Pichler et al., 2019),  
69 the Kimberly region, Australia (Dandan et al., 2015; Schoepf et al., 2015), and in mangrove lagoons of New Caledonia (Camp  
70 et al., 2017) and the US Virgin Islands (Yates et al., 2014).

71 These natural laboratories have become a common experimental asset in climate change research. However, ~~it-has-been-argued~~  
72 ~~that~~ the lack of empirical characterization of the physical and biogeochemical conditions, including diurnal and seasonal  
73 fluctuations, ~~have been argued to may~~ bias the interpretation of the biological mechanisms that trigger the ~~organismal~~  
74 responses ~~of organisms (e.g., (Vizzini et al., 2013; (Camp et al., 2018; (Aiuppa et al., 2021)-)~~. Using limited environmental  
75 descriptors makes it difficult to unequivocally identify the main driver(s) of the biological response among the primary factors  
76 (i.e., acidification, warming and/or deoxygenation), the potential secondary factors (e.g., pollution, water flow, tide, seawater  
77 nutrients and organic content, turbidity, etc.), and their combination. For instance, at CO<sub>2</sub> seeps, pH variability can  
78 unexpectedly go beyond projected future values (e.g., Hall-Spencer et al., 2008; Kerrison et al., 2011) and the potential  
79 emission of toxic compounds, such as sulphur, arsenic, and metal trace elements (Vizzini et al., 2013) compromises the  
80 attribution of specific responses to ocean acidification. Water temperature, pH and dissolved oxygen can also co-vary  
81 negatively or positively and combine with other secondary factors, acting synergistically or antagonistically with unknown  
82 effects on benthic community responses. Their extreme values and the extent to which organisms are exposed are ~~key-crucial~~  
83 in shaping biological responses (Boyd et al., 2016; Rivest et al., 2017). For instance, early studies suggest that temperature

84 fluctuations due to diel or tidal variations could expose corals to stressful temperatures long enough to induce acclimatization  
85 or adaptation, but short enough to avoid coral mortality (Craig et al., 2001; Oliver and Palumbi, 2011; Castillo et al., 2012;  
86 Palumbi et al., 2014; DeCarlo et al., 2019). Coral reef organisms from such thermally variable environments are expected to  
87 respond positively to future heat events (Rivest et al., 2017). Besides, corals naturally subjected to high  $p\text{CO}_2$  variability have  
88 shown immune defences when experimentally exposed to high temperatures, thus buffering the magnitude of thermal stress  
89 during heat waves (Wall et al., 2020). The extreme tidal range in the Kimberly region (Northwest of Australia) exposes corals  
90 to short-term temperature maxima of up to 37 °C, and fluctuations of up to 7 °C daily. Despite the high temperature, also  
91 combined with strong currents and turbid waters, diverse and probably resilient coral reefs have been described there (Dandan  
92 et al., 2015; Schoepf et al., 2015).

93 Overall, ~~at natural analogues laboratories only a parts of these natural laboratories' the~~ physical and biogeochemical  
94 parameters have been quantified and only during short periods of fieldwork due to logistic constraints. Long-term monitoring  
95 of seawater parameters and their fluctuation is essential to ~~understand~~ better understand the mechanisms used by resilient reef  
96 organisms in these natural laboratories and ~~interpret predict~~ how marine taxa will respond to future biogeochemical changes  
97 in the environment.

98 The semi-enclosed lagoon of Bouraké (New Caledonia, SW Pacific Ocean) has been ~~put forward to be as considered~~ one of  
99 the most suitable natural ~~analogues laboratories for~~ future extreme environmental conditions (Camp et al., 2019). In a  
100 preliminary study, Camp et al., (2017) reported a series of compelling short-term data of seawater carbonate chemistry and a  
101 general survey of the coral populations. In this first assessment of the Bouraké lagoon, the authors measured diel fluctuations  
102 of temperature (ranging from 25.9-33.1 °C), pH (ranging from 7.24-7.91  $\text{pH}_T$  units) and dissolved oxygen (DO) (ranging from  
103 1.80-6.97  $\text{mg L}^{-1}$ ) regulated by a one-meter tide. They revealed that about 20 species of corals were exposed 44 % of the time  
104 to a  $\text{pH}_T$  of 7.7-7.8, and 71 % of the time to temperatures predicted for the end of the century under the IPCC scenario RCP4.5  
105 (IPCC, 2014). These striking preliminary findings qualified the Bouraké lagoon as a unique site where potentially adapted  
106 corals withstand extreme environmental conditions.

107 ~~These findings give hope to the future of coral reefs in the face of climate change, and suggest that Bouraké might play as a~~  
108 ~~refuge for corals since it already hosts resistant reef species. However, the~~The extent to which the Bouraké species are exposed  
109 to sub optimal conditions remains unclear. ~~and~~ We believe that the ~~road map to test for such an~~ best way to assess these very  
110 encouraging ~~hypothesis findings is first to start with~~ fully characterizing the main environmental parameters and the daily  
111 and seasonal fluctuations to which reef species have been subjected during their entire life. Here we used a multi-scale  
112 approach to map and describe the benthic community living in the Bouraké lagoon and report on new evidence based on three  
113 years of data ~~collected at this remarkable natural laboratory. B~~ In particular, because of the size of the area, vast area affected,  
114 the close vicinity of a dense mangrove forest, and the demonstrated tide effect on the local environmental conditions, we  
115 hypothesized that (1) environmental conditions fluctuate regularly but are spatially heterogeneous throughout and differ  
116 ~~spatially in the~~ Bouraké lagoon, and (2) only a limited number of species ~~are able to can~~ resist to the extreme physical and  
117 chemical conditions at the study site, when compared to adjacent bay-sheltered reefs.

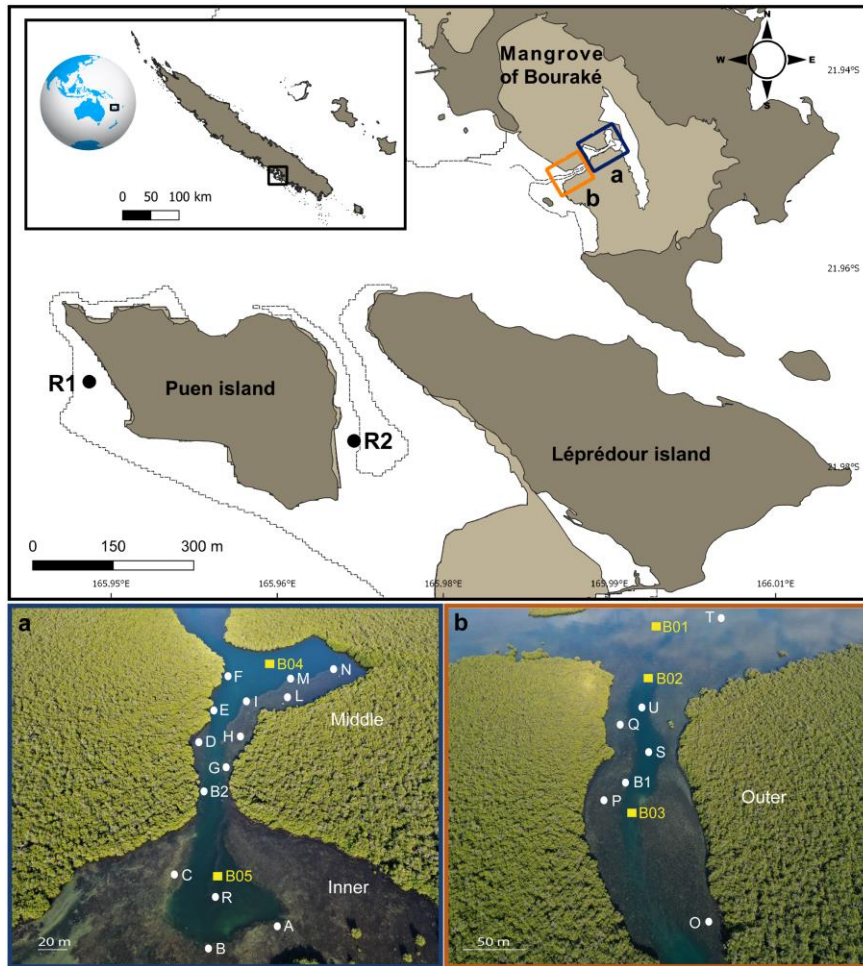

118

119 **2 Methods**

120 **2.1 Study sites**

121 ~~From Starting in~~ February 2016, we studied the semi-enclosed coral reef lagoon of Bouraké (South Province, Grande Terre,  
122 New Caledonia) and adjacent reference reefs (Fig. 1). The mangrove of Bouraké is located in a semi-arid geographical area,  
123 and it lacks rivers input typical of mangrove estuaries.

124  
125 **Figure 1.** Map of the study site (top panel) showing the semi-enclosed mangrove lagoon of Bouraké and reference reefs (R1  
126 and R2). Photos (a) and (b) (bottom panels) are aerial pictures (taken at 130 m above the Bouraké lagoon) of the inner (bottom)  
127 and middle reefs (a) and the outer reef (b). White dots and yellow squares indicate the sampling stations used for physical

Mis en forme : Centré

128 and chemical environmental monitoring, respectively. [Georep New Caledonia database \(https://georep.nc/\)](https://georep.nc/) and QGIS software  
129 were used to build the figure (top panel).  
130

131 In Bouraké, a channel of more than 80 m wide and 0.5 to 6 m deep penetrates a dense mangrove forest made by *Avicennia*  
132 *marina* and *Rhizophora stylosa*, and it expands into side pools and a large reservoir in the inner part of the mangrove system.  
133 A preliminary calculation of its surface and seawater volume of the main area (i.e., without the large seawater reservoir  
134 covered by the mangrove forest) using the 3ds Max Model gives underestimated values of 192,100 m<sup>2</sup> and 246,060 m<sup>3</sup>,  
135 respectively (Rodolfo-Metalpa et al., in prep.). Terraces extend from the mangrove, on both sides of the channel, and form  
136 diverse and compact reefs at their ends. Coral species are less abundant and diverse near the mangrove roots, where the bottom  
137 substrate is composed of fine sediment and mud. There, reefs are exposed to air only at low tide during the spring tidal  
138 eyeletides (1.1 m maximum tidal range). We subdivided the lagoon into three main areas: an external, an intermediate, and  
139 an inner reef (hereafter called outer, middle and inner reefs; panels a & b in Fig. 1). A series of sampling stations were selected,  
140 and some of the main seawater chemical and physical environmental parameters were measured at the study site and at two  
141 adjacent reference reefs, namely R1, a typical fringing reef, and R2, a semi-enclosed shallow and relatively large bay. Both  
142 reefs were located 4.8 and 3.2 km from the entrance of the Bouraké lagoon, respectively.

## 143 2.2 Environmental monitoring

### 144 2.2.1. Oceanographic sensors deployment and short- to long-term measurements

145 From ~~March-February~~ 2016 to December 2020 up to eight YSI 600 OMS-M, three Seabird SeaFET™ pH loggers, and four  
146 Hobo water temperature Pro V2, were set at 10-min logging intervals and used individually or in combination to assess short-  
147 , medium-, or long-term variations across depth (as a proxy of the tide), temperature (°C), dissolved oxygen concentration  
148 (DO, mg L<sup>-1</sup>), seawater pH<sub>T</sub> (total scale), and salinity. A summary of the deployments is given in Supplementary Table S1.  
149 YSI dissolved oxygen optical sensors were calibrated against zero, and 100 % saturated seawater at 25 °C. Two SeaFETs  
150 were calibrated by the manufacturer, while the third was corrected before deployment by measuring its deviation from the  
151 two others in the same seawater.

152 Short-term (i.e., 24-h) spatial and depth-related variations in pH and DO were simultaneously measured at several  
153 stations in the Bouraké lagoon in March and April 2018 (Fig. 1). Spatial variations were assessed i) within the inner (St A-C  
154 for pH, and A-G for DO), the middle (St H-N for DO), and the outer (St O-Q for DO) reefs, ii) between the outer and the  
155 inner reefs (St B1, B2 for pH), and iii) between the outer and the reef outside the semi-enclosed lagoon (St U vs T for pH). In  
156 the Bouraké lagoon, we recorded differences between the surface (shallow) and the bottom water: i) at the outer reef (St S for  
157 pH), ii) at the middle reef (St I and N for DO), and iii) at the inner reef (St R for pH, and DO). Salinity was measured in July  
158 2019 (St R1, R2, B1 and B2) and ~~in~~ December 2020 (St R1, R2, T and B2).

