Abstract. The rewetting of drained peatlands supports long-term nutrient removal in addition to reducing emissions of carbon dioxide (CO_2) and nitrous oxide (N_2O). However, rewetting may lead to short-term nutrient leaching into adjacent water and high methane (CH_4) emissions. The consequences of rewetting with brackish water on nutrient and greenhouse gas (GHG) fluxes remain unclear, although beneficial effects such as lower CH_4 emissions seem likely. Therefore, we studied the actively induced rewetting of a coastal peatland with brackish water, by comparing pre- and post-rewetting data from the peatland and the adjacent bay.

Both the potential transport of nutrients into adjacent coastal water and the shift of GHG fluxes (CO_2, CH_4, N_2O) accompanying the change from drained to inundated conditions were analyzed based on measurements of the surface water concentrations of nutrients (dissolved inorganic nitrogen (DIN), phosphate (PO_4^{3-})), oxygen (O_2), components of the CO_2 system, CH_4, and N_2O together with manual closed-chamber measurements of GHG fluxes.

Our results revealed higher nutrient concentrations in the rewetted peatland than in the adjacent bay, indicating that nutrients leached out of the peat and were exported to the bay. A comparison of DIN concentrations of the bay with those of an unaffected reference station showed a significant increase after rewetting. The maximum estimated nutrient export out of the peatland was calculated to be 33.8 ± 9.6 t yr^{-1} for DIN-N and 0.24 ± 0.29 t yr^{-1} for PO_4-P, depending on the endmember (bay vs. reference station).

The peatland was also a source of GHG in the first year after rewetting. However, the spatial and temporal variability decreased and high CH_4 emissions, as reported for freshwater rewetting, did not occur. CO_2 fluxes decreased slightly from 0.29 ± 0.82 g m^{-2} h^{-1} (pre-rewetting) to 0.26 ± 0.29 g m^{-2} h^{-1} (post-rewetting). The availability of organic matter (OM) and dissolved nutrients were likely the most important drivers of continued CO_2 production. Pre-rewetting CH_4 fluxes ranged from 0.13 ± 1.01 mg m^{-2} h^{-1} (drained land site) to 11.4 ± 37.5 mg m^{-2} h^{-1} (ditch). After rewetting, CH_4 fluxes

Summary of Comments on Blank

Page: 1

on the formerly dry land increased by 1 order of magnitude (1.74 ± 7.59 mg m^{-2} h^{-1}), whereas fluxes from the former ditch decreased to 8.5 ± 26.9 mg m^{-2} h^{-1}. These comparatively low CH$_4$ fluxes can likely be attributed to the suppression of methanogenesis by the available O$_2$ and sulfate, which serve as alternative electron acceptors. The post-rewetting N$_2$O flux was low, with an annual mean of 0.02 ± 0.07 mg m^{-2} h^{-1}.

Our results suggest that rewetted coastal peatlands could account for high, currently unmonitored nutrient inputs into adjacent coastal water, at least on a short time scale such as a few years. However, rewetting with brackish water may decrease GHG emissions and might be favored over freshwater rewetting in order to reduce CH$_4$ emissions.

1.   Introduction

Pristine peatlands are natural sinks for nutrients, in particular nitrate (NO$_3^-$), and greenhouse gases (GHG) such as carbon dioxide (CO$_2$) and nitrous oxide (N$_2$O) (Strack, 2008; Kaat and Joosten, 2009). Globally, peatlands store up to 550 Gt of carbon (C), which is twice the C stock of total forest biomass (Moore et al., 1998; Joosten and Clarke, 2002; Kaat and Joosten, 2009).

The drainage of peatlands leads to the mineralization of the topmost peat layer and the accumulation of nutrients (Cabezas et al., 2012). After rewetting, peatlands can therefore be sources of nutrients, especially ammonium (NH$_4^+$) and phosphate (PO$_4^{3-}$) (Lamers et al., 2002; Cabezas et al., 2012; Duhamel et al., 2017). Conversely, due to the anoxic conditions in the water-saturated peat, rewetted peatlands can also act as nutrient sinks, mainly for NO$_3^-$ (Fisher and Acreman, 2004). Whether rewetting leads to nutrient release or uptake is, besides other factors, controlled by the degree of peat decomposition (Zak and Gelbrecht, 2007; Cabezas et al., 2012), the water level (Duhamel et al., 2017) and the salinity (Liu and Lennartz, 2019). Nutrient release is highest in strongly degraded peat in formerly drained peatlands (Zak and Gelbrecht, 2007; Cabezas et al., 2012). Therefore, removal of the topsoil before rewetting has been recommended as a measure to greatly reduce the release of PO$_4^{3-}$ and nitrogen (N) (Harpenslager et al., 2015; Zak et al., 2017). However, nutrient release from peat after rewetting has mostly been assessed in laboratory and incubation studies. To our knowledge, field data on nutrient leaching and potential exports to adjacent waters are lacking.

The GHG exchange of peatlands is strongly influenced by the prevailing biogeochemical and physical conditions, which in turn are largely determined by vegetation and the water level and thus the ratio of oxic and anoxic conditions (Kaat and Joosten, 2009). In drained peatlands, the low water table enables the aerobic decomposition of peat, which is accompanied by increased CO$_2$ emissions (Joosten and Clarke, 2002). In rewetted peatlands, CO$_2$ emissions are regulated by photosynthesis, decomposition, and temperature within the upper oxygen-rich soil layer and the overlying water column (Parish, 2008; Oertel et al., 2016). In the anoxic water-saturated zones, the formerly oxygen-induced decomposition of organic matter (OM) is slowed and relies on alternative terminal electron acceptors (TEAs) such as NO$_3^-$, manganese (Mn^{4+}), iron (Fe^{3+}), and sulfate (SO$_4^{2-}$), leading to lowered CO$_2$ emissions (Strack, 2008; Dean et al., 2018). However,

please provide some primary references for these claims, at least in relation to N2O

Number: 6 Author: au30574   Subject: Sticky Note   Date: 04-12-2022 11:00:45
I don't think this lab study on rewetting fen peat is a valid primary reference for the claim. Further, in relation to the next sentence, where the same paper is cited, it also
seems the paper finds that "...Under all scenarios considered in this study, fen rewetting was
shown to be a valid strategy to recover the function of fens as DN sinks." Please be sure to include proper references that support the arguments presented

methanogenesis, as the last step in the mineralization of OM and a depletion of TEAs, may become more important in anoxic zones.

65   Methane (CH_4) emissions in drained peatlands are virtually negligible at water levels < 20 cm below the surface (Jurasinski et al., 2016). Although CH_4 is formed in anoxic zones via methanogenesis, most of it is oxidized as it passes through the oxic soil layer (Kaat and Joosten, 2009; Dean et al., 2018). Consequently, drained peatlands are a minor source of atmospheric CH_4. In rewetted peatlands, CH_4 is microbially produced in water-saturated, anoxic soil layers mainly by archaea, when all other TEAs are depleted (Schönheit et al., 1982; Oremland, 1988; Segers and Kengen, 1998), so rewetted

70 peatlands are often significant sources of CH_4 (Hahn et al., 2015). However, in coastal peatlands that receive marine water and therefore SO_4^{2-}, the contribution of methanogenesis might be reduced, as methanogenic archaea are outcompeted by sulfate-reducing bacteria (SRB) (Bartlett et al., 1987; Capone and Kiene, 1988; Oremland, 1988; Jørgensen, 2006). Additionally, any CH_4 produced may be oxidized by anaerobic methane oxidation coupled to SO_4^{2-} reduction (e.g. Boetius et al., 2000).

75   N_2O is an intermediate in microbial processes, mostly nitrification, denitrification and nitrifier-denitrification (Kool et al., 2011). In degraded peatlands, all of these processes are fueled by the accumulated nutrients. Drained peatlands can be weak (Martikainen et al., 1993) or strong sources of N_2O (Liu et al., 2019), depending mainly on the climate zone and land use (Petersen et al., 2012; Leppelt et al., 2014). Rewetted, and thus water-saturated, peat usually acts as N_2O sink over long-term scales, due to the formation of anoxic zones where N_2O is consumed (Strack, 2008). However, rewetting can increase

80 the N_2O production and thus its release into the atmosphere due to the high nutrient availability in strongly degraded peat, which enables higher rates of nitrification and denitrification (Moseman-Valtierra et al., 2011; Chmura et al., 2016; Roughan et al., 2018).

        In temperate latitudes, coastal peatlands are widespread at the interface between marine and terrestrial ecosystems. However, for many coastal peatlands, the sinking of their ground level due to degradation and peat shrinkage over decades

85 has made them vulnerable to rising sea level and sinking coasts (Jurasinski et al., 2018). In Mecklenburg-Vorpommern (northeastern Germany), currently drained coastal peatlands along the low-lying coastline cover an area of ~360–400 km² (Bockholt, 1985; Holz et al., 1996). Nowadays, peatlands are rewetted to restore their habitat function and biodiversity, thereby preventing CO_2 and N_2O emissions and, in the long-term, reestablishing their C- and N-storage capacity (Strack, 2008; Zielinski et al., 2018).