159 Medium-term measurements (i.e., 2-3 weeks) of the DO and pH were recorded at the reference (St R1, R2) and  
160 Bouraké reefs (St B1, B2) between 2016-7 and 2019.

161 Long-term measurements (>1 year) of seawater temperature were recorded at R1 and R2 starting ~~in~~ from January  
162 2019 and September 2017, respectively, and at B1 and B2 ~~beginning in~~ from October 2018 and September 2017, respectively.  
163 Only temperature data ~~from between~~ October 2018 ~~and to~~ April 2020 were ~~used to~~ compared between sites.

164 Short-term pH and DO data and long-term temperature data were compared between stations using General Linear  
165 Modelling (GLM), and the Tukey' HSD *post hoc* test was used when significant factor effects were found. When data did not  
166 conform to normality or homogeneity of variance, ~~we used~~ the Kruskal-Wallis test followed by the Dunn's multiple  
167 comparisons test (Bonferroni-adjusted) or the Wilcoxon test ~~were performed~~. Statistical analyses were ~~performed-carried out~~  
168 using either Statistica® or R version 3.4.4 (R Core Team, 2018), the latter using "stats", "FSA", and "MASS" packages.

### 169 2.2.2. Phase averaged and tidal harmonic analyses for diurnal and semidiurnal oscillations

170 Medium-term pH and DO changes were investigated by averaging time and tidal phases for diurnal and semi-diurnal  
171 oscillations. To do this, all data were overlaid on a daily period and a tidal phase. First, we calculated a predicted tide for the  
172 study area using the Nouméa harbour tide (50 km south of our study site) modified with coefficients from the Naval  
173 Hydrographic and Oceanographic Service (SHOM; <http://data.shom.fr>). The predicted tide was used to assign a semidiurnal  
174 tidal phase (12 h) to each sampling time, and the data were averaged for each of these tidal phases. Similarly, the data were  
175 averaged for each hour of the day (24 h). Because tides at sea are a sequence of sinusoidal harmonic components that are  
176 different for each location, we performed a harmonic tidal analysis on the DO and pH data. We used the "UTide"-*ut\_solv()*  
177 tidal analysis package (Codiga, 2011) ~~using-with~~ the principal semidiurnal lunar constituent ( $M_2$ ), principal semidiurnal solar  
178 constituent ( $S_2$ ), and solar diurnal constituent ( $S_1$ ). For each parameter, the amplitudes of the tidal harmonics  $M_2$  (12.4 h),  $S_2$   
179 (12 h), and  $S_1$  (24 h) were calculated with a 95% confidence interval based on the 200 Monte-Carlo simulations.

### 180 2.2.3. Diel cycles of carbonate chemistry and chemical parameters

181 Surface water samples were collected across ~~a~~ diel ~~tidal~~ cycles in June 2017, and July 2019 for pH, total alkalinity ( $A_T$ ),  
182 dissolved inorganic carbon (DIC), nutrients (orthosilicic acid [ $\text{Si}(\text{OH})_4$ ], nitrogen oxide [ $\text{NO}_x$ ], ammonium [ $\text{NH}_4^+$ ], phosphate  
183 [ $\text{PO}_4^{3-}$ ], dissolved organic carbon (DOC), particulate organic carbon (POC), and particulate organic nitrogen (PON). A  
184 summary of the total sampling is given in Supplementary Table S2. Dissolved inorganic nitrogen (DIN) and total organic  
185 carbon (TOC) were calculated as [ $\text{NO}_x$ ] + [ $\text{NH}_4^+$ ], and DOC + POC, respectively. ~~The most important ratios were calculated~~  
186 ~~(e.g., DOC:TOC;  $\text{Si}(\text{OH})_4$ :DIN) and contrasted between stations. ~~To~~~~ To evaluate the availability of nutrients and organic matter  
187 in the Bouraké lagoon (Jacquet et al., 2006; Leopold et al., 2017), ~~the most important ratios were calculated (e.g., DOC:TOC;~~  
188  ~~$\text{Si}(\text{OH})_4$ :DIN) and contrasted between stations.~~

189 In 2017, during three consecutive days (from May 31<sup>st</sup> to June 02<sup>nd</sup>), seawater was sampled six times: twice during  
190 both high and low tide, and ~~once-time~~ at both rising and falling tide. In total, we sampled one reference station (R2), three  
191 stations at the outer reef of the Bouraké lagoon (Outer: St B01-B03), one at the middle reef (Middle: St B04), and one at the  
192 inner reef inside the lagoon (Inner: St B05) (Fig. 1). The whole collection lasted about 30 minutes.

193 In 2019, during three consecutive days (from July 16<sup>th</sup> to 18<sup>th</sup>), sampling was carried out every hour from 8 am to 3  
194 pm. We sampled B1 and B2 on the first day, R1 on the second and R2 on the third day.

195 ~~During diel cycles, a~~At each station and sampling time, pH and temperature were measured at the surface (0.5 m deep) using  
196 a portable pH-meter (913, Metrohm) calibrated with TRIS buffer (Dickson lab, batch #T28). A subsample (50 mL) was  
197 filtered through 0.45- $\mu\text{m}$  Whatman™ Puradisc CA filters using a syringe and poisoned with 20  $\mu\text{L}$  saturated  $\text{HgCl}_2$  to further  
198 measure  $A_T$ . Two 20 mL subsamples were analysed using an auto titrator (EcoTitrator, Metrohm), and  $A_T$  was calculated from

199 the Gran function. Results were corrected against  $A_T$  standards (A. Dickson, batch #155, Scripps, USA). The seawater  
200 carbonate parameters  $p\text{CO}_2$ ,  $\text{CO}_3^{2-}$ , and aragonite saturation state ( $\Omega_{\text{ara}}$ ) were then calculated from the  $\text{pH}_T$ ,  $A_T$ , temperature,  
201 and mean salinity (35) using the free-access  $\text{CO}_2\text{SYS}$  package (Pierrot et al., 2006).

202 Ammonium concentration was determined on a 40 mL subsample of unfiltered seawater, collected using a 60 mL  
203 Schott bottle and stored in the dark. Samples were processed using a fluorimeter (Turner Designs) between six and 18 h after  
204 two mL of OPA reagent (o-phthaldialdehyde) was added (Holmes et al., 1999).

205 The sampling of nutrients was performed using two replicate 20 mL polypropylene vials, rinsed three times using  
206 filtered seawater (Whatman™ Puradisc CA syringe filters 0.45  $\mu\text{m}$ ), filled with the sample and immediately poisoned with  
207 20  $\mu\text{L}$  saturated  $\text{HgCl}_2$ . Measurements of  $\text{PO}_4^{3-}$ ,  $\text{NO}_x$ , and  $\text{Si(OH)}_4$  nutrients were performed by colourimetry (Seal  
208 Analytical).

209 Seawater samples for DIC were collected in two replicate glass vials (20 mL), filled with unfiltered water and  
210 poisoned with 10  $\mu\text{L}$  saturated  $\text{HgCl}_2$ . The vials were immediately closed, the absence of bubbles was visually checked, and  
211 the samples were stored in the dark at room temperature for later analysis on a Shimadzu TOC-L analyser (Non-Dispersive  
212 Infrared, NDIR). Typical analytical precision was less than  $\pm 2 \mu\text{mol kg}^{-1}$ . The accuracy was verified using regular  
213 measurements of reference material (CRM) from A. Dickson's laboratory.

214 Seawater samples for DOC were collected in two pre-combusted (4h at 450 °C) glass ampoules filled with water  
215 filtered using a glass syringe filtration system (SGE™) with two pre-combusted 25-mm GF/F Whatman™ filters. Samples  
216 were then acidified with ultrapure orthophosphoric acid ( $\text{H}_3\text{PO}_4$ ), sealed, and stored in the dark at room temperature for later  
217 analysis by high-temperature catalytic oxidation (HTCO) (Sugimura and Suzuki, 1988; Cauwet, 1994) on a Shimadzu TOC-  
218 L analyser. Typical analytical precision was  $\pm 0.1\text{-}0.5 \mu\text{M C}$  (SD). Consensus reference materials  
219 (<http://www.rsmas.miami.edu/groups/biogeochem/CRM.html>) were injected every 12 to 17 samples to ensure stable  
220 operating conditions. DOC concentrations are only available for the 2017 sampling because of a sample's pollution in 2019.

221 Finally, one litre of unfiltered seawater was collected in a borosilicate glass bottle and stored on ice during sampling  
222 for later measurement of POC and PON contents. In the lab, particulate matter was collected on pre-combusted (4h at 450  
223 °C) Whatman™ GF/F filters using a Nalgene® vacuum system. The filters were dried at 60 °C in the oven for 24 h and stored  
224 in airtight glass vials at 4 °C in the dark until analysis on a CHN Perkin Elmer 2400.

225 All glass bottles and vials used were pre-combusted, washed with HCl solutions (10 %) and rinsed using milliQ water.  
226 Seawater chemistry data were pooled by sampling area (R1, R2, Outer, Middle, Inner), and differences were tested using the  
227 Kruskal-Wallis test followed the Conover Multiple comparison test (Benjamini-Hochberg-adjusted). We focused on the effect  
228 of the tidal phases (i.e., falling and rising tide) on the seawater chemical composition in the Bouraké lagoon only, by attributing  
229 each sample a tidal phase between 0 (high tide) and 6 hours (low tide), and between 6 and 12 hours (high tide). Multiple linear  
230 regression was used to assess the adjusted  $R^2$  and significance ( $p < 0.05$ ) of the data from 0 to 6 h (falling tide) and from 6 to  
231 12 hours (rising tide) separately. Statistical analyses were performed using either Statistica® or R (version 3.2.4, R Core  
232 Team, 2018), the latter using the "FSA", "stats", and "Conover.test" packages.

### 233 2.3 Benthic community characterization and distribution

234 The benthic community and bottom substrate of the Bouraké lagoon, referred hereafter as biotic and abiotic descriptors,  
235 respectively, were assessed in April 2018. Twenty-four 30 m-long geo-referenced transects (T1-T24) were laid in the lagoon

236 along the terraces' edge at similar depths (i.e. ~ 1 m), targeting coral dominated benthic assemblages. On each transect, a 0.5  
237 x 0.5 m PVC quadrat was placed every meter, and a picture was taken with a waterproof photo-camera (Nikon AW 130)  
238 parallel to the substrate. ~~W~~For each transect, we made a general description of the bottom (i.e. the various substrates) and a  
239 list of the most common and identifiable sessile species for each transect. For each of the 835 pictures collected, we estimated  
240 the cover of abiotic (i.e., mud, sand, rock, rubble, dead corals and unreadable) and biotic descriptors (i.e., branching, massive  
241 and soft corals, sponges, macroalgae and "others") with photoQuad software both by automatic multi-scale image  
242 segmentation regions and manual grid cell counts when necessary.

243 We used the photos of quadrats, the many other pictures collected during fieldworks, and laboratory morphological  
244 observations on collected samples to produce a non-exhaustive species list of corals, macroalgae and sponges. Corals were  
245 comprehensively sampled throughout the Bouraké lagoon and on the reference reef R2, while dominant macroalgal and  
246 sponges species were collected in the Bouraké lagoon alone and only if they were encountered at least three times along a  
247 transect, likely leading to an underestimation of their diversity. Coral diversity was assessed through photographic and  
248 ~~destructive~~-sampling during time-based open search swims and SCUBA dives (Hill and Wilkinson, 2004). Whenever possible,  
249 scleractinian corals were identified to species level *in situ* by photographic sampling only. ~~In case of doubtful~~When  
250 identification ~~was doubtful~~ *in vivo*, or ~~when of taxa were~~ characterized by small corallite size (<1 mm in diameter) and  
251 ~~requiring additional~~ morphological examination of the skeleton ~~for positive to confirm~~ identification (e.g. genera *Acropora*,  
252 *Montipora* and *Porites*), a fragment of the colony was collected, tagged, cleaned in sodium hypochlorite overnight, rinsed in  
253 freshwater and dried. The reference collection is housed at IRD Nouméa. Microscopic examination of the skeletal features  
254 allowed species-level identification following the reference literature (Veron, and Wallace, 1984; Wallace, 1999; Veron,  
255 2000). Sponges were identified ~~either~~-based on their spicules' morphological characteristics (i.e., ~~shape~~, length and width), or  
256 using a series of morphological descriptors (e.g., shape, size, colour, texture, surface ornamentations, fibres) for species  
257 without spicules. In the lab, a subsample of the collected sponges ~~were was~~ immediately digested using HNO<sub>3</sub>, and spicules  
258 were measured with an optical stereomicroscope. For species without spicules, hand-cut sections of the choanosome and  
259 ectosome were observed under a stereomicroscope. Species were identified using the taxonomical keys of Rützler (1978),  
260 Hooper and Van Soest (2002), and Pons et al. (2017). Macroalgae and corals identification were based on morphological and  
261 anatomical observations following the dedicated literature and ~~by referring to the collections of~~ specimens housed at IRD  
262 Noumea.