90   Coastal drained peatlands may be rewetted in different ways depending on the available water source. The rewetting can consist of permanent flooding with freshwater (from groundwater or rivers), episodical inundations with brackish water and permanent brackish water flooding. While the effects of freshwater rewetting (Richert et al., 2000; Hogan et al., 2004; Zak and Gelbrecht, 2007) and episodical inundations with brackish water on nutrient dynamics and GHG have been investigated (Chmura et al., 2011; Neubauer et al., 2013; Hahn et al., 2015; Koebsch et al., 2019), less is known about the

95 impact of permanent brackish water flooding.

Number: 1   Author: au30574   Subject: Sticky Note   Date: 04-12-2022 11:11:13

but anaerobic mineralization leads to release of N as NH4+, which may not be oxidized to NO3- under anoxic condition. Thus not supporting denitrification. Please, consider your clain in the light of the IPCC default EF for N2O emission from rewetted organic soils

In this study we examined the immediate effects of rewetting with brackish water on nutrient (NO_3^-, nitrite (NO_2^-), NH_4^+ and PO_4^{3-}) and GHG fluxes (CO_2, CH_4, N_2O) in a low-lying, highly degraded coastal peatland at the German Baltic Sea coast, by comparing pre- and post-rewetting conditions. Due to the unique formation of a permanent brackish water column above formerly drained peat, this is the first study to combine marine shallow-water and terrestrial peatland research.

100 We investigated how the rewetting with brackish water affects (1) nutrient leaching and the potential transport from a nutrient-enriched, flooded peatland to the adjacent bay driven by frequent water exchange, (2) the GHG dynamics in the surface water within the first year after rewetting and (3) the GHG fluxes along the transition from drained to inundated conditions.

2.   Material and methods

105 ### 2.1   Study area

The study area is a low-lying, highly degraded coastal peatland that had been transformed from a drained, agriculturally used polder to a brackish wetland. The "Polder Drammendorf" (referred to in the following as "peatland") is located at the northeastern German Baltic Sea coast, on the western part of the island of Rügen (Mecklenburg-Vorpommern, Germany), bordering on the Kubitzer Bodden (Figure 1). The climate is oceanic, with a mean annual air temperature of 9.1 °C and a

110 mean annual precipitation height of 626 mm (Deutscher Wetterdienst (DWD), 1991–2020). The central Kubitzer Bodden has a mean surface water temperature of 11.4 ± 6.6 °C and a mean surface salinity of 8.5 ± 4 (referred to in the following as "central bay", data retrieved from a monitoring station of the Landesamt für Umwelt, Naturschutz und Geologie Mecklenburg Vorpommern (LUNG MV), 2006–2020, 54.40° N, 13.11° E, Figure 1b). For comparison, the Arkona Basin, a near-by open Baltic Sea basin, has a mean surface water temperature of 10.2 ± 5.6 °C and a mean surface salinity of

115 8.0 ± 0.5 (MARNET, data originator: Leibniz Institute for Baltic Sea Research Warnemünde, Germany, 2006–2020, 54.88° N, 13.86° E).

consider if the reader needs this info?

Figure 1. (a) Overview of the study area located in the southern Baltic Sea. (b) Coastline of northeast Germany in Mecklenburg-Vorpommern and study area location ("*Polder Drammendorf*", red) on the island of Rügen, bordering on the Kubitzer Bodden, where a monitoring station served as reference ("central bay", purple). Data retrieved from IEA, NOAA.

Like most peatlands in northern Germany, Drammendorf was artificially drained for agricultural use (pasture and grassland) in the 1960s, by establishing a sandy dike and an extensive ditch system that affected an area of 2.2 km². The northwestern part (mostly mineral soil, higher elevation) served as grassland while the northeastern part was used for agriculture with seasonal fertilizer application only until the 1990s (10 t N m^{-2} yr^{-1}). The southern compartment (organic soil) provided an area for cattle grazing (~30 cows). The topsoil of the central part consists of up to 50–70 cm highly degraded peat (Brisch, 2015), classified as H7 according to the von Post humification scale (Wang et al., 2021). This highly degraded topsoil layer was not removed prior to rewetting. Underneath the degraded topsoil follows a well-preserved peat layer with a thickness of ~100 cm. Peat deposits of up to 220 cm thickness are largest in the western part, near the former dike. The long-lasting drainage and ongoing peat degradation have led to the formation of a local land depression with an average soil elevation of around −0.5 meters above sea level (masl). To control the water expansion after rewetting, a new dike was built in the southern part before flooding (Figure 2a). Additionally, a drainage ditch that receives water from the catchment was rebuilt and a new pumping station was installed. A significant input of nutrients from this additional water supply can be excluded due to the low pumping activity and the absence of a permanent hydrological connection to the study area (Wasser- und Bodenverband Rügen (WBV), pers. comm., 2020).

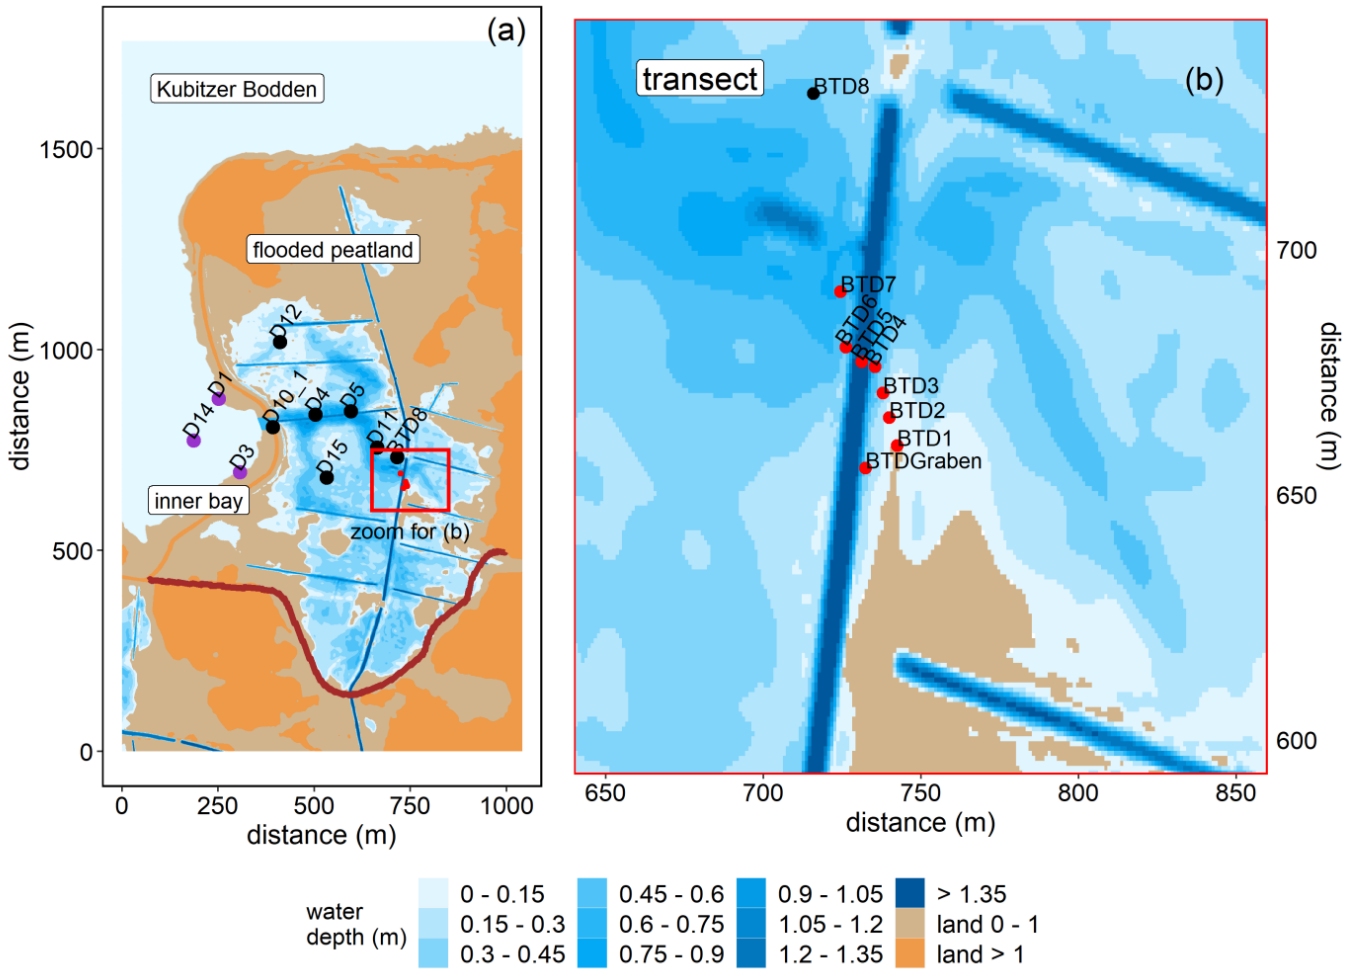
I guess most readers are used to see this as 100 kg N ha-1 yr-1; but that is up to you


Figure 2. Topography of the study area and overview of the stations in the inner bay (purple), the flooded peatland (black) and along the transect of the GHG flux measurements (red). (a) Water coverage at mean sea level. The new dike is shown in dark red. (b) Transect stations that were sampled for atmospheric chamber-based GHG flux measurements (before and after rewetting) and for surface water GHG concentration measurements (after rewetting). Data from station BTD7 were used for a comparison of the chamber-based measurements with the calculated air-sea fluxes after rewetting. Topography data retrieved from LfGVK, LAiV MV.

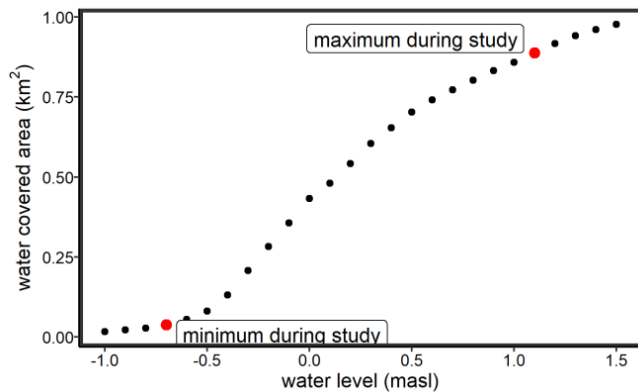
The area was rewetted by the targeted removal of a 20 m wide dike section in November 2019 that caused an immediate flooding of the low-lying area behind the dike. The newly built channel represents the only permanent hydrological connection between the peatland and the Kubitzer Bodden that allows major surface water exchange. The remaining section of the dike (~650 m) was removed down to the surface elevation level and is hence only flooded at very high water levels.

The restored area covers ~0.8 km^2 in total and is characterized by a permanently water-covered area of ~0.5 km^2, with a mean water depth of ~0.5 m, compared to 1.0–1.5 m in the Kubitzer Bodden. The extent of the inundated area depends directly on the water level of the Baltic Sea, which is highly dynamic despite the absence of regular tides (Figure A1). Therefore, minor changes in the water level lead to major changes in the water-covered area. For instance, if the water level rises from −0.5 to + 0.5 masl, the water-covered area increases from 0.08 to 0.7 km^2 (Figure 3, Figure A2). The ditch

Number: 1 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 11:26:51
write out the source

150 system was only partly removed and hence, some deeper areas with water depths of up to 4 m remained. It is noteworthy that in the first months after rewetting, former grassland and ditch vegetation (*Elymus repens* L. (Gould) (Couch grass), *Phragmites australis* (Cav.) Trin. ex Steud. (Common reed)) died almost completely and the cover of emergent macrophytes was then negligible. However, Phragmites was able to grow back during the growing season and expanded especially around the ditches.


155

Figure 3. Hypsographic curve of the study area, in increments of 0.1 m. The red dots represent the observed range of the water level during the study. For a water level time series during the sampling period, see Figure A1.

2.2 Sampling

2.2.1 Surface water sampling

160 Before rewetting, surface water samples for nutrients (NO_3^-, NO_2^-, NH_4^+, PO_4^{3-}) and chlorophyll a were collected from the inner Kubitzer Bodden (referred to in the following as "inner bay") at station D1 (Figure 2a) and irregularly at a second station right in front of the now removed dike section, which was abandoned after rewetting and therefore merged with station D1. Both stations were reached from land and sampling was conducted monthly from June to November 2019, except in August.

165 After rewetting, surface water samples were collected with a small boat and the sampled variables were extended for the concentrations of GHGs (CO_2, CH_4, N_2O) and dissolved organic carbon (DOC). The first sampling took place one week after the dike removal. Sampling was continued over one year (25 sampling dates until December 2020) at weekly (December 2019 to January 2020) or biweekly (February 2020 to September 2020, except for August) intervals. From October 2020 to December 2020, sampling was conducted monthly. In the inner bay, three stations (D1, D3, D14), and in the

170 flooded peatland six stations (D4, D5, D11, D12, D15, BTD8) were sampled (Figure 2a). The inner bay station "D14" was sampled from March 2020 onwards. DOC sampling started in April 2020. For the air-sea gas exchange calculation, data from station D10_1, located in the channel, were also included.

Number: 1 Author: au30574   Subject: Sticky Note   Date: 04-12-2022 11:32:23
This fig. should just be shown in the supplement

Moreover, surface water samples for the analysis of GHG concentrations (CO_2, CH_4, N_2O) were sampled at eight stations along a transect (Figure 2b). This sampling was carried out simultaneously with the sampling described in Sect. 175 2.2.2 to link GHG air-sea exchange calculations based on surface water samples with chamber-based flux measurements.

Surface water temperature, dissolved oxygen (O_2), and salinity were measured directly in the field using a HACH HQ40D multimeter (HACH Lange GmbH, Germany) equipped with two outdoor electrodes (LDO10105, CDC40105). Depending on the prevailing water depth, additional measurements were conducted in the peatland 15 cm above the soil surface (excluding the ditches) on 22 of the 25 sampling dates. The precision of the electrodes was ± 0.3 °C, ± 0.8 %, and 180 $\boxed{1}$ 0.1 for temperature, O_2 saturation, and salinity, respectively.

Surface water samples were taken using a horizontal 7 L Niskin bottle to sample the upper 20 cm of the water column. These included 250 mL subsamples for CH_4/N_2O analysis (bottles capped with butyl rubber stoppers and crimp-sealed), analysis of the CO_2 system (one bottle each for total CO_2 (C_T), total alkalinity (A_T), and pH) and 15 mL subsamples for the analysis of nutrients and DOC. Water for chlorophyll a determination was taken using 3 L canisters.

185 In the laboratory, CH_4/N_2O and CO_2 samples were poisoned with 500 µL and 200 µL of saturated $HgCl_2$, respectively, and stored in the dark at 4°C until analysis. Subsamples for nutrients and DOC were filtered in the field with pre-combusted (450 °C for 4 h) 0.7 µm glass-fiber filters (GF/F, Whatman®) and stored at −20 °C. Samples for chlorophyll a were filtered in the laboratory with non-combusted 0.7 µm glass-fiber filters (GF/F, Whatman®) and likewise stored at −20 °C.

190 2.2.2   Chamber-based atmospheric GHG flux sampling for CO_2 and CH_4

Starting in June 2019, nearly 6 months before rewetting, GHG exchange was regularly measured using dynamic closed chambers (Livingston and Hutchinson, 1995) along a transect representing a soil humidity gradient (Figure 2b). The measurements were conducted twice a month, for a total of 11 sampling days at six peatland stations and two additional stations in the north-south-oriented main ditch. Each station was sampled up to eight times per sampling day, resulting in 195 overall 418 CO_2 and 184 CH_4 pre-rewetting flux measurements.

For each measurement, the chambers were placed on permanently installed collars and connected through an air-tight seal, with a closure period between 180 and 300 s. To ensure coverage of photosynthetic and respiration activity, CO_2 measurements were conducted using opaque and transparent chamber to cover a broad spectrum of solar radiation, two additional measurements were conducted with cloth-covered transparent chambers, resulting in a reduced photosynthetically 200 active photon flux density (PPFD). Changes in GHG concentrations in the chamber headspace were measured using a portable laser-based analyzer (Picarro G4301, GasScouter, Santa Clara, USA; LI-820, LI-COR Biosciences, Lincoln, USA and an Ultraportable Greenhouse Gas Analyzer (UGGA), Los Gatos Research Inc., Mountain View, Calif., USA).

After rewetting, the stations along the transect covered a gradient of ground elevations, including stations that fell dry at low water levels and stations that remained permanently flooded. Atmospheric GHG fluxes were measured twice a 205 month using floating opaque chambers placed on the water surface above the same sampling locations of the flooded

Number: 1 Author: au30574 Subject: Comment on Text Date: 04-12-2022 11:35:03
units

Number: 2 Author: au30574 Subject: Sticky Note Date: 04-12-2022 11:46:01
please give some few more details on this. It should be made clear for readers, e.g., how you vented chambers back to atm CO2 between consecutive measurements. As you should mention that you measure Reco and NEE

peatland. Since the flooding caused most plants to die, and almost all measurement locations were covered by water during the study period, we skipped the NEE [1] measurements with transparent chambers. Approximately six measurements per station were made during 23 sampling days between December 2019 and December 2020, with a total of 698 CO_2 and 482 CH_4 fluxes determined during the post-rewetting year.

2.3 Data processing, statistics, and definition of seasons and means

Data analysis and visualization were performed using R (R Core Team, 2020) and the packages *tidyverse* (Wickham et al., 2019), *lubridate* (Grolemund and Wickham, 2011), *patchwork* (Pedersen, 2020) *car* (Fox and Weisberg, 2019), and *flux* (Jurasinski et al., 2014). The relationships between environmental variables, nutrient concentrations, and GHG concentrations/fluxes were investigated in linear regression analyses. The significance level was set to $p < 0.05$.

To describe temporal patterns during the entire sampling period, we defined two pre- and four post-rewetting periods, roughly [2]kin to seasons (Table 1). For a direct comparison between the pre- and post-rewetting periods, we compared nutrient and GHG flux data from summer and autumn 2019 with those from summer and autumn 2020 (Table 3) by using the Mann-Whitney-U test.