263 Abiotic and biotic cover percentages, averaged per transect, and species richness, calculated as the number of species  
264 in the transect, were plotted using non-metric multidimensional scaling (nMDS) based on Bray-Curtis dissimilarities ("~~vegan~~"  
265 package in R) of square-root transformed data. Finally, the best number of clusters for the whole Bouraké lagoon was  
266 determined ~~by~~-using the gap statistic method ("~~cluster~~" and "~~factorextra~~" packages in R) and used for the hierarchical  
267 clustering representation (Ward, 1963). The cluster separation was verified with a two-way analysis of similarity ANOSIM.  
268 Within each cluster, the benthic community and bottom substrate were averaged between transects, and the dominant biotic  
269 and abiotic descriptors were selected and used to define the cluster.

270 Principal component analysis (PCA) was used to visualize the correlation between environmental parameters and  
271 the ~~transects'~~-benthic descriptors of transects inside the Bouraké lagoon. The analysis was performed in R (package  
272 "~~FactorMineR~~", version 3.2.4, R Core Team, 2018) using data of biotic descriptors (averaged per transect) and the seawater  
273 parameters averaged for each sampling area (i.e., outer, middle and inner reefs).

274

### 275 3 Results

#### 276 3.1 Variability of physical environmental parameters

277 *Tidal phases.* The predicted tide in the study area (SHOM data) is close to what we measured at R1 and R2 (Fig. 2).

278

279 **Figure 2.** Temporal shift between the averaged tides recorded at the reference (St R1 and R2) and at the Bouraké reefs (St B1  
280 and B2) and the predicted tide calculated for the study area (see SHOM: <http://data.shom.fr> for the Nouméa harbour).

281

282 It is semidiurnal with a diurnal inequality ( $M_2 = 0.44$  m,  $S_2 = 0.16$  m) and has a small diurnal component ( $S_1 = 0.15$  m). It  
283 varies between 0.4 and 1.7 m, depending on the phase of the moon, with a mean of 1.1 m. The tidal range inside the Bouraké  
284 lagoon is lower and varies between 0.4 and 1.2 m, with a mean of 0.9 m. At B1 and B2, the tidal signal at B1 and B2 lags  
285 both the predicted and the measured tide at the reference stations by an average of 1.5 h for low tide and up to 45 min for high  
286 tide.

287 *Temperature.* Our results indicate that the water temperature has an annual cycle with lower values during ~~the austral~~  
 288 winter (May-October) and higher values in summer (November-April). Daily averaged temperatures at R2, B1 and B2 were  
 289 not significantly different, while the temperature at R1 was cooler in summer and warmer in winter (Fig. 3a; Tables 1)  
 290 compared to the other stations. On a weekly ~~basisse~~, the averaged diel temperature variation was significantly different  
 291 between stations:  $1.34 \pm 0.39$  °C at R1 and  $3.73 \pm 0.74$  °C at B2 (Fig. 3b; Tables 1). In a single day, we recorded temperature  
 292 fluctuations of up to 3.4 °C at R1 and 6.5 °C at B2.

293

294  
 295 **Figure 3.** Long-term temperature monitoring from October 2018 to April 2020 at the reference (St R1 and R2) and Bouraké  
 296 reefs (St B1 and B2). Data are plotted using ~~weakly~~ averaged temperature (a) and ~~weakly-weekly~~ averaged diel changes  
 297 (b).

371 *Seawater pH.* During the entire study period, pH was measured during 22, 72, 31, and 72 semidiurnal tidal cycles at

372 R1, R2, B1, and B2, respectively. We overlaid all data on a single tidal phase of 12.4 h (Fig. 4a) and a 24-hours cycle (Fig.

373 4b).

374

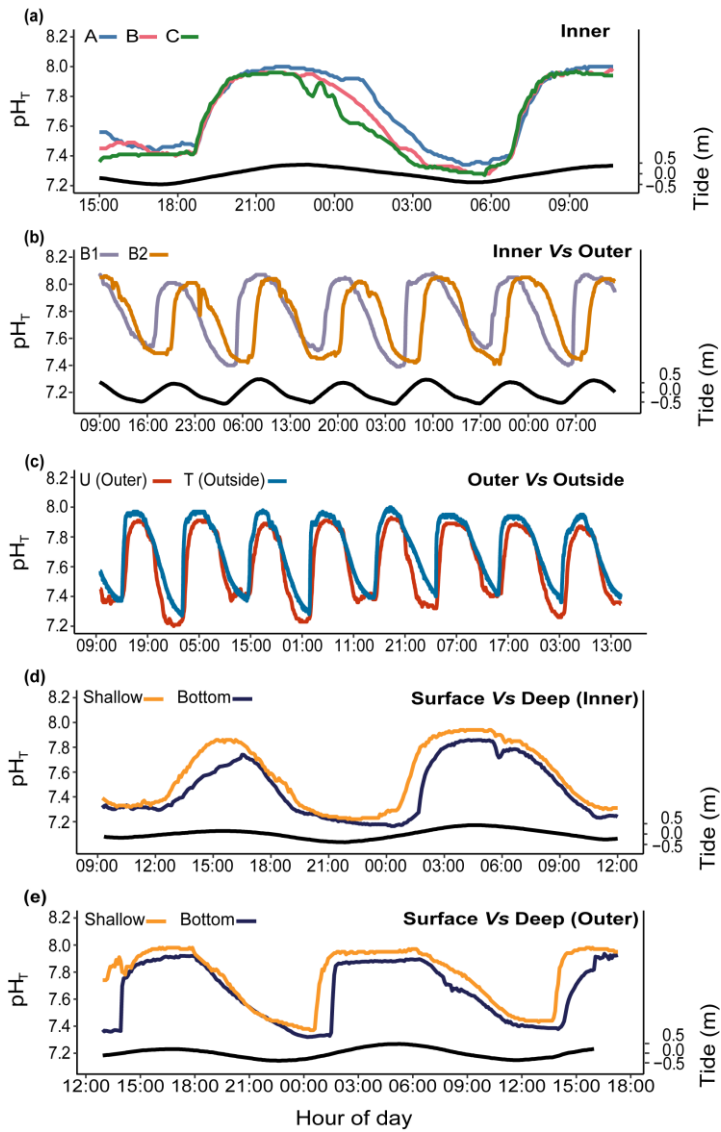

375  
 376 **Figure 4.** Seawater pH<sub>T</sub> (a), (b) and dissolved oxygen (DO) (c), (d) variations recorded at the reference (St R1 and R2) and  
 377 Bouraké reefs (St B1 and B2). Data were ~~superimposed-overlaid~~ in a single tidal phase (12 h) (a), (c); and in a 24-hours cycle  
 378 (b), (d). Data are 22, 72, 31, and 72 semi-diurnal tidal cycles for pH, and 36, 79, 34 and 42 semi-diurnal tidal cycles for DO,  
 379 for R1, R2, B1 and B2, respectively.

380  
 381 The pH differed significantly between stations. ~~During the studied period, w~~We recorded means of  $8.01 \pm 0.04$  and  $7.89 \pm$   
 382  $0.08$  pH<sub>T</sub> units at R1 and R2, and  $7.80 \pm 0.22$  and  $7.67 \pm 0.23$  pH<sub>T</sub> units at B1 and B2, respectively. At both B1 and B2, pH  
 383 was strongly correlated with the tidal cycle (Fig. 4a, 82 and 73 % of the total variance were explained by the tidal harmonic  
 384 analysis, respectively). ~~In contrast, while it was eorrelated~~ only marginally ~~correlated~~ with the 24-hours cycle (Fig. 4b).

Mis en forme : Centré

385 During each tidal phase, the pH changed on average by about 0.6 units and reached a minimum of 7.23 and a maximum of  
386 8.06 at B2 at low and high tide, respectively ([data not shown](#)). The pH oscillations were mainly semidiurnal ( $M_2 = 0.27 \pm$   
387  $0.01$ ,  $S_2 = 0.05 \pm 0.01$  pH<sub>T</sub> units, for B1;  $M_2 = 0.24 \pm 0.01$ ,  $S_2 = 0.09 \pm 0.01$  pH<sub>T</sub> units for B2). At stations R1 and R2, pH ~~was~~  
388 ~~closely linked to tidal oscillations. It~~ changed on average by about 0.1 pH<sub>T</sub> units and was mostly dependent on the 24-hours  
389 cycle ([Fig. 4b](#),  $S_1 = 0.058 \pm 0.004$  and  $S_1 = 0.049 \pm 0.007$  pH<sub>T</sub> units for R1 and R2, respectively). Simultaneous short-term pH  
390 measurements showed significant spatial differences (Fig. 5; Tables 1), between i) stations A and C, ii) stations B1 and B2,  
391 and iii) the outer reef in the Bouraké lagoon (St U) and the station outside the system (St T). There were also significant depth-  
392 related differences between shallow reefs and bottom water at stations R and S. In both spatial and depth-related analyses,  
393 differences were approximately 0.05 to 0.1 pH<sub>T</sub> units, and we found the lowest values at stations C and B2; and ~~at~~ the bottom  
394 of the channel (St R and S).

395  
 396 **Figure 5.** Spatial and depth-related short-term changes (24 h) in  $pH_T$  at stations in the Bouraké lagoon (see Figure 1 for the  
 397 stations' location). Spatial variations were assessed: (a) within the inner reef (St A-C); (b) between the inner and the outer  
 398 reefs (St B1, B2); (c) between the outer reef (but still inside the Bouraké lagoon), and the reef outside the semi-enclosed  
 399 lagoon (St U vs T). Depth-related variations were assessed between shallow reefs and the bottom of the channel: (d) at the

*Dissolved oxygen (DO).* DO was measured during 36, 79, 34 and 42 semidiurnal tidal cycles at R1, R2, B1 and B2, respectively. We overlaid all data on a single tidal phase of 12.4 h (Fig. 4c) and a 24-hours cycle (Fig. 4d). As with pH, the mean diel DO was higher at the reference reefs than in the Bouraké lagoon. ~~During the studied period, m~~Mean DO values were  $4.89 \pm 1.18$  and  $5.23 \pm 0.89$  mg L<sup>-1</sup> at B1 and B2, respectively, and  $6.45 \pm 0.95$  and  $6.48 \pm 1.05$  mg L<sup>-1</sup> at R1 and R2, respectively.