Table 1. Defined seasons of the investigation period

	Pre-rewetting		Post-rewetting			
season	summer 2019	autumn 2019	winter 2019/2020	spring 2020	summer 2020	autumn 2020
months	June–August	September–November	December–February	March–May	June–August	September–December

We analyzed the data of the peatland and the inner bay stations, [3]respectively, in order to verify the use of means for each sampling site and date. The difference between spatial (sampling stations) and temporal (sampling seasons) data variability was tested by using a Two-Way ANOVA and showed a higher temporal variability ($p < 0.05$). Therefore, we decided to [4]combine the stations of the peatland and the inner bay, respectively, to report mean values and standard deviations (single values can be found in the published data set). The Two-Way ANOVA was also used to identify seasonal differences between the peatland and the inner bay (Table 2).

At station D3, in the inner bay, the pH, CH_4, and pCO_2 values differed significantly from those of the remaining stations of the inner bay during the year after rewetting (ANOVA, Kruskal-Wallis [5]test). Since the differences in water temperature, salinity, and O_2 were not significant, we decided to include the data [6] from D3 for these variables to obtain a larger data pool for the inner bay and to exclude D3 for all other variables.

not clear. the use of 'respectively' does not make the sentence clear. please rewrite, so it is clear whether you merge data across each site, but not across peatland and inner bay

Number: 5 Author: au30574   Subject: Sticky Note   Date: 04-12-2022 13:47:09
this seems as a somewhat selective data handling. I think it would be more consistent to either exclude or include the site. At least you should argue that the former variables (pH, CH4 and PCO2) are related to biological activity which may vary although the more more physically influenced variables (temp, salinity and O2) are rather constant

2.4 Nutrients (NO_3^-, NO_2^-, NH_4^+, PO_4^{3-}), chlorophyll a and DOC

2.4.1 Analysis

Nutrient analyses were carried out according to standard photometric methods (Grasshoff et al., 2009) by using a continuous segmented flow analyzer (SEAL Analytical QuAAtro, SEAL Analytical GmbH, Norderstedt, Germany). Detection limits

235   were 0.2 µmol L^{-1} for NO_3^-, 0.05 µmol L^{-1} for NO_2^-, 0.5 µmol L^{-1} for NH_4^+ and 0.1 µmol L^{-1} for PO_4^{3-}. Measurements of the nutrient concentrations were partly below the detection limit for the peatland, the inner bay and the central bay (flagged in the published dataset). For example, for measurements below detection limit, it is recommended to use the actual values of these measurements (e.g. Fiedler et al., 2022) to achieve a robust statistical analysis. Since these data were not available, we decided to use randomly generated values between 0 and the respective detection limit with a uniform distribution for these

240   measurements.

Chlorophyll a was extracted from glass-fiber filters (GF/F, Whatman®) by incubation with 96 % ethanol for 3 h and afterwards analyzed by using a fluorometer (TURNER 10-AU-005, Turner Designs, San José, USA) at 670 nm after Edler (1979). DOC was analyzed after high-temperature combustion using a Multi 2100S instrument (Analytik Jena GmbH, Jena, Germany) and detected by non-dispersive infrared spectrometry after ISO 20236, ISO 8245 and EN 1484.

245   ### 2.4.2 Use of reference data from a monitoring station

Coastal nutrient data (NO_3^-, NO_2^-, NH_4^+ and PO_4^{3-} concentrations) from a monitoring station in the Kubitzer Bodden ("central bay", Figure 1b) ~15 km away from the study area were obtained as reference. Monitoring data from 2016 to 2020 were included. In detail, these data were used (1) to compare them with nutrient concentrations from the inner bay before and after rewetting to detect potentially higher concentrations, resulting from nutrient leaching within the peatland and a

250   subsequent export into the inner bay and (2) to calculate the total possible export out of the peatland (Sect. 2.4.3) by using the monitoring station as a second, unaffected endmember besides the inner bay, which is by contrast potentially affected by the rewetting. Due to transformations and potential losses along the way to the monitoring station, especially of the nitrogen species, the calculated total possible export has to be considered as maximum estimate.

2.4.3 Nutrient transport calculation (DIN-N and PO$_4$-P)

255   To calculate the bulk exchanges of dissolved inorganic nitrogen (DIN-N) and PO_4-P between the flooded peatland and the inner bay/central bay, the water level was transformed to water volume by creating a hypsographic curve with increments of 0.1 m and a resolution of 1x1 m (Figure 3). Water level data from a nearby monitoring station ("Barhöft", 54.43° N, 13.03° E) and topography data with a resolution of 1x1 m were obtained from the Wasserstraßen- und Schifffahrtsamt Ostsee (WSA) and the Landesamt für innere Verwaltung MV, respectively. To ensure that the water level data of the

260   monitoring station were valid for the peatland, the water level data of the latter, measured between August and December

estimates

2020, were compared with the data from the monitoring station, which showed a strong correlation ($r_S = 0.95$, $p < 0.001$, 15-min intervals, data not shown).

A water level of -1.6 masl, as the lowest recorded water level within the last 25 years, was used as the starting point to derive the cumulative water volumes of the peatland. The water volumes were then assigned to the corresponding water levels to finally calculate the water volume changes (Q, in $m^3\ s^{-1}$) according to Eq. (1):

$$Q(t) = \frac{dV}{dt} \tag{1}$$

where V is the water volume and t the time. Positive volume changes ($Q > 0$) indicate an inflow of water into the peatland and *vice versa*. For each season, the mean inflow (Q_{in}) and outflow (Q_{out}) volumes were calculated according to Eqs. (2) and (3):

$$Qin = \frac{1}{\Delta T} \int_{t}^{t+\Delta T} Q^{positive} dt \quad for\ Q > 0 \tag{2}$$

$$Qout = \frac{1}{\Delta T} \int_{t}^{t+\Delta T} Q^{negative} dt \quad for\ Q < 0 \tag{3}$$

where ΔT denotes the season length. Note that Q_{out} is negative. Seasonal mean values of nutrient concentrations (DIN and PO_4^{3-}) were calculated and converted from $\mu mol\ L^{-1}$ to $kg\ m^{-3}$ by using the molecular masses of the basic elements N and P to derive DIN-N and PO_4-P. After the conversion, nutrient masses of the peatland ($c_{peatland}$) and the inner bay (c_{IB}) vs. peatland and central bay (c_{CB}), respectively, were multiplied by Q_{out} and Q_{in} and integrated to calculate the net nutrient transport (NNT, in tonnes) according to Eqs. (4) and (5):

$$NNT = \int_{t}^{t+\Delta T} Q_{in}\, c_{IB}\, dt + \int_{t}^{t+\Delta T} Q_{out}\, c_{peatland}\, dt \tag{4}$$

$$NNT = \int_{t}^{t+\Delta T} Q_{in}\, c_{CB}\, dt + \int_{t}^{t+\Delta T} Q_{out}\, c_{peatland}\, dt \tag{5}$$

Negative values indicate a net nutrient export from the peatland into the inner/central bay, and positive values display a net nutrient import into the peatland. Uncertainty ranges for the seasonal NNTs (u_{NNT}, as 95 % confidence level) were calculated as standard errors (SE) by using an error propagation according to Eq. (6):

$$u_{NNT} = \sqrt{\left(c_{bay}\, dt\, u_{Qin}\right)^2 + \left(c_{peat}\, dt\, u_{Qout}\right)^2 + \left(Q_{out}\, dt\, u_{cpeat}\right)^2 + \left(Q_{in}\, dt\, u_{cbay}\right)^2} \tag{6}$$

where terms with "u" denote the respective SE as 95 % confidence level. To gain the annual SE of the NNT, all seasonal SE were added up.

2.5 GHG concentrations and fluxes

2.5.1 Inorganic carbon system analysis

Directly measured variables (C_T, A_T, pH)

Number: 1 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 13:57:28
rather use: Mg

Number: 2 Author: au30574   Subject: Inserted Text   Date: 04-12-2022 13:58:51
derive

The inorganic carbon system was determined by analyzing the total CO_2 (C_T), total alkalinity (A_T), and pH of the water samples. C_T was measured with an automated infrared inorganic carbon analyzer (AIRICA, S/N #027, Marianda, Kiel, Germany). The system acidifies a discrete sample volume (phosphoric acid, 10 %), whereby the inorganic carbon species of C_T are shifted to $CO_{2(g)}$. A carrier gas stream (99.999 % N_2) transfers the gaseous components to a Peltier device and a Nafion® drying tube (Perma Pure Nafion®, Ansyco GmbH, Karlsruhe, Germany) to remove water residues. The produced $CO_{2(g)}$ is detected by an infrared detector (LICOR 7000; LI-COR Environmental GmbH, Bad Homburg, Germany). Certified reference materials (CRM; Scripps Institution of Oceanography, University of California, San Diego, USA) were used for calibration. Triplicate measurements were conducted for each sample, and a precision of ± 5 µmol kg^{-1} was achieved.

A_T was measured by potentiometric titration (glass electrode type LL Electrode plus 6.0262.100, Metrohm, Filderstadt, Germany) in the open-cell configuration, after Dickson et al. (2007). The system was calibrated with the same CRM as used for C_T and resulted in the same precision.

The pH was analyzed spectrophotometrically using the pH-sensitive indicator dye m-cresol purple (mCP, 2 mmol L^{-1}, Contros System and Solution GmbH, Kiel, Germany). The measurement principle and instrumental setup are described elsewhere (Dickson et al., 2007; Carter et al., 2013). In brief, absorption was measured using the Agilent 8453 UV-visible spectroscopy system (Agilent Technology, Waldbronn, Germany); pH parameterization for brackish water was calculated following Müller and Rehder (2018). Quality control was performed by measuring buffer solutions (salinity of 20) prepared according to Müller et al. (2018). An external buffer solution with a salinity of 35 (Scripps Institution of Oceanography, University of California, San Diego, USA) was additionally used. All pH values are reported given on the total scale (pH_T).

Calculated variables

The CO_2 partial pressure in the water phase (pCO_2), the value of which was required for the CO_2 air-water flux calculations (Sect. 2.5.3), was calculated from C_T and pH using the R packages *seacarb* (Gattuso et al., 2019), with K_1 and K_2 from Millero (2010), K_s from Dickson (1990), and K_f from Dickson and Riley (1979). C_T and pH were preferred because non-oceanic components, in particularly organic acid-base systems, contribute significantly to A_T (Kuliński et al., 2014). A_T was also calculated from C_T and pH and the values compared with measured values, thus revealing the magnitude of the contributions of those components to A_T.

2.5.2 Dissolved CH$_4$ and N$_2$O concentration analysis

Dissolved CH_4 and N_2O concentrations were determined by gas chromatography on an Agilent 7890B instrument (Agilent Technologies, Santa Clara, USA) coupled to a flame ionization detector (FID) and an electron capture detector (ECD). A purge and trap technique, explained in detail in Sabbaghzadeh et al. (2021) was used. In brief, a helium gas stream was used to purge 10 mL of seawater to extract volatile compounds. The gas stream passed through a purifier (VICI Valco Instruments Co. Inc., Houston, USA) and was dried using a Nafion® tube (Perma Pure Nafion®, Ansyco GmbH, Karlsruhe, Germany) and a SICAPENT® tube (Merck KGaA, Darmstdt, Germany). The relevant compounds were enriched by cryofocusing on a

permil, I guess

use units for salinity throughout

trap filled with HayeSep D® (CS Chromatographie Service GmbH, Langerwehe, Germany) maintained at −120 °C using an ethanol/nitrogen cooling bath. After 10 minutes of heating in a 95 °C water bath, the compounds were desorbed and separated by two capillary columns linked to the detectors by a Deans Switch (Pönisch, 2018).

For quality control, a calibration standard (gas composition: 1.9379 ppm CH_4 (± 0.0159 ppb) and 1982.07 ppm N_2O
320 (± 3.77 ppb)) was measured daily before and after the sample measurements; the standard deviation was < 1 %. The calibration range was adjusted using multi-loop injection of the calibration gas to ensure that the samples were within the limits of the calibration. The standard was recalibrated according to high-precision standards (ICOS-CAL laboratory, Max Planck Institute, Jena, Germany).

2.5.3 GHG flux calculations

325 **Atmospheric fluxes based on closed-chamber measurements**

CO_2 and CH_4 fluxes were calculated using the ideal gas law (Livingston and Hutchinson, 1995), as formulated in Eq. (7):

$$F = \frac{MpV}{RTA} * \frac{dc}{dt} \tag{7}$$

where F is the GHG flux (g m^{-2} h^{-1}), M is the molar mass of the gas (g mol^{-1}), p is the standard air pressure (101,300 Pa), V is the chamber volume (m^3), R is the gas constant (m^3 Pa K^{-1} mol^{-1}), T is the temperature in the chamber (K), A is the surface area of the measurement collar (m^2), and dc/dt is the change in concentration over time. The latter was derived from
330 the slope of a near median-based regression. The atmospheric sign convention was applied; thus, positive fluxes indicated a release of GHG by the soil and negative fluxes GHG uptake by the soil. The fluxes were estimated using the function *fluxx()* of the R package *flux* (Jurasinski et al., 2014) and the SLP method.

Atmospheric fluxes based on air-sea gas exchange parameterization (velocity k model)

The air-sea gas exchange (F, g m^{-2} h^{-1}) is a function of the gas transfer velocity (k) and the concentration difference between
335 the bulk liquid (C_w) and the top of the liquid boundary layer adjacent to the atmosphere (C_a). It was calculated as reported in Wanninkhof (2014) and as shown in Eq. (8):

$$F = k (Cw - Ca) \tag{8}$$

where k was derived from an empirical relationship between a coefficient of gas transfer (0.251) and the wind speed $\langle U^2 \rangle$ (Wanninkhof, 2014) and Schmidt number (Sc), as expressed by Eq. (9):

$$k = 0.251 < U^2 > (Sc/660)^{(-0.5)} \tag{9}$$

Wind speeds originated from the nearby (~15 km away) monitoring station Putbus and were measured at 10 m height
340 (DWD; 54.3643° N, 13.4771° E, WMO-ID 10093). The average wind speed was defined in this study ± 3 h from midday, because the wind speed over 24 h was lowest at night and highest at midday and because sampling was usually conducted within the selected time interval. The Schmidt number was approximated by a linear interpolation between the freshwater and seawater values. Atmospheric-equilibrium conditions (C_a) were calculated using the atmospheric data for CO_2 and CH_4 obtained from the ICOS station "Utö" (Finnish Meteorological Institute, Helsinki). Due to the seasonal changes in the

please indicate what this approach means to the data analysis

345 atmospheric dry molar fraction of CO_2 and CH_4, mean values for each season were computed. For N_2O, the atmospheric dry mole fraction from station Mace Head was selected (National University of Ireland, Galway; data from the NOAA GML carbon cycle cooperative global air sampling network (Dlugokencky et al., 2019a, 2019b)). A mean value of the atmospheric N_2O concentration during the investigation period was calculated due to its minor seasonality. Equilibrium concentrations were then calculated using the solubility coefficient (K_0) from Weiss and Price (1980). We acknowledge that the air-sea

350 exchange model we used (Wanninkhof, 2014) was developed for open ocean waters and is a doubtful approach for deriving fluxes in small enclosed areas such as our working area. However, the lack of an appropriate parameterization, and the convincing result of the comparison of our two approaches (see below and Appendix C) justify our approach.

Comparability of two independent approaches to atmospheric flux determination

We evaluated the comparability of the two previously described methods by comparing the results of a representative station

355 (BTD7) for each post-rewetting season. The comparison showed no significant differences between the fluxes of CO_2 and CH_4 derived with the different methods and therefore, it seems appropriate to combine the fluxes for each GHG into one pooled post-rewetting data set. The pooled post-rewetting flux values were compared with the pre-rewetting values to investigate the effect of rewetting on CH_4 and CO_2 fluxes (Table 3). For more details concerning the comparability assessment, see Appendix C. Due to the large variability and the pooling of chamber-based measurements with k model data,

360 the GHG fluxes after rewetting are hardly suitable for upscaling and thus, the single values in the published data should be used.

3.   Results

3.1   Surface water properties (temperature, salinity, O_2, DOC, chlorophyll a)

In the first year after rewetting, there were no significant differences between the peatland and the inner bay with respect to

365 surface water temperature, salinity and O_2 saturation (Figure 4a−c, Table 2), suggesting a pronounced water exchange between the peatland and the inner bay that was driven by frequent changes in the water level (Figure A1). Additionally, no significant differences between summer and autumn 2019 and summer and autumn 2020 were found in the inner bay.

Temperature and salinity measurements near the peat surface showed no significant differences between the surface and bottom water over the year ($n_{surface} = 140$, $n_{bottom} = 86$, data not shown), which suggested that vertical exchange processes

370 and mixing were highly pronounced. However, the significant difference in O_2 saturation between the surface and bottom water in summer ($p < 0.01$) indicated that local and temporary gradients are possible.

This page contains no comments
Figure 4. Time series of the mean (a) temperature, (b) salinity, (c) O$_2$ saturation, (d) DOC concentration and (e) chlorophyll a concentration (± standard deviations) in the surface water from June 2019 to December 2020. Data from the flooded peatland (n = 6) are shown in blue and data from the inner bay (n = 2 or 3, as explained in Sect. 2.3) in black. The vertical black line indicates the rewetting event.

DOC concentrations were significantly higher in the peatland than in the inner bay in spring and summer, with the highest concentration (~30 mg L^{-1}) measured in the peatland (Figure 4d, Table 2). Chlorophyll a concentrations after rewetting showed clear seasonal and spatial differences, with significantly higher concentrations in the peatland in spring and summer (max. ~125 µg L^{-1}, Figure 4e, Table 2). A comparison of pre- and post-rewetting chlorophyll a concentrations in the inner bay in summer and autumn showed higher concentrations after rewetting (pre-rewetting: 2.5 ± 0.9 µg L^{-1}, post-rewetting: 15.4 ± 11.5 µg L^{-1}).