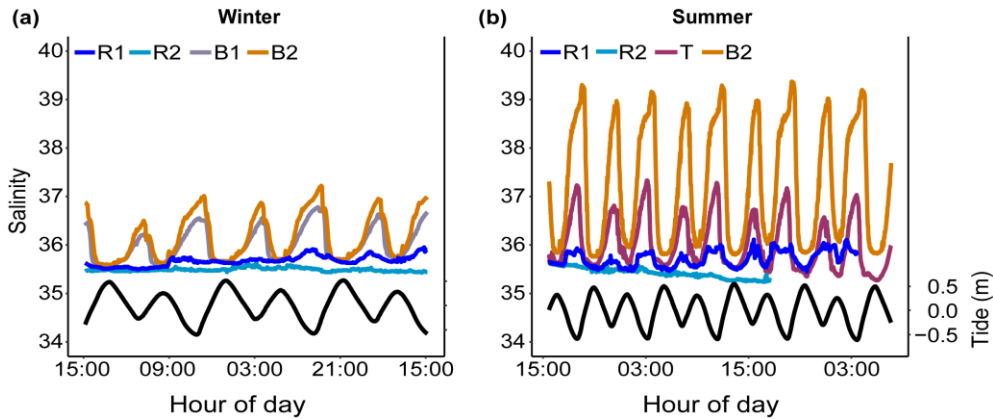

At stations B1 and B2, DO was strongly correlated with the tidal cycle (Fig. 4c, 82 and 72 % of the total DO variance were explained by the tidal harmonic analysis, respectively), ~~and only marginally with the 24-hour cycle (Fig. 4d).~~ DO oscillations were mainly semidiurnal ( $M_2 = 1.17 \pm 0.08$  mg L<sup>-1</sup>, and  $M_2 = 0.83 \pm 0.09$  mg L<sup>-1</sup> for B1 and B2, respectively) with a substantial diurnal component ( $S_1 = 1.12 \pm 0.04$  mg L<sup>-1</sup>, and  $S_1 = 0.681 \pm 0.04$  mg L<sup>-1</sup> for B1 and B2, respectively). During a semidiurnal tidal cycle, DO was lower at low tide (Fig. 4c, 3.7 mg L<sup>-1</sup> and 4.6 mg L<sup>-1</sup> at B1 and B2, respectively) ~~and higher at high tide (Fig. 4c, 6.0 mg L<sup>-1</sup> and 6.1 mg L<sup>-1</sup> at B1 and B2, respectively). The minimum (1.89 mg L<sup>-1</sup>), and the maximum (7.24 mg L<sup>-1</sup>) DO value were both measured at B1 during low and high tide, respectively (data not shown).~~ During a 24-hours cycle, DO was lower in the early morning (Fig. 4d, 4.0 and 4.3 mg L<sup>-1</sup> at B1 and B2, respectively) and higher in the middle of the day (Fig. 4d, 5.8 and 5.45 mg L<sup>-1</sup> at B1 and B2, respectively). In a single day, we recorded DO fluctuations of up to 6.37 mg L<sup>-1</sup> at R1 and 4.91 mg L<sup>-1</sup> at B2. ~~The minimum DO value, 1.89 mg L<sup>-1</sup>, was measured during low tide, and the maximum DO value, 7.24 mg L<sup>-1</sup>, was measured at B1 during high tide (data not shown).~~ At stations R1 and R2, DO was mainly diurnal ( $S_1 = 1.34 \pm 0.06$  mg L<sup>-1</sup> and  $S_1 = 1.53 \pm 0.09$  mg L<sup>-1</sup> for R1 and R2, respectively) with lower values during the night (Fig. 4d, 5.5 mg L<sup>-1</sup> at both stations), and higher values in the middle of the day (Fig. 4d, 7.8 mg L<sup>-1</sup>, both stations). Simultaneous short-term DO measurements (Fig. 6; Table 1) did not show significant differences over a 24-hours cycle at the inner (St A-G; except for some specific deviations, e.g., St A), the middle (St H-N) or the outer reef (St O-Q). Dissolved oxygen did not change on a vertical gradient at stations R and I, but the bottom DO was significantly lower at station N.

423  
 424 **Figure 6.** Spatial and depth-related short-term measurements (24 h) ~~in-of~~ dissolved oxygen (DO) at stations in the Bouraké  
 425 lagoon (see Figure 1 for the location of the stations). Spatial variations were assessed on (a) the inner reef (St A-G), (b)  
 426 the middle reef (St H-N), and (c) the outer reef (St O-Q). Depth-related variations between shallow reefs and bottom water within  
 427 the Bouraké lagoon were assessed (d) at the inner reef (St R); and (e, f) at the middle reef (St I and N). Tide (black line) refers  
 428 to St B2.

429  
 430  
 431  
 432

433 Salinity (*S*). Salinity was measured only during two short-term periods in winter 2019 and summer 2020 (Fig. 7).

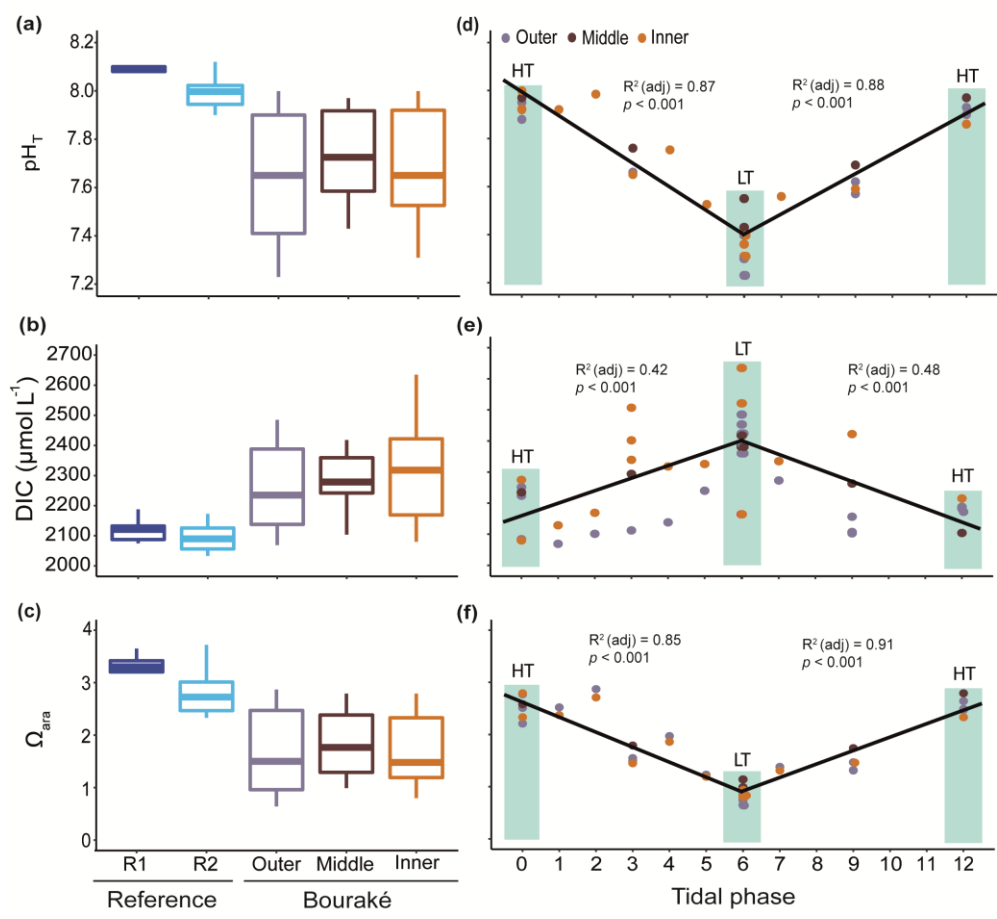

434 **Figure 7.** Short-term salinity monitoring during (a) the winter of 2019 (from 15/07/2019 to 18/07/2019) at the reference (St  
435 R1 and R2) and Bouraké reefs (St B1 and B2); (b) the summer of 2020 (from 29/11/2020 to 04/12/2020) at the reference (St  
436 R1 and R2) and Bouraké reefs (St T and B2). Tide (black line) refers to St B2.  
437

438 ~~Its~~ Salinity variations in the Bouraké lagoon ~~was-were~~ strongly correlated with the tidal cycle, and the highest mean values  
439 were measured during both winter and summer. Salinity was lower at reference reefs ~~during both the winter and summer~~  
440 ~~seasons~~ (Fig. 7a-b). The mean salinity during the winter of 2019 was  $35.49 \pm 0.04$  at R1,  $35.67 \pm 0.10$  at R2,  $36.00 \pm 0.35$  at  
441 B1, and  $36.17 \pm 0.47$  at B2 with significant differences between stations (Tables 1). Salinity in the Bouraké lagoon peaked at  
442 37.22 at B2 during low tide, while it was 35.65 at R1. During the summer of 2020, the mean salinity increased significantly  
443 in the Bouraké lagoon, with  $37.22 \pm 0.53$  at B2, reaching ~~up to~~ 39.37, while it remained lower at R1 with  $35.42 \pm 0.10$  and  
444 ~~at~~ R2 with  $35.71 \pm 0.16$ . ~~In the~~ During summer of 2020, we also measured short-term variations in salinity at station T, which  
445 is outside the Bouraké system. Although its distance from the ~~entrance of the lagoon~~ lagoon entrance, the water mass  
446 discharged during falling tide increased seawater salinity also at this station where we measured a maximum value of 37.33  
447 during low tide.

### 448 3.2 Diel cycles of carbonate chemistry and chemical parameters

449 We monitored diel cycles in June 2017 and July 2019 at two reference reefs and three reefs within the semi-enclosed lagoon  
450 of Bouraké (i.e., the outer, the middle and the inner reefs). The seawater carbonate chemistry differed significantly between  
451 the reference and the Bouraké lagoon reefs (Fig. 8a-c; Supplementary Fig. S1; Tables 1, 2).

452  
 453 **Figure 8.** Seawater carbonate chemistry measured ( $pH_T$ ) and calculated (DIC and  $\Omega_{\text{ara}}$ ) during diel cycles in 2017 and 2019  
 454 (pooled data, see also Supplementary Figure S1) at R1, R2 and the Bouraké reefs (outer, middle and inner) (a-c). Boxes (n =  
 455 6-14) represent the interquartile range (25<sup>th</sup> and 75<sup>th</sup> percentile); the horizontal line is the median, and the whiskers represent  
 456 the data range (i.e., minimum and maximum). Changes are illustrated across a 12-hour tidal phase in the Bouraké lagoon (d-  
 457 f). Linear regression lines are plotted for each falling (HT to LT) and rising tide (LT to HT). Shaded boxes have only a  
 458 graphical significance and only suggest the tide changes during measurements.

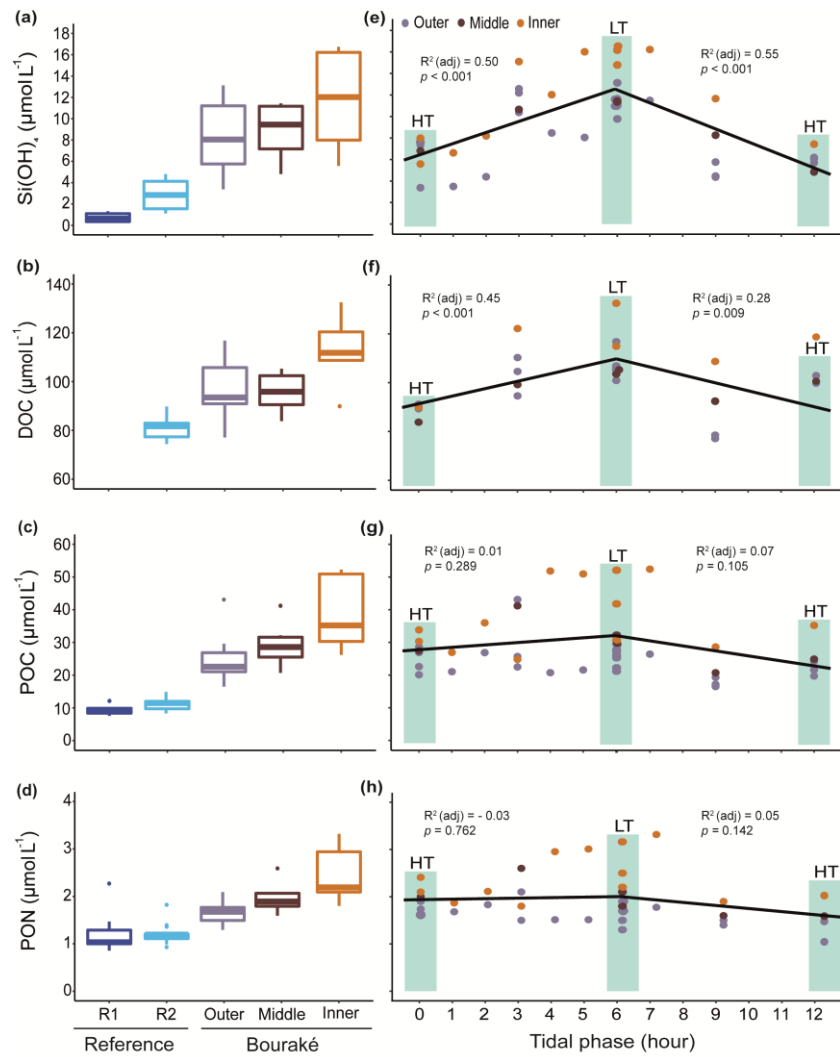

459  
 460  
 461

462 **Table 2.** Summary of the seawater physical and chemical data (mean  $\pm$  SD) measured in July 2017 and June 2019 and calculated  
 463 using the CO<sub>2</sub>SYS package. Data were pooled and averaged per station. nd = not determined. Reference reefs: St R1 and R2;  
 464 Bouraké lagoon stations: outer, middle and inner.