Number: 1 Author: au30574   Subject: Sticky Note   Date: 04-12-2022 14:25:30
why are there no data for the 'before rewetting', except for chl a ?

Number: 2 Author: au30574   Subject: Sticky Note   Date: 04-12-2022 14:26:10
and why have you consistently no unit for salinity?

Table 2. Seasonal comparison of the surface water means (± standard deviation) in the peatland ("peat") as opposed to the inner bay ("bay") for all in situ variables. The number of observations is shown in parentheses, and significant seasonal differences ($p < 0.05$) between the inner bay and the peatland are indicated in bold.

3.2 Nutrients (NO_3^-, NO_2^-, NH_4^+, PO_4^{3-})

3.2.1 Pre- and post-rewetting spatio-temporal dynamics and comparison with a nearby monitoring station

In the inner bay, all N-nutrient concentrations were substantially higher at the first sampling after rewetting than prior to rewetting, while PO_4^{3-} concentrations were only slightly higher post-rewetting (Figure 5). This increase of N-nutrients led to a drastic increase of the N:P ratio from ~73 in autumn 2019 before rewetting to ~1600 shortly after rewetting in winter 2019. A comparison of the same pre- and post-rewetting seasons (summer and autumn 2019/2020) showed generally higher N-nutrient concentrations in the inner bay after rewetting which could not be confirmed statistically (Mann-Whitney-U-test, Table 3).

During winter, all N-nutrients were high in the peatland and inner bay. After a rapid decrease in spring, N-nutrient concentrations reached their lowest values during summer, with NH_4^+ and NO_2^- then increasing in autumn again. PO_4^{3-} concentrations followed a different pattern, with the highest concentrations determined in summer and fewer fluctuations over the year.

The spatial differences in nutrient concentrations between the inner bay and the peatland after rewetting varied greatly between the nutrient species. From the N-nutrients, only NO_2^- concentrations were significantly higher once in winter, shortly after rewetting, whereas NH_4^+ and NO_3^- concentrations showed no significant differences in any season (Table 2). Significantly higher PO_4^{3-} concentrations in the peatland occurred during spring and summer ($p < 0.05$). Some significant correlations between nutrient species were found (Figure D1), especially between NO_2^-/NH_4^+ and NO_3^-/NO_2^- both in the peatland and the inner bay.

Nutrient concentrations of the monitoring station ("central bay") showed a low inter-annual variability during the years 2016-2020 and often lower concentrations than the inner bay (Figure 6). A detailed comparison of nutrient data from the monitoring station with those from the inner bay showed that before rewetting, only the NH_4^+ concentrations were

Number: 1   Author: au30574   Subject: Comment on Text   Date: 04-12-2022 14:32:31
have ditch measurements been described?

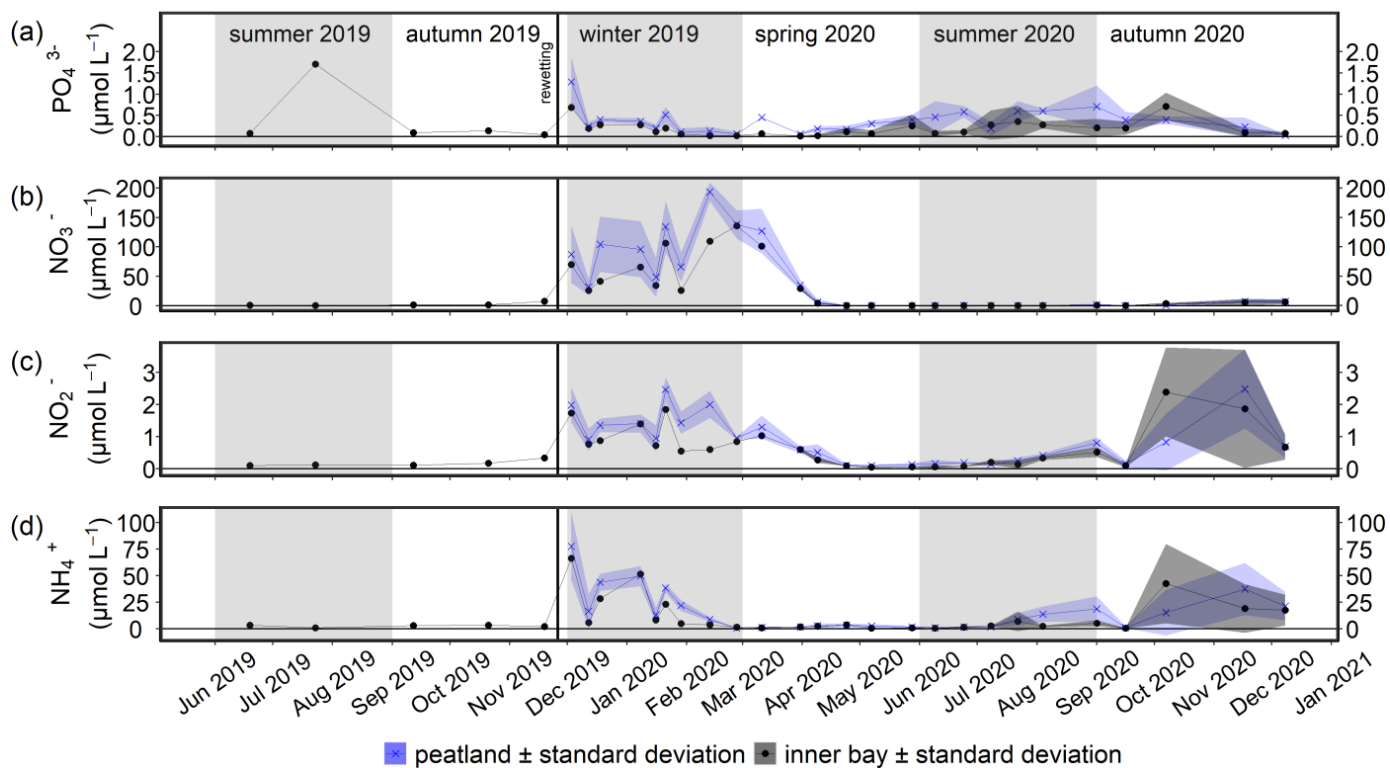
significantly higher in the inner bay. After rewetting, NO_3^- and NO_2^- concentrations in the inner bay increased and were significantly higher than in the central bay ($p < 0.001$ and $p < 0.05$, respectively). In spring, N-nutrient concentrations were similar at the two locations whereas in summer, all N-nutrients were significantly higher in the inner bay ($p < 0.01$). In autumn, NO_2^- and NH_4^+ concentrations increased again and thus, showed significantly higher concentrations in the inner bay. PO_4^{3-} again followed a pattern different from that of the N-nutrients. Shortly before rewetting, its concentrations in the inner bay were significantly lower than those in the central bay ($p < 0.05$). After rewetting, PO_4^{3-} concentrations showed no significant differences in any season.


Figure 5. Time series of the mean (a) PO_4^{3-}, (b) NO_3^-, (c) NO_2^-, and (d) NH_4^+ concentrations (± standard deviations) in the surface water from June 2019 to December 2020. Data from the flooded peatland (n = 6) are shown in blue and data from the inner bay (until 11 March 2020: n = 1, thereafter: n = 2) in black. The vertical black line indicates the rewetting event.