465		R1	R2	Outer	Middle	Inner
467	<i>Measured</i>					
468	Temp (°C)	22.54 $\pm$ 0.31	22.69 $\pm$ 1.50	23.57 $\pm$ 1.31	24.05 $\pm$ 1.20	23.00 $\pm$ 1.46
469	pH <sub>T</sub>	8.09 $\pm$ 0.01	8.02 $\pm$ 0.07	7.66 $\pm$ 0.25	7.73 $\pm$ 0.22	7.68 $\pm$ 0.24
470	DO (mg L <sup>-1</sup> )	7.20 $\pm$ 0.64	6.91 $\pm$ 1.01	6.11 $\pm$ 0.68	nd	5.98 $\pm$ 0.67

489	DOC:TOC	nd	0.87 $\pm$ 0.01	0.80 $\pm$ 0.03	0.77 $\pm$ 0.02	0.78 $\pm$ 0.03
490	Si(OH) <sub>4</sub> :DIN	2.43 $\pm$ 1.31	4.14 $\pm$ 2.18	12.17 $\pm$ 8.99	9.90 $\pm$ 2.10	16.34 $\pm$ 6.38
491	DIN:DIP	0.47 $\pm$ 0.12	4.22 $\pm$ 1.28	nd	4.65 $\pm$ 0.52	2.78 $\pm$ 1.21
492	Si(OH) <sub>4</sub> :DIP	1.11 $\pm$ 0.63	15.11 $\pm$ 6.36	37.01 $\pm$ 17.16	46.79 $\pm$ 14.23	37.51 $\pm$ 24.46

494 The reference reefs R1 and R2 had higher pH, CO<sub>3</sub><sup>2-</sup> and Ω<sub>ara</sub>, and ~~consequently~~ lower DIC and pCO<sub>2</sub> than the outer, middle  
 495 or inner reefs in the Bouraké lagoon. The range of values in the lagoon was similar to our previous measurements (see above),  
 496 with levels of pCO<sub>2</sub> > 2,000 μatm and levels of Ω<sub>ara</sub> < 1. By assigning a tidal phase (from 0 to 12 h) to each sample taken in  
 497 the Bouraké lagoon (all reefs combined), our diel measurements showed significant regressions, either positive or negative,  
 498 depending on the seawater carbonate parameter and the tide phase (Fig. 8d-f; Supplementary Fig. S1; Supplementary Table  
 499 S3). For example, the DIC reached the highest value of 2,635 μmol L<sup>-1</sup> during low tide on the inner reef with an average of  
 500 2,315.1  $\pm$  168.1 μmol L<sup>-1</sup>, while CO<sub>3</sub><sup>2-</sup> reached the lowest value of 50.10 μmol kg<sup>-1</sup> during low tide on the inner reef with an  
 501 average of 109.02  $\pm$  45.59 μmol kg<sup>-1</sup>.

502 Most of ~~the~~ chemical parameters were, in general, more concentrated (up to 5-times) in the Bouraké lagoon than ~~on~~ ~~at~~ the  
 503 reference reefs R1 and R2, and increased from the outer to the inner reef (Fig. 9a-d; Supplementary Fig. S2; Tables 1, 2).

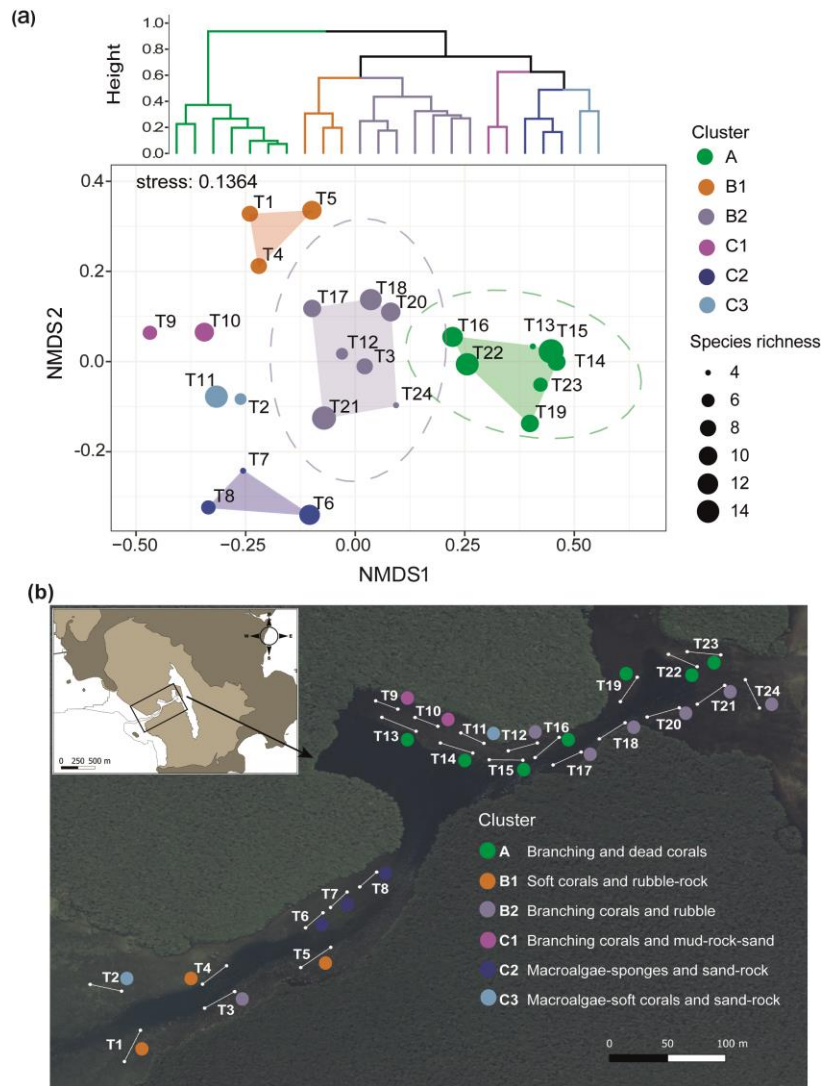

504  
 505 **Figure 9.** Orthosilicic acid, organic carbon and nitrogen parameters measured during diel cycles in 2017 and 2019 (pooled  
 506 data, see also Supplementary Figure S2) at R1, R2 and the Bouraké reefs (outer, middle and inner) (a-d). Boxes (n = 6-14)  
 507 represent the interquartile range (25<sup>th</sup> and 75<sup>th</sup> percentile); the horizontal line is the median, and the whiskers represent the  
 508 data range (i.e., minimum and maximum). Changes are illustrated across a 12-h tidal phase in Bouraké (e-h). Linear regression  
 509 lines are plotted for each falling (HT to LT) and rising tide (LT to HT). Shaded boxes have only a graphical significance and  
 510 only suggest the tide changes during measurements.

511 In addition, despite the Bouraké lagoon receives new seawater during the rising tide, only  $\text{Si(OH)}_4$  had a decent regression  
512 coefficient showing either positive and negative correlation with the falling and the rising tide (Fig. 9e-h; Supplementary Fig.  
513 S2; Supplementary Table S3). It reached the highest value of  $16.74 \mu\text{mol L}^{-1}$  during low tide on the inner reef with an average  
514 of  $11.93 \pm 4.27 \mu\text{mol L}^{-1}$ , and the lowest value of  $3.38 \mu\text{mol L}^{-1}$  during high tide on the outer reef with an average of  $8.22 \pm$   
515  $3.14 \mu\text{mol L}^{-1}$ , 3- to 6-time higher than at the reference stations R2 and R1. The lack of a clear effect of the tide for the other  
516 chemicals causes their accumulation inside the lagoon system. Ratios of organic and inorganic carbon, nitrogen, and nutrients  
517 showed significant differences between the Bouraké lagoon and the reference reefs (Tables 1, 2) with higher average  
518 POC:PON, POC:DOC,  $\text{Si(OH)}_4$ :DIN,  $\text{Si(OH)}_4$ :DIP and DIN:DIP(  $\text{PO}_4^{3-}$ ), and lower average DIC:DIN and DOC:TOC in the  
519 Bouraké lagoon compared to reference reefs.

### 520 3.3 Benthic community distribution and species identification

521 *Benthic community distribution.* The cluster analysis and nMDS allowed grouping the 24 transects in the Bouraké lagoon in  
522 six clusters corresponding to habitat descriptors, namely clusters A, B1, B2, C1, C2, and C3 (Fig. 10a; see Supplementary  
523 Fig. S3 for details of the community descriptors, and Table S4 for transect averaged data). The nMDS produced an exhaustive  
524 representation of the Bouraké lagoon benthic communities and abiotic features (2-dimensional stress = 0.136) confirmed by  
525 ANOSIM (Global R = 0.948,  $p = 0.001$ ). For the benthic community distribution, a clear separation (95% of-confidence  
526 interval represented by the ellipse in Fig. 10a) was found for cluster A and B2, including most of the transects located on the  
527 middle and inner reefs (Fig. 10b).

528  
 529 **Figure 10.** Benthic community and bottom substrate characterization in the Bouraké lagoon. Hierarchical Ward's method  
 530 cluster dendrogram (top) and non-metric multidimensional scaling (nMDS) of abiotic and biotic percent cover and species  
 531 richness per transect (T1-T24) (a). Colored circles represent clusters of transects identified in the dendrogram; circle size  
 532 corresponds to species richness. Ellipses represent 95% confidence intervals. Dominant biotic and abiotic descriptors were  
 533 used to describe the benthic community and bottom substrate for each cluster in (b). The satellite image is from georep New  
 534 Caledonia database (<https://georep.nc/>), and the QGIS software was used for transect georeferencing.

535 For both, branching corals were the dominant biotic descriptor with 81 % and 31 % coverage, respectively) (Supplementary  
 536 Fig. S3), with a maximum of 96 % in cluster A (T23, Supplementary Table S4). Among branching corals, the two most  
 537 abundant genera were *Acropora* and *Montipora* (data not shown). For the abiotic features of the substrate, dead corals and  
 538 rubbles characterized transects in clusters A and B2, respectively. Species richness (Fig. 10a) was high in all transects of the  
 539 Bouraké lagoon, except T13 and T24, both found at the middle and inner reefs' limits. The abiotic substrate of cluster C1 was  
 540 characterized by 66 % mud, 12 % rocks and 10 % sand (see Supplementary Table S4 for detailed cover data per transect).  
 541 Only a few branching corals (<10 %) were found, but species richness was relatively high (6 at T9 and 10 at T10). Cluster C2  
 542 was distinct, which is not surprising due to its location in a relatively shallow convergence zone that divides the lagoon into  
 543 two parts. There, the substrate is made of coarse sand (13 %) and rocks (12 %) and is mainly colonized by macroalgae and  
 544 sponges (31 % and 32 %, respectively). Species richness in the area was heterogeneous and ranged from 4 to 12. *Dictyota*  
 545 spp. and *Halimeda discoidea* were the main macroalgal species, while *Rhabdastrella globostellata* was the dominant sponge  
 546 species in the area. Cluster B1, located on the outer reef, is characterized by an abundance of soft corals (48 %) and rubbles  
 547 (21 %), and high biological richness (Fig. 10a). Cluster C3 is characterized by coarse sand (49 %), rocks (17 %) and a few  
 548 benthic organisms such as macroalgae (10 %) and soft corals (8 %).  
 549 Principal component analysis (PCA) reduced the multicollinearity problem and the first two Principal Components  
 550 accounted for a cumulative 71.2 % of the dataset variance. In particular, the PCA plot (Fig. 11) allowed us to assign the  
 551 transects to three distinct groups depending on their position in the study area.

552  
 553 **Figure 11.** Principal component analysis (PCA) between benthic community (macroalgae, sponges, corals, branching corals  
 554 and massive corals) data and environmental parameters (PON, POC, DOC, Si(OH)<sub>4</sub>, PO<sub>4</sub><sup>3-</sup>, NO<sub>x</sub>, and NH<sub>4</sub><sup>+</sup>) measured for  
 555 each transect (n = 24). The length of the vectors indicates the contribution of each parameter. The first dimension explains  
 556 48.1 % of the variance, and the second dimension explains 23.1 % of the variance. Red dots indicate the transects. Colors  
 557 refer to the cluster subdivision (Fig. 10).

558 The distinction among transects groups in the biplot is clear and they are grouped based on their location in the outer, middle  
559 or inner lagoon reefs. The outer reef sites are characterized by ~~the presence of~~ sponges, macroalgae and soft corals, which  
560 appear to correlate with NOx. Conversely, branching corals are the shared and characteristic feature of the middle and inner  
561 reef sites. ~~However, these two reef groups, however,~~ differ in their major correlation to NH<sub>4</sub><sup>+</sup> for middle reef sites and POC,  
562 DOC, Si(OH)<sub>4</sub>, and PO<sub>4</sub><sup>3-</sup> for the inner sites.