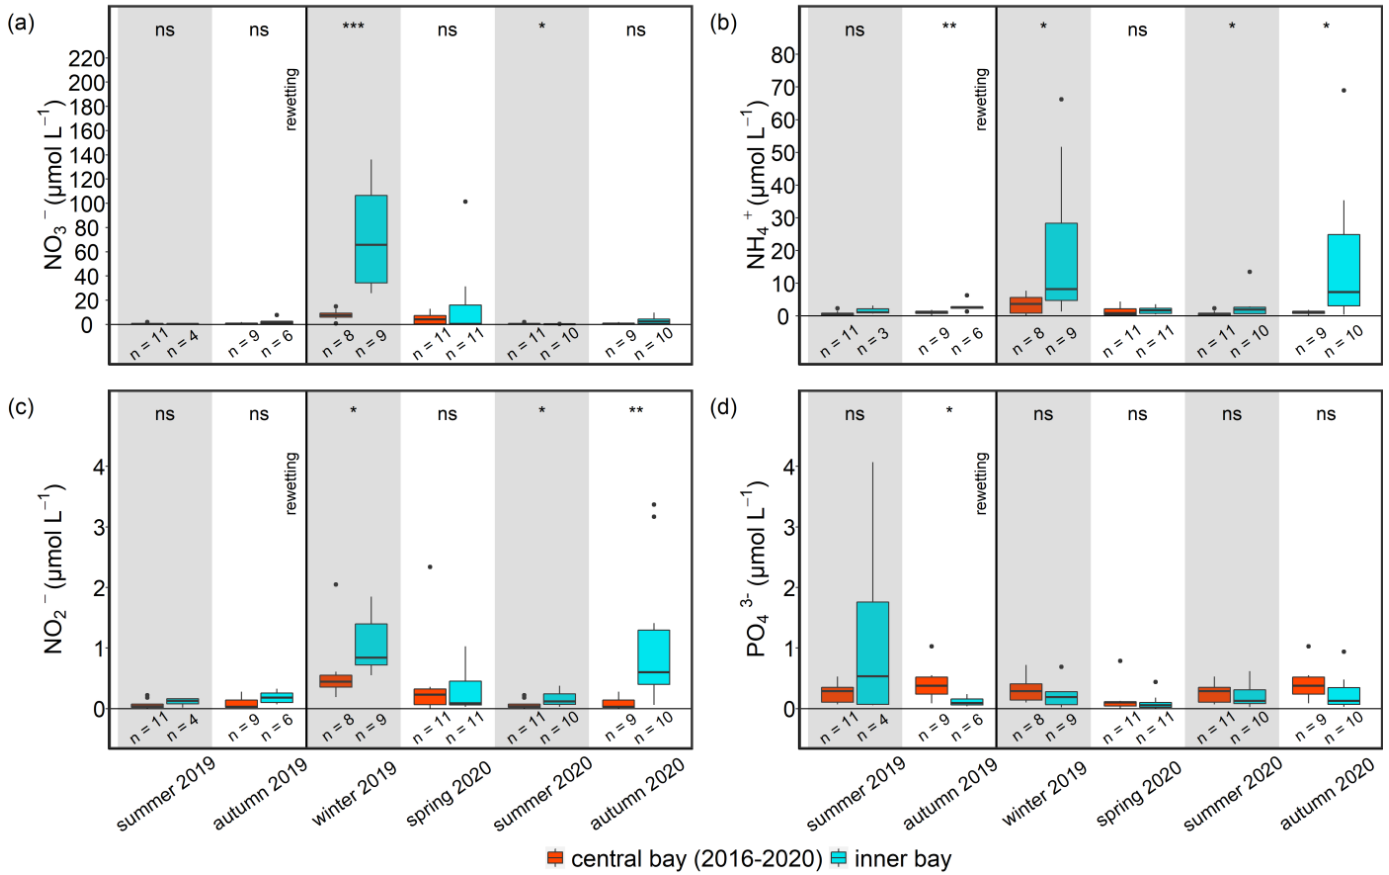

Figure 6. Seasonal nutrient concentrations of (a) NO_3^-, (b) NH_4^+, (c) NO_2^-, and (d) PO_4^{3-} at the nearby monitoring station (central bay, red) and in the inner bay (inner bay, blue) from pre- to post-rewetting. The vertical black line indicates the rewetting event. Note that 5-year-data (2016–2020) are shown for the central bay (see Sect. 2.4.2). ns = not significant, * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$.

3.2.2   Nutrient export from the rewetted peatland into the inner bay

The rewetted peatland was a net source of DIN-N and PO_4-P for the inner bay (Table B1). During the first year after rewetting, 10.8 ± 17.4 t yr^{-1} DIN-N and 0.24 ± 0.29 t yr^{-1} PO_4-P were exported into the inner bay. DIN-N export was highest during the winter directly after rewetting (8.6 ± 9.9 t) and lowest during summer (0.3 ± 0.5 t). DIN-N and PO_4-P were only exported from the peatland into the inner bay in all seasons.

N-nutrient concentrations showed a gradient from the peatland through the inner bay to the central bay. Therefore, nutrient data from the central bay were also taken into account to estimate the total possible export from the peatland to the sea. This resulted in an estimated total net export of 33.8 ± 9.6 t yr^{-1} DIN-N. In contrast to the comparison of the peatland and the inner bay, PO_4-P was once imported from the central bay into the peatland in autumn (0.03 ± 0.10 t). Additionally, it was noticeable that the PO_4-P concentrations in the central bay were permanently higher than in the inner bay, leading to a lower annual export of 0.09 ± 0.32 t yr^{-1} PO_4-P.

always make sure the reader knowns which kind of dispersion around the mean that you report

3.3 GHG in the surface water after rewetting

440 **3.3.1 Inorganic C system**

During the winter after rewetting, the differences in the CO_2 system (C_T, A_T, pH, pCO_2) between the inner bay and the peatland were not significant (Figure 7, Figure 8a). All variables increased slightly until spring, coinciding with a slight increase in salinity over the same period. From spring onwards, however, the components of the CO_2 system followed contrasting patterns, with C_T and A_T remaining relatively constant in the inner bay but reaching significantly higher values in

445 the peatland ($p < 0.05$), including maximum values in summer (Table 2). The pH also showed significant seasonal differences, with lower values and a minimum in summer in the peatland ($p < 0.05$). C_T and A_T values in the inner bay and in the peatland aligned in autumn whereas the pH remained significantly different ($p < 0.05$). The mean pCO_2 (calculated from C_T and pH) of the surface water in winter was 1050.0 ± 55.7 µatm in the inner bay and 1403.9 ± 674.8 µatm in the peatland (Figure 8a). The pCO_2 values were highest during the first few weeks after inundation and then steadily decreased, with the

450 lowest mean values occurring in spring (peatland) and summer (inner bay). The summer was characterized by high pCO_2 values in general, including earlier and stronger increases in the peatland than in the inner bay that resulted in significant differences in spring and summer ($p < 0.05$ for both seasons). pCO_2 values were highest in summer with 4016.7 ± 2120.0 µatm (peatland) and 1161.7 ± 1275.5 µatm (inner bay) (Table 2). In October, all of the examined CO_2 quantities had a short-term inversion of the prevailing pattern.

Figure 7. Time series of the mean (a) total CO_2 (C_T), (b) total alkalinity (A_T), and (c) pH ($\pm$ standard deviations) in the surface water after rewetting, as measured from December 2019 to December 2020. Data from the flooded peatland (n = 6) are shown in blue and data from the inner bay (until 11 March 2020: n = 1, thereafter: n = 2) in black. The vertical black line indicates the rewetting event.

3.3.2   CH$_4$

460   During the first few months after flooding (in winter), the CH$_4$ concentrations in both the inner bay and the peatland were low and did not differ significantly (Figure 8b, Table 2): 48.0 ± 49.5 nmol L^{-1} (peatland) and 81.4 ± 107.0 nmol L^{-1} (inner bay), ~~respectively~~. From mid-spring onwards, CH$_4$ concentrations in the inner bay and the peatland increased such that during summer and autumn 2020, the differences at the two areas were significant ($p < 0.05$). Mean CH$_4$ values were highest in summer and amounted 1502.4 ± 693.4 nmol L^{-1} in the peatland and 502.5 ± 479.3 nmol L^{-1} in the inner bay. Further, the

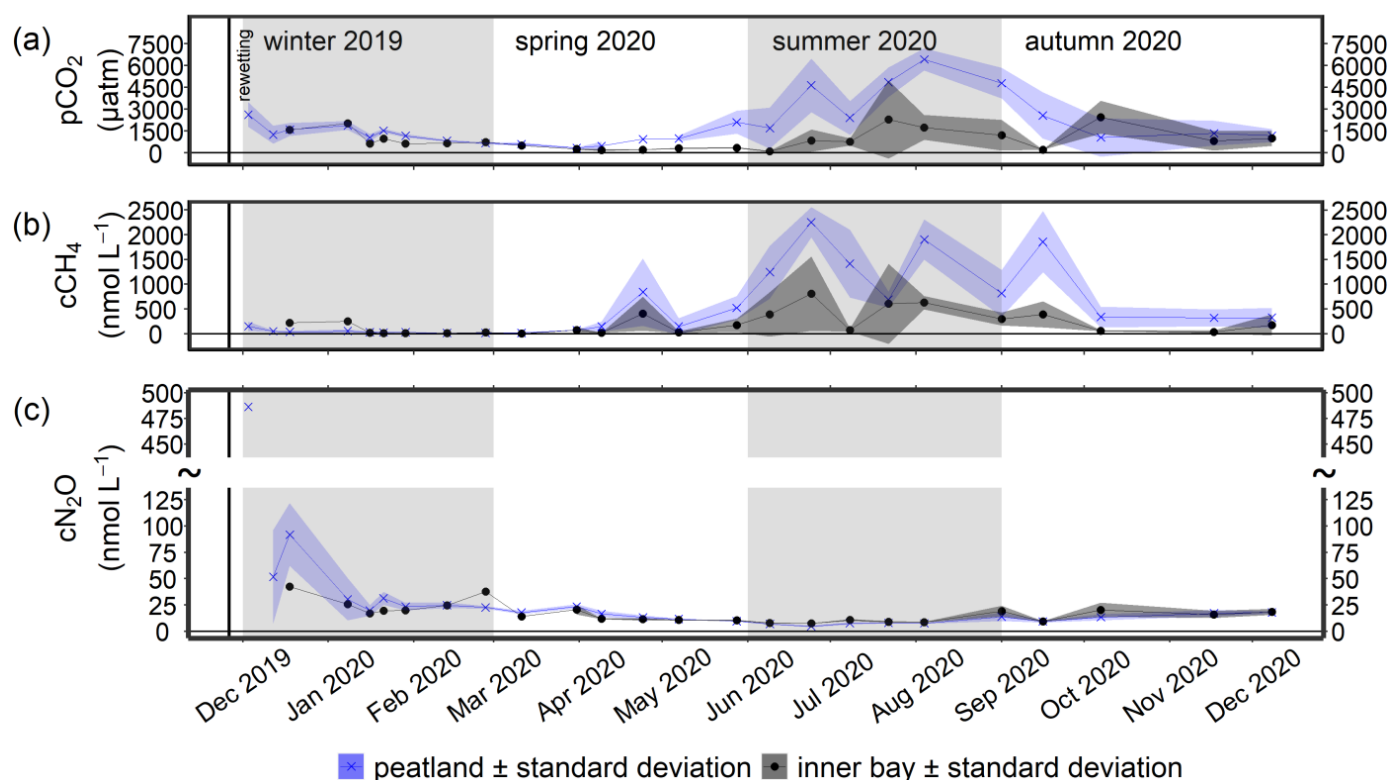
465   peatland was characterized by a considerable short-term variability in spring and summer, expressed in four peaks representing elevated concentrations. A positive significant correlation ($r_S = 0.73$, n $= 72$, $p < 0.001$) was found in the peatland between the surface water CH$_4$ concentrations and a water temperature > 10 °C, but not < 10 °C.