563 *Species identification.* A total of 66 coral species were identified from the Bouraké lagoon (Supplementary Table  
564 S5). Most of the species belong to the family Acroporidae (17 *Acropora* species, 2 *Anacropora* and 4 *Montipora*) and  
565 Merulinidae (15 species). ~~A total of~~ 58 species were identified from the reference reef R2, 29 of which were also found  
566 in the Bouraké lagoon. Overall, the hard coral fauna within the lagoon was characterized by species commonly found around  
567 the Grande Terre, with some of them typically found in turbid coastal environments such as *Pseudosiderastrea tayamai* and  
568 *Heliofungia actiniformis*. They were not encountered at the reference site. Remarkably, two New Caledonia endemic coral  
569 species, ~~namely~~ *Cantharellus noumeae* and *Polycyathus fulvus*, both described from coastal habitats characterized by  
570 terrigenous sediment inputs (Noumea lagoon and Prony Bay, respectively), were common in the innermost reef of the Bouraké  
571 lagoon. The Bouraké lagoon also had 28 species of macroalgae (14 Phaeophyceae, 9 Chlorophyta and 5 Rhodophyta),  
572 including the crustose coralline algae *Lithothamnium* sp., *Lithophyllum* sp., and *Hydrolithon reinboldii*, and 11 sponge species  
573 belonging to eight families of the class Demospongiae (Supplementary Tables S5 and S6), which were found mainly in the  
574 coral matrix and sediment.  
575

## 576 4 Discussion

577 Marginal and extreme natural environments are increasingly used to predict the future of reefs in a changing world (Camp et al., 2018). In these environments, one or the combination of more environmental conditions differ from present-day values, 578 providing an opportunity to assess the resilience of organisms and to study their adaptive mechanisms in a natural 579 environment. Coral reefs, ~~that are~~ exposed to seawater pH and temperature values ~~that are~~ close to or even worse than those 580 expected for the future, have likely developed physiological trade-offs and expressed molecular changes that allow them to 581 survive sub-optimal ~~and extreme, climate-change-like~~ conditions (Kurihara et al., 2021). When using these natural 582 laboratories to predict species responses to future environmental conditions, it is essential to ~~assess~~ take a multi-scale approach 583 that incorporates the spatial and temporal variability of the key physical and chemical parameters characterizing the study site 584 (e.g., Vizzini et al., 2013; Camp et al., 2018; Aiuppa et al., 2021). ~~In this study~~ Here, we mapped the spatial and temporal 585 variability of these physical ~~and~~ chemical parameters in the semi-enclosed lagoon of Bouraké, which is likely one of the most 586 suitable natural laboratories ~~known to date~~ to study the adaptation of corals to the combination of acidification, warming and 587 deoxygenation (Camp et al., 2017). There, we found an unprecedented number of benthic species, including two New 588 Caledonia endemics, thriving under chronic suboptimal conditions that fluctuate with the tide. While the exact mechanism/s 589 explaining their resilience remains to be discovered, our study provides a compelling basis and fundamental baseline for using 590 this site as a natural laboratory to investigate species' responses to a combination of stresses in their natural environment. 591

### 592 4.1 Physical and chemical characteristics of the Bouraké lagoon

593 The Bouraké lagoon covers an estimated area of *ca.* 20 ha that penetrates a mangrove forest, large enough to assess the 594 combined effects of extreme environmental conditions on an established coral reef ecosystem. Our multi-scale approach 595 confirmed previous findings (Camp et al., 2017), showing that the Bouraké lagoon is hottest (ranging from ~~17.57 – 33.83~~ 596 °C), deoxygenated (ranging from 1.87–7.24 mg L<sup>-1</sup>), and acid (ranging from 7.23–7.92 pHT units) when compared to 597 neighboring reefs. Besides, we found that salinity was significantly higher than at the reference reefs ~~in during~~ both winter 598 and summer (with maxima of 37.22 and 39.37, respectively). ~~Although corals seem to possess cellular mechanisms to~~ 599 ~~counteract short-term osmotic changes (Mayfield and Gates, 2007), high and fluctuating salinity is possible additional stress~~ 600 ~~that corals living in the Bouraké lagoon have to face daily, adding up to the already long list of suboptimal environmental~~ 601 ~~parameters. Further experiments are needed to assess the effect of high and fluctuating salinity on their physiology.~~

602 We found several marked differences in the environmental conditions between the Bouraké lagoon and the reference reefs, 603 both in the absolute range, and in the variability of the measured environmental parameters.

604 First, the seawater temperature is higher in summer in the Bouraké lagoon (Fig. 3), but it is also colder during winter, 605 ~~occasionally more than 25 °C~~ resulting in an annual temperature range of 17.5-33.8 °C. ~~When we compared~~ temperatures 606 recorded at Bouraké lagoon to those of the reference St R2, which showed the most typical temperature range for shallow 607 water temperatures in the south of New Caledonia (i.e., 22–28 °C, (Varillon et al., 2021); ~~We~~ notice that in Bouraké, 608 temperatures were 40% of the time above 28 °C during the summer of 2020, while winter temperatures were on average 46.5 609 % of the time lower than 22 °C. While warming is considered the main threat for coral reefs, low temperatures (< 20 °C) can 610 cause coral bleaching by inducing responses similar to high temperatures, including a reduction in the *Symbiodiniaceae* cell 611 density and chlorophyll *a* content (e.g., Saxby et al., 2003; Hoegh-Guldberg and Fine, 2004; Hoegh-Guldberg et al., 2005; 612 Kemp et al., 2011; (Bellworthy and Fine, 2021). The negative effect of cold temperatures is even more substantial during

613 neap tides when colonies on the reef crest are exposed to air for hours at low temperatures during cold winters. For example,  
614 Porter et al. (1982) and Davis (1982) reported > 90 % coral mortality in shallow (< 2 m) reefs of the Dry Tortugas following  
615 the winter of 1976–1977 when temperatures reached 14 °C. This is consistent with our observations (data not shown) during  
616 the cold winter of 2019 when we found that the upper 12–20 cm of several massive and branching corals had died.  
617 Second, in the Bouraké lagoon, benthic assemblages are continuously exposed to ~~suboptimal-large~~ fluctuations in the main  
618 environmental parameters, ~~toward sub-optimal values, and~~ Some of these environmental fluctuations are entirely predictable.  
619 For instance, marine organisms are exposed to a temperature fluctuation of about twice the reference reefs' amplitude (up to  
620 6.5 °C vs 3.5 °C) in a single day. Dissolved oxygen fluctuations were similar between stations but in a significantly different  
621 range: 3.7 to 6.8 mg L<sup>-1</sup> at B2 and 5.4 to 7.8 mg L<sup>-1</sup> at the reference stations. According to the organisms tolerance to DO  
622 fluctuation, which is quite unknown in corals, low DO concentrations can change fish tidal migration in the mangrove (Dubuc  
623 et al., 2019). Besides, our tidal modelling revealed that, at the reference reefs, pH, DO (Fig. 4), and temperatures (data not  
624 shown) slightly increased in the afternoon and decreased during the night. This finding agrees with what should be expected  
625 from reef metabolic activities and daily cycles but, in the Bouraké lagoon, these parameters, including salinity (Fig. 7), are  
626 entirely driven by tides. Here, seawater pH and DO varied between extremely low values at low tide and close-to-normal  
627 values during high tide (see also Fig. 8a-c for pH). Finally, we found that the timing of the tide was out of phase between  
628 sites, with a delay of about 45 minutes at high tide and 1.5 h at low tide in the Bouraké lagoon (Fig. 2).

629 The unique environmental conditions measured in the Bouraké lagoon are ~~mainly due~~linked to ~~the its unique~~ topographical  
630 and geomorphological characteristics, ~~of this unique site~~, the resulting water circulation and the direction of the tide. New  
631 water from the lagoon enters through the channel at each rising tide and flows into the semi-enclosed lagoon towards the large  
632 mangrove area behind it. This water originally initially had ambient values of pH, temperature and dissolved oxygen, but,  
633 during the trip, it mixes with the acidic, warm and deoxygenated water in the system and the mangrove area, therefore  
634 gradually changing from its original values. AtInside the mangrove areaforest, we hypothesize that the water chemistry further  
635 changes due to the metabolic reactions in the sediments, coral reefs and mangrove roots (e.g., (Alongi et al., 2004); (Bouillon  
636 et al., 2007); (Gleeson et al., 2013); (Call et al., 2015)). Conversely, on a falling tide, the seawater becomes gradually more  
637 acidic, hot and oxygen-depleted because the water that resided in the mangrove area gradually drains out of the system. This  
638 takes about 6 hours, during which the vast reservoir of shallow mangrove water continues to be chemically altered, becoming  
639 increasingly acidic, oxygen-depleted and hot. As a result, we measured significant spatial differences in pH between the outer  
640 reef (the entry of the lagoon) and the inner reef (near the mangrove forest), as well as a considerable delay in the  
641 synchronization of the tidal shift (Fig. 5b). Interestingly, because the volume of seawater discharged in 6 hours is so large, it  
642 affects also the area outside the system where we measured similar seawater conditions as inside, even if it mixes with the  
643 main lagoon's water (see Fig. 5c, St U vs St T). It means that the area (and the organisms) affected by the suboptimal  
644 parameters is larger than previously thought. ~~It is likely that~~ the species living in this area have likely developed specific  
645 mechanisms to withstand the very fluctuating environmental conditions, and as such, they warrant further attention.

646 ~~It could be argued that because~~Since the fluctuations are linked to tidal phases, ~~it could be argued that~~ organisms living in the  
647 Bouraké lagoon may benefit from periods of normal conditions at high tide, during which they can recover from the stress  
648 they have experienced at low tide (e.g., (Rivest et al., 2017)). While this could be partially the case for species living on the  
649 outer reef, close to the main lagoon, the environmental conditions inside the Bouraké lagoon rarely reach normal values (Fig.  
650 8a-c), and also persist longer since as the low tide is delayed by 1.5 h compared to the reference reef (Fig. 2).

651 Preliminary results from a hydrodynamic model of the study site ~~also~~ suggest that tide-associated water mass movements are  
652 spatially heterogeneous and likely to play an essential role in shaping coral resilience to extreme conditions (see discussion  
653 below). Indeed, one can imagine a single water mass moving with the same physical characteristics from the mangrove area  
654 towards the outer reefs or in the opposite direction depending on the tide. However, the complex geomorphology of the  
655 Bouraké lagoon, its bottom topography and the complex web of coral reefs and mangrove trees on the edges deviate and  
656 probably change the seawater physical and chemical properties. We measured significant spatial differences in pH within  
657 each reef area (inner, middle and outer reefs; Fig. 5a, b), as well as throughout the water column (i.e., between the surface  
658 and the bottom; Fig. 5d,e). In general, bottom seawater was 0.1-0.2 pH<sub>T</sub> units lower than the surface, probably due to a  
659 pumping mechanism by the water mass of more acidic pore water from the sediments. The pH also differed spatially within  
660 the inner reef, by up to 0.3 pH<sub>T</sub> units (for instance St. A vs St. C; Fig. 5a), perhaps due to the influence of stagnant water on  
661 the mangrove edges of the mangrove or a more intense metabolic activity by the local benthic community. Dissolved oxygen  
662 concentrations between the surface and the bottom were only significantly different on at St. N on the middle reef (Fig. 6f),  
663 and only at St. N. This station, which is mainly characterized by mud as the current there is lower than anywhere else in the  
664 Bouraké lagoon. Here, the sediment's biological activity possibly traps the oxygen making it less available to the water  
665 column.

666 We can assume that, throughout the Bouraké lagoon, organisms are exposed to extreme and fluctuating suboptimal physical  
667 parameters, such as pH, and DO which are more pronounced on the bottom and last longer, and with more extreme values,  
668 on the inner reefs. It is also true for some of the seawater chemistry-chemical parameters we measured, which with show  
669 higher concentrations in the Bouraké lagoon than on the reference reefs (see Table 2). For instance, we found that orthosilicic  
670 acid, phosphate, dissolved and particulate organic carbon, and particulate organic nitrogen were 1.4 to 4.2-fold more  
671 concentrated on the inner reef than at station R2. Within the Bouraké lagoon in general, chemicals increased from the outer  
672 to the inner reef, and with the exception of except for [NO<sub>x</sub>], [NH<sub>4</sub>]<sup>+</sup>, [PO<sub>4</sub>]<sup>3-</sup>, they never return to “normal” values despite the  
673 Bouraké system receives new seawater during the rising tide. The high concentrations in orthosilicic acid and organic  
674 compounds, both dissolved and particulate are due to the combined effect of more acidic and organic-rich water coming out  
675 of the mangrove forest during a falling tide (Fig. 9) and the particular-system's particular morphology, of the system which  
676 limitslimiting the full-complete renewal of the seawater-renew, especially at the inner reefs.

#### 677 4.2 Effects of physical and chemical conditions on species distribution

678 Extreme environmental conditions, such as those measured in the Bouraké lagoon, are known to strongly affect the  
679 metabolism, growth and even survival of several marine organisms, particularly those that-tolerating only a narrow range of  
680 environmental changes are commonly-considered-stenotopic-like-such as scleractinian corals (e.g., Coles and Jokiel, 1977;  
681 Hoegh-Guldberg and Smith, 1989; Hoegh-Guldberg, 1999; Fitt et al., 2001). For instance, *in situ* studies at volcanic CO<sub>2</sub>  
682 seeps have shown that chronic exposure to ocean acidification (near-future pCO<sub>2</sub> levels) can cause a reduction in coral  
683 diversity and lower the-lower recruitment and abundances of structurally complex hermatypic corals. Moreover, shifts in  
684 competitive interactions between taxa and a decrease in cover and richness of soft corals and sponges were also observed  
685 (e.g., Fabricius et al., 2011; Enochs et al., 2015; Sunday et al., 2017; Agostini et al., 2018; Teixidó et al., 2018). However,  
686 the Bouraké lagoon features high coral, sponge, macroalgae and CCA cover and species richness, adding at the check-list  
687 proposed by Camp et al., (2017) an additional 46 coral species (totaling 66 species and 33 genera), 283 species of macroalgae

Mis en forme : Centré

688 and 11 species of sponges (Supplementary Table S5). Such a high number of species has never been reported for mangrove  
689 systems characterized by marginal conditions, at least ~~with regard to~~ concerning the three major benthic groups taxa  
690 investigated here (e.g., Yates et al., 2014; Camp et al., 2019). In general, given the extensive literature demonstrating the  
691 negative effects of suboptimal abiotic conditions on corals, our findings are unexpected and suggest that corals in the Bouraké  
692 lagoon may have developed unique survival and adaptive mechanisms. Some studies have reported similar findings, but none  
693 has ever reported such ~~a~~ high coral species diversity (e.g., Yates et al., 2014; Schoepf et al., 2015; Shamberger et al., 2018;  
694 Camp et al., 2019). For instance, in Palau (Micronesia), the highest coral cover (> 60%) and species diversity (21 scleractinian  
695 genera) were found at the lowest pH study site of the Nikko Bay station (Barkley et al., 2015). Studies in the Virgin Islands'  
696 mangrove system have reported over 30 coral species growing in marginal conditions (Yates et al., 2014; Rogers, 2017).  
697 Similarly, in a recent study of two Australian mangrove lagoons, ~~both~~ characterized by relatively extreme environmental  
698 conditions (low pH, low oxygen and high temperature), Camp et al., (2019) identified 12 and 29 scleractinian coral species  
699 in the Woody Isles and at Howick Island, respectively. Among the 66 species we identified, ~~a total of~~ 29 of the most abundant  
700 coral species in New Caledonia ~~are shared between~~ were found at both the reference reef and in the Bouraké lagoon, indicating  
701 that species living at our study site are not very different ~~than~~ from a typical bay-sheltered fringing reef. There is not an  
702 apparent selection in the coral form; since massive (e.g., *Porites* spp.), corymbose (e.g., *Pocillopora digitata*), phaceloid  
703 (*Galaxea fascicularis*) and branching (*Acropora* spp.) species are equally abundant, as well as in their thermal and pH  
704 tolerance. Further experiments are underway at both the molecular and phenotypic level to better understand the mechanisms  
705 of resilience used by the corals from Bouraké.

706 Remarkably, the two coral species, currently considered New Caledonia endemics, thrive in the innermost benthic  
707 assemblages of the Bouraké lagoon, making it not only a unique natural laboratory ~~but also as well as~~ a potential conservation  
708 priority site ~~in light of its overall uniqueness characterized in this study~~. In the Bouraké lagoon, benthos species richness was  
709 very high throughout the system and the distribution of branching and massive corals was spatially heterogeneous (Fig. 10b;  
710 Supplementary Fig. S3). Coral cover decreased near the mangrove, where the accumulation of fine sediments and exposure  
711 to air during low tide do not allow corals' survival, ~~but the percent cover reached up to 90 % on the reef margin~~ (Supplementary  
712 Fig. S3). Branching corals were particularly abundant on the inner and middle reefs, ~~with the highest cover of 96 % in the~~  
713 ~~inner reef (T23, Supplementary Table S4)~~. They became sparse on the outer reef, even absent at the system's entrance where  
714 soft and massive corals dominated. Macroalgae and sponges, including CCA (data not shown), were quite cryptic throughout  
715 the Bouraké lagoon; but found almost everywhere ~~both~~ in the coral matrix and buried in the sediment. They are particularly  
716 abundant ~~only~~ in a shallow area that divides the lagoon into two parts (transects T6-T8). There, a Venturi effect generates a  
717 strong current, and the substrate ~~is made~~ consists of coarse sand and rocks. ~~T~~ Both the high flow and the bottom characteristics  
718 ~~are both~~ likely to promote macroalgae and sponge occurrences (averaged 30 % and 32 % cover, respectively). There, ~~the~~  
719 sponge *Rhabdastrella globostellata* is particularly abundant (up to 40 % cover) and forms massive banks embedding adjacent  
720 coral colonies. In general, macroalgae and sponges diversity ~~was~~ is not particularly rich, with ~~respectively~~ only 28 and 11  
721 species ~~have been detected, respectively~~, likely due to the sampling method. However, ~~sponge diversity~~, in the Indo-pacific  
722 mangrove systems, ~~sponge diversity is~~, in general, is not extremely high, especially if compared to the Caribbean (Nagelkerken  
723 et al., 2008). Few studies are available from Indo-Pacific mangrove sponges. ~~T~~ and the highest diversity was reported in a  
724 study in the mangrove of Banka Island (North Sulawesi, Indonesia), where 19 species ~~of sponges~~ were found (Calcinai et al.,

725 2017). Our findings on mangrove sponges in such a unique mangrove area in New Caledonia ~~improve-add to~~ the limited  
726 knowledge ~~on-the-of~~ sponge species diversity in Pacific mangrove systems.

727 Water flow may play a critical role in the response of organisms to acidification (Cornwall et al., 2014; Hurd, 2015; Comeau  
728 et al., 2019), warming (Schoepf et al., 2018) and deoxygenation (Hughes et al., 2020). It has been reported to affect the  
729 diffusion boundary layer (i.e., a thin layer of stagnant water located around aquatic organisms) of corals, CCA and other  
730 calcareous macroalgae, altering their ability to calcify at low pH and to excrete metabolic wastes (reviewed in Nelson and  
731 Altieri, 2019). Knowing that flow speed could play a ~~key-critical~~ role ~~which-and that~~ deserves further investigations and  
732 measurements at the study site, we found two hypotheses to explain the high diversity of the Bouraké species and their  
733 resilience to suboptimal parameters: i) the species may benefit from the constant fluctuations of the ~~physio-chemical~~physical  
734 and chemical parameters, ii) the species may benefit from heterotrophic inputs of the mangrove (in term of nutrients and  
735 organic matter).

736 ~~With regards to~~Regarding environmental fluctuations, we measured averaged daily variations in temperature, DO, and pH of  
737 about 3.79 °C, 3.80 mg L<sup>-1</sup>, and 0.63 pHT units, respectively. ~~The (Temperature changed-offluctuated by~~ up to 6.55 °C ~~on-in~~  
738 a single day. Frequent exposure to stressful temperatures can induce acclimatization or adaptation in corals if the period of  
739 exposure is short enough to avoid mortality (Oliver and Palumbi, 2011; Palumbi et al., 2014; Schoepf et al., 2015; Rivest et  
740 al., 2017; Safaie et al., 2018). For example, in the Kimberly region (Australia), corals regularly exposed to temperatures up  
741 to 37 °C<sub>s</sub> with daily variations of up to 7 °C<sub>s</sub> appear less prone to bleaching and grow and calcify at rates comparable to ~~these~~  
742 corals in more thermally stable environments (Dandan et al., 2015; Schoepf et al., 2015; 2020). ~~However, although~~ they are  
743 not immune to extreme heat stress events (Le Nohaïc et al., 2017). Another example is the corals in the back reef and shallow  
744 pools around the island of Ofu (American Samoa), which despite occasional daily fluctuations of up to 6 °C, and an average  
745 daily temperature of 29 °C in summer (Piniak and Brown, 2009; Oliver and Palumbi, 2011) sustain reasonable levels of coral  
746 cover (25--26 %) and high diversity (Craig et al., 2001). Some studies tend to indicate that corals depended on the *a priori*  
747 'frontloading' of genes involved in heat resistance in the coral host and/or the host's ability to adjust its physiology during  
748 short-term (weeks) environmental changes (Barshis et al., 2013; Palumbi et al., 2014). However, physiological adjustments  
749 have an energetic cost that corals cannot sustain in the long term, affecting other metabolic functions such as calcification. It  
750 could explain in part the lower calcification rates observed in some coral species, as seems to be the case for corals in the  
751 Bouraké lagoon (e.g., Camp et al., 2017). There is also evidence that exposure to short-term oscillations in low pH, alone or  
752 in combination with high temperature, can mitigate the impact of extreme environmental stressors on corals (Warner et al.,  
753 1996; Oliver and Palumbi, 2011; Dufault et al., 2012; Schoepf et al., 2015; Safaie et al., 2018). Species in the Bouraké lagoon  
754 appear to be thriving despite ~~With regard to~~ the large seawater pH variability (up to 0.6 pHT units). ~~variability, species in the~~  
755 Bouraké lagoon appear to be thriving. In general, species exposed to pCO<sub>2</sub> fluctuations above 500 µatm in their natural  
756 environment display enhanced plasticity to future ocean acidification scenarios (Vargas et al., 2017; Carstensen and Duarte,  
757 2019). For example, fluctuations in pH could increase CCA tolerance to ocean acidification by providing respite periods at  
758 ambient low-pH (Rivest et al., 2017), during which organisms can calcify at a standard rate, compensating for decreased  
759 calcification during periods of lower pH (Comeau et al., 2013; Cornwall et al., 2018). Diurnal variability in pH, typical of  
760 more variable pH habitats, may confer tolerance to resident calcifying species via the selection of individuals better adapted  
761 to survive in these environments (Rivest et al., 2017; Kapsenberg and Cyronak, 2019), although transgenerational  
762 acclimatization is required (Cornwall et al., 2020).

763 In addition to changes in temperature and pH, which are the two most commonly tested environmental parameters, oxygen  
764 must also be considered. ~~Although-Despite~~ the impact of reduced oxygen levels and its natural fluctuations on coral reefs ~~have~~  
765 ~~has~~ yet to be established, ~~it appears that~~ low DO (2-4 mg L<sup>-1</sup>) ~~seems to increase~~ the sensitivity of branching corals, resulting  
766 in a decline in coral health, bleaching, and tissue loss (Haas et al., 2014; Hughes et al., 2020; Alderdice et al., 2021). ~~However,~~  
767 ~~o~~Our study shows that although the Bouraké system can reach conditions close to hypoxia ~~for several coral species~~ (< 3 mg  
768 L<sup>-1</sup>; Fig. 4), ~~species-these latter~~ seem to have promoted compensation mechanisms that allow them to survive in these  
769 conditions. The natural laboratory of Bouraké, where DO fluctuates with the tide, in combination with other environmental  
770 stressors, offers a perfect setting to test the practically unknown effects of deoxygenation ~~and hypoxia thresholds~~ in reef-  
771 building corals exposed to acid and hot conditions (Nelson and Altieri, 2019; Hughes et al., 2020).  
772 ~~A~~Although corals ~~seem appear to~~ possess cellular mechanisms to counteract short-term osmotic changes (Mayfield and Gates,  
773 2007), high and fluctuating salinity is possible additional stress that corals living in the Bouraké lagoon have to face daily,  
774 adding up to the already long list of suboptimal environmental parameters. ~~In situ studies have demonstrated that acute acute,~~  
775 ~~rapid and prolonged changes decrease in salinity can induce coral death (e.g., (Jokiel et al., 1993). Such death is attributed to~~  
776 ~~the effects of salinity on the affect the coral photosynthesis of zooxanthellae efficiency, resulting in a reduction of the amount~~  
777 ~~of energy transferred to corals (Muthiga and Szmant, 1987), (Manzello and Lirman, 2003), and induce coral death (e.g., Jokiel~~  
778 ~~et al., 1993). The response of corals to a change in salinity is related to the strength and duration of the hypo-hypersaline~~  
779 ~~exposure and the species tolerance considered. For example, Stylophora pistillata seems able to acclimate more effectively to~~  
780 ~~hypo- rather than to hyper-saline conditions (Ferrier-Pagès et al., 1999). Further experiments are needed to assess the effect~~  
781 ~~of high and fluctuating salinity on the coralstheir physiology of corals in Bouraké.~~  
782 Besides the hypothesis that environmental variability improves the metabolism of organisms, particularly their resilience to  
783 extreme conditions, a series of other physical (e.g., current flow) and chemical parameters (e.g., organic matter) in the Bouraké  
784 lagoon may work in combination to offset or enhance these effects. Mangrove habitats are highly productive ecosystems and  
785 are sites of intense carbon processing, with a high potential impact on the global carbon budget (e.g., Borges et al., 2003;  
786 Dittmar et al., 2006; Bouillon et al., 2014). In the Bouraké lagoon, benthic communities might have access to a range of  
787 heterotrophic inputs, nutrients, carbon, and nitrogen sources. These sources can be metabolized by the species to increase  
788 their energy budget and cope with the suboptimal parameters, but they can also become toxic, if too concentrated, or depleted,  
789 leading to functional limitations. We measured ~~particularly exceptionally~~ high concentrations of organic and inorganic carbon  
790 and nitrogen, but also of some nutrients, notably silicates and phosphorus, and we confirmed the potential contribution of the  
791 mangrove in those inputs, especially during the falling tide (Fig. 8 and 9; Supplementary Fig. S1 and S2; Table 2). We found  
792 that dissolved organic carbon contributes significantly to the TOC pool (POC+DOC), with ~~an increasing~~ concentration  
793 ~~increase~~ between the reference sites and the Bouraké lagoon, reaching maximum values on the inner reef. High organic matter  
794 content can increase DOC availability to corals, providing the ~~with~~-sustainable energy to withstand extreme environmental  
795 conditions (Levas et al., 2015). Some studies showed that the high organic matter of turbid reefs can support elevated coral  
796 heterotrophy that can facilitate energy maintenance during periods of stress (Anthony and Fabricius, 2000).  
797 We also found that nutrients could partially explain the distribution of organisms throughout the Bouraké lagoon (Fig. 11).  
798 Indeed, NO<sub>x</sub> concentrations were higher on the outer reef, dominated by sponges, macroalgae and soft corals, while NH<sub>4</sub><sup>+</sup> was  
799 high on the middle reef and POC, DOC, Si(OH)<sub>4</sub>, and PO<sub>4</sub><sup>3-</sup> were higher on the inner reef. Both the middle and inner reefs are  
800 characterized by the highest branching coral cover. Nitrates can accumulate inside the host cells, ~~which could be in favor~~

801 ~~of possibly favoring~~ sponges and macroalgae, while ammonium is the preferred source used by coral symbionts (Raven et al.,  
802 1992). ~~While it is not obvious to demonstrate experimentally~~ However, the nutrient negative or positive effect on corals'  
803 physiology ~~is difficult to demonstrate experimentally~~ (Atkinson et al., 1995; Szmant, 2002; Bongiorni et al., 2003). Van De  
804 Waal et al., (2009) have shown that the performance of organisms ~~does not only depends~~ on concentrations ~~of, and, but also~~  
805 ~~on the~~ ratios between, different nutrients, and between organic and inorganic matter/components and the possible imbalance  
806 due to environmental changes. We found that the Bouraké lagoon is mostly N-limited (DIN:DIP < 10 and Si(OH)<sub>4</sub>:DIN > 1),  
807 which confirms the findings of Justić et al. (1995) and is similar to the conditions observed in other New Caledonian  
808 mangroves (Jacquet et al., 2006). ~~On the other hand, it~~ Nutrients limitation has been ~~experimentally~~ demonstrated ~~that nutrient~~  
809 ~~limitation to~~ lowers the temperature effect at which coral bleaching occurs (Wiedenmann et al., 2013; Ezzat et al., 2016a;  
810 2019), which ~~is in contrast with to~~ the ~~resilience of~~ Bouraké coral's ~~resilience~~ to the warming ~~of in the~~ summer ~~of~~ 2016 (10-  
811 20 % bleaching only) compared to other reefs in New Caledonia (up to 90 % bleaching) (Benzoni et al., 2017). Corals  
812 symbionts recycle their host's metabolic wastes and take up dissolved inorganic nitrogen (DIN) and phosphorus (DIP) from  
813 seawater (Grover et al., 2003; Pernice et al., 2012; Rosset et al., 2015), both of which are used to produce vital organic  
814 molecules. Nutrient starvation can occur when the availability of one type of essential nutrient decreases, resulting in an  
815 imbalanced N:P ratio of inorganic nutrients in seawater (Wiedenmann et al., 2013; D'Angelo and Wiedenmann, 2014). Based  
816 on our measurements, the N:P ratio in the Bouraké lagoon was 2.8:1 and 4.6:1 ~~on at~~ the middle and the reference reefs,  
817 respectively, which is lower than the range calculated for average reef waters of 4.3:1 to 7.2:1 (Crossland et al., 1984, Furnas  
818 et al., 1995). Although these data should be considered ~~with caution~~ cautiously, they suggest that the Bouraké lagoon seawater  
819 is not limited in phosphorus, ~~a key an essential~~ nutrient in coral resilience to bleaching (Ezzat et al., 2016b; Rosset et al., 2017).  
820 Seawater in the Bouraké lagoon was not limited in Si (Si(OH)<sub>4</sub>:DIP > 10 and Si(OH)<sub>4</sub>:DIN > 1; (Justić et al., 1995), and Si  
821 was six times more abundant on the inner reef than elsewhere in the system (Fig. 9; Table 2). Silicates are an important source  
822 of nutrition and skeletal construction for primary producers such as sponges. Orthosilicic acid is a biologically available form  
823 of silicon that is poorly soluble at a very low pH. In the Bouraké lagoon, pH fluctuates with the tide, and ~~it one~~ can ~~be expected~~  
824 that orthosilicic acid would rise during ~~the~~ falling tide. This elevated concentration of orthosilicic acid could be involved in  
825 the growth and persistence of the Bouraké large banks of *Rhabdastrella globostellata*, as previously reported for other sponges  
826 in the shallow hydrothermal vents in the Pacific Ocean (Maldonado et al., 1999; Cárdenas and Rapp, 2013; Bertolino et al.,  
827 2017).

828 We are still missing information about light, turbidity, current, bacteria biomass, ~~and~~ phytoplankton sources as well as other  
829 biological communities ~~(e.g., fish)~~ to fully understand this complex and dynamic system and the functioning of ~~its coral~~  
830 ~~community~~ ~~this complex and dynamic coral ecosystem~~. However, ~~we our data already recognize demonstrate~~ the Bouraké  
831 lagoon's uniqueness as a natural laboratory for studying the adaptive responses of corals and other reef species to the  
832 combination of multiple suboptimal environmental parameters, which are, ~~to some extent, similar to or perhaps~~ worse than  
833 those projected for the future. Our investigations indicate that the geomorphology of this unique site has not changed for the  
834 last 80 to 100 years, ~~probably certainly~~ longer. With this in mind, we assume that, ~~at least in the previous century, the situation~~  
835 ~~is similar for~~ environmental conditions ~~remained unchanged~~, and ~~that~~ the corals of the Bouraké lagoon have experienced the  
836 current extreme conditions for several generations. Most importantly, the species found in the Bouraké lagoon are not unique  
837 to the mangrove habitat; ~~T~~ they are common throughout New Caledonia ~~as well as in and~~ the SW Pacific region, suggesting  
838 that they have used specific strategies to cope with the suboptimal environmental conditions.

Mis en forme : Anglais (États-Unis)

Mis en forme : Centré

839 We are also unsure how the different parameters will fluctuate at bay-sheltered reefs over time and under future climate  
840 change conditions and if the variability measured in the Bouraké lagoon is representative of the natural fluctuations expected  
841 for coastal habitats in the future. Indeed, earth system model simulations, which are ~~mostly-mainly~~ based on open-ocean  
842 system models, project that the seasonal amplitude ~~for of~~ pH and  $p\text{CO}_2$  ~~in the future climate~~ will increase by 81 % ~~in the~~  
843 ~~future climate~~ (Kwiatkowski and Orr, 2018). ~~Projections also indicate that and~~ ocean acidity extremes will be more frequent  
844 (Burger et al., 2020), which could mean that future diel pH variability will increase even more at sites with the most significant  
845 variability today. The situation could be similar for seawater temperature, a parameter that is already high in Bouraké, and  
846 likely close to the coral's thermal tolerance threshold. If this were to happen in the following decades, the is the ease, coral  
847 reef ~~in of~~ Bouraké ~~will-would~~ face ~~in the next decades~~ ~~incredibly~~ harsh environmental conditions since physical and  
848 biogeochemical parameters measured ~~in during~~ this study already exceed future climatic simulations.

849

## 850 5 Conclusion

851 We used a multi-scale approach to characterize the physical and chemical environmental parameters of one of the most  
852 ~~suitable-realistic~~ natural ~~analogue-laboratory~~ for ~~extremefuture~~ environmental conditions, the semi-enclosed lagoon of  
853 Bouraké (New Caledonia), and accurately map its benthic community for the first time. We studied several ~~physico-~~  
854 ~~chemiea~~~~physical and chemical~~ parameters such as pH, dissolved oxygen, temperature, and salinity, but also nutrients and  
855 organic matter, and we found that: i) they fluctuate between low and high tides, ranging from suboptimal-extreme to near  
856 normal values; ii) although predictable according to the tide, they differed spatially, and iii) suboptimal values persisted longer  
857 and were more acute on the inner reef. Our data clearly show that fluctuations are: i) predictable, at least for some (~~pH, DO,~~  
858 ~~temperature and salinity~~) of the physical parameters for which we have enough data (~~i.e., pH, DO, temperature and salinity~~);  
859 ii) mainly driven by the tide; and iii) that seawater nutrient imbalance and organic inputs increase during the falling tide and  
860 originate from the mangrove forest and associated sediments. Although several studies suggest that ocean acidification,  
861 warming and, to some extent, deoxygenation will lead to a reduction in biodiversity, increase in bleaching and reef dissolution,  
862 in the Bouraké lagoon, we found ~~a rich and~~ healthy reef with high coral cover and species richness, but also sponges and  
863 macroalgae (including CCA). It was beyond the scope of this ~~already multidisciplinary~~ study to assess the contribution of  
864 environmental variability and nutrient imbalance to the organism' stress tolerance under extreme conditions. However, both  
865 coexist in the Bouraké lagoon, and we believe there is evidence of their contribution to the survival of organisms ~~to-in future-~~  
866 ~~like-extreme~~ environmental conditions. Our study provides evidence that this is possible in ~~existing~~ natural ~~habitatse~~, giving  
867 a glimmer of hope for the future of coral reefs. Further experiments are needed to reveal the mechanisms involved in the  
868 organisms' resilience to such conditions ~~and the potential role of this unique site as a refuge for organisms threatened by~~  
869 ~~climate change~~~~future extreme conditions~~. ~~However~~~~Finally~~, we ~~also~~ provides the compelling basis for using this site as a  
870 natural laboratory and ~~to-better~~ study ~~better~~ the multitude of complex stressors acting together on life-long adapted coral reefs.  
871

872 *Author contribution.* R.R.-M. conceived and designed the project with input from F.M. for the benthic community distribution  
873 study. F.M. and R.R.M. collected the data. F.B., C.P., C.C. and B.C. identified the corals, macroalgae and sponges,  
874 respectively. M.P.-P. performed all the chemical analyses. F.M. conducted the data analysis with the help of J.A. and R.R.-M.  
875 F.M. drafted the manuscript in collaboration with R.R.-M. All co-authors read and edited the final version of the manuscript.

877 *Competing interests.* The authors declare that they have no conflict of interest.

878 *Acknowledgements.* This study was supported by the French grant scheme Fonds Pacifiques (n. 1976; project SuperCoraux)  
879 and data were collected during the SuperNatural 1 & 2 cruises on board R/V Alis (Flotte Océanographique Française  
880 <https://doi.org/10.17600/17003400>). Funds for that were awarded to R.R.-M. We wish to express our thanks to captains of  
881 the IRD vessels and the diving technical staff for their fieldwork assistance. Thanks to the LAMA laboratory~~yies~~ (IRD,  
882 Nouméa) ~~and LOMIC laboratory (Banyuls sur mer, France)~~ for the analysis and use of their instruments and facilities. F.M.  
883 ~~was granted~~~~received a by the University of New Caledonia for her~~ PhD fellowship (project REEF-ENGINE) ~~from the~~  
884 ~~University of New Caledonia~~. Thanks also to the "Province Sud" for samples collection permits (n. 3413-2019).