Figure 8. Time series of the mean (a) pCO$_2$, (b) CH$_4$ concentration (cCH$_4$), and (c) N$_2$O concentration (cN$_2$O) ($\pm$ standard deviations) after
470   rewetting in the surface water from December 2019 to December 2020. Data from the flooded peatland (n = 6) are shown in blue and data from the inner bay (until 11 March 2020: n = 1, thereafter: n = 2) in black. The vertical black line indicates the rewetting event.

3.3.3 N_2O

The highest N_2O concentration of 486.3 nmol L^{-1} was measured in the peatland one week after rewetting (Figure 8c), followed by 4–5 of still elevated N_2O concentrations between 19.9 and 91.8 nmol L^{-1}. During winter, significant positive

475   correlations were determined in the peatland between N_2O and NH_4^+ (r_s = 0.61, n = 45, $p < 0.001$) and between N_2O and NO_2^- (r_s = 0.46, n = 45, $p < 0.01$). From spring onwards, N_2O decreased rapidly, both in the peatland and the inner bay, with the lowest values of 4.7 to 7.9 nmol L^{-1} reached in summer. Other positive correlations of N_2O with N-nutrients in the peatland included NO_3^- (r_s = 0.74, n = 35, $p < 0.001$) and NO_2^- (r_s = 0.70, n = 35, $p < 0.001$) in spring and all N species in autumn (NO_3^-: r_s = 0.85, n = 30, $p < 0.001$; NO_2^-: r_s = 0.70, n = 30, $p < 0.001$; NH_4^+: r_s = 0.80, n = 30, $p < 0.001$).

480   Spatial differences in N_2O concentrations between the inner bay and the peatland were low and not significant in winter, spring or autumn, whereas significantly lower concentrations were measured in the peatland during summer (Table 2).

3.4   Pre- and post-rewetting GHG fluxes (CO_2, CH_4, N_2O)

Terrestrial CO_2 fluxes before rewetting, during summer and autumn 2019, were highly variable ranging from −3.3 to

485   3.0 g m^{-2} h^{-1} with a mean of 0.29 ± 0.82 g m^{-2} h^{-1} (Figure 9a). Within the ditch, pre-rewetting CO_2 fluxes ranged from −0.008 to 0.6 g m^{-2} h^{-1}, but on average were comparable to the fluxes determined at the terrestrial (dry) surface.

After rewetting, formerly terrestrial CO_2 fluxes decreased in amplitude (−0.5 to 1.4 g m^{-2} h^{-1}), while the summer and autumn averages were unchanged compared to the pre-rewetting fluxes (Table 3). In the ditch, the mean and minimum post-rewetting CO_2 fluxes were within the range of those determined pre-rewetting (mean: 0.26 ± 0.29 g m^{-2} h^{-1}, min:

490   −0.02 g m^{-2} h^{-1}) but the maximum flux (1.1 g m^{-2} h^{-1}) was almost twice as high as the pre-rewetting ditch flux (max: 0.6 g m^{-2} h^{-1}).

Pre-rewetting CH_4 fluxes in summer and autumn 2019 varied between −0.9 to 8.4 mg m^{-2} h^{-1} (terrestrial) and −1.1 to 193.6 mg m^{-2} h^{-1} (drainage ditch; Figure 9b). While mean terrestrial CH_4 fluxes were 0.13 ± 1.01 mg m^{-2} h^{-1}, the mean ditch fluxes were 11.4 ± 37.5 mg m^{-2} h^{-1}. In summer and autumn 2020, after rewetting, average CH_4 fluxes on formerly

495   terrestrial land increased slightly but significantly (1.74 ± 7.59 mg m^{-2} h^{-1}), whereas in the ditch they decreased considerably (8.5 ± 26.9 mg m^{-2} h^{-1}). Flux amplitudes at the ditch station before and after rewetting were comparable.

Data on N_2O fluxes are available only for the post-rewetting period. The rewetted peatland was a small source of N_2O, with an annual mean flux of 0.02 ± 0.1 mg m^{-2} h^{-1} in the first year after rewetting (Figure 9c). The highest N_2O flux of 0.4 mg m^{-2} h^{-1} occurred one week after rewetting, followed by lower N_2O fluxes between 0.007 and 0.2 mg m^{-2} h^{-1} within

500   the following 4–5 weeks. Afterwards, N_2O fluxes remained constantly close to zero. Negative fluxes, indicating N_2O uptake, were measured only in summer.

weeks?
Figure 9. Time series of the mean (a) CO_2, (b) CH_4, and (c) N_2O fluxes ($\pm$ standard deviations) from June 2019 to December 2020. Fluxes of the permanently wet drainage ditch are shown in purple and those derived from the two methods employed in this study in green. The vertical black line indicates the rewetting event.

4. Discussion

4.1 Nutrient dynamics and export

The seasonal dynamics of the nutrients followed a typical course over the year. Thus, after rewetting, NH_4^+, NO_3^-, and NO_2^- concentrations were high in winter and autumn, which is typically due to the mineralization of OM followed by nitrification (Voss et al., 2010). By contrast, the low DIN concentrations during spring and summer reflected the consumption of nutrients by plants and phytoplankton. The very high chlorophyll a concentration (up to 125 µg L^{-1}) in the peatland indicated the presence of a highly phototrophic community, likely driven by the higher availability of nutrients compared to the inner bay. Due to these distinct seasonal differences with the lowest nutrient concentrations in spring and summer, a rewetting within these seasons would probably be more beneficial to reduce a potential nutrient export into the inner bay, at least during the first few months after rewetting.

To assess whether the flooded peatland served as a nutrient source for the inner bay, nutrient concentrations of the peatland were compared with those of the inner bay and of an unaffected monitoring station ("central bay") and showed generally higher mean concentrations. Due to drainage, the mineralization of upper peat layers can lead to an accumulation

Number: 1 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 15:12:37
yes as long as the site is not anoxic

of nutrients within the soil (Zak and Gelbrecht, 2007; Cabezas et al., 2012). After rewetting, nutrient concentrations in the
520 porewater and ultimately in the overlying water increase (van de Riet et al., 2013; Harpenslager et al., 2015; Zak et al.,
2017). The leaching of nutrients is driven by concentration differences across the soil-water interface, but it is also dependent
on factors such as salinity (Rysgaard et al., 1999; Steinmuller and Chambers, 2018), the oxygen availability in the soil
(Lennartz and Liu, 2019), and the effects of the latter on microbial processes (Burgin and Groffman, 2012), as well as on the
degree of peat decomposition (Cabezas et al., 2012). For instance, highly degraded peat, such as at our study area, can store
525 and release more nutrients than less degraded peat (Cabezas et al., 2012), meaning that the highly degraded peat of our study
area was prone to leach high amounts of nutrients. Occasional measurements of porewater nutrient concentrations in the peat
[1]f your study area revealed DIN and PO_4^{3-} concentrations up to 1 [3]rder of magnitude higher than those in the surface water
(Anne Breznikar, unpublished data), providing further support for the leaching of nutrients out of the peatland and into the
inner bay.

530 The estimated annual nutrient exports from the peatland of 10.8 ± 17.4 t yr^{-1} DIN-N and 0.24 ± 0.29 t yr^{-1} PO$_4$-P
(peatland/inner bay) and 33.8 ± 9.6 t yr^{-1} DIN-N and 0.09 ± 0.32 t yr^{-1} PO$_4$-P (peatland/central bay) were high, given the
small size of the flooded peatland (~0.5 km² at 0 masl). For comparison, the Warnow, a small river that flows into the Baltic
Sea near the city of Rostock, Mecklenburg-Vorpommern, draining an area of ~3300 km², had a mean annual DIN-N and
PO$_4$-P export of 1200 ± 500 t yr^{-1} and 19.9 ± 7.6 t yr^{-1}, respectively, over the last 25 years (HELCOM, 2019). Therefore, the
535 total nutrient export from the flooded peatland to the inner bay and to the central bay in the first year after rewetting
accounted for ~1 and ~3 %, respectively, of the annual DIN-N and PO$_4$-P loads of the Warnow. When normalized to the
same dimensions, our study area exported 21.6–67.6 t DIN-N km^{-2} yr^{-1} and 0.18–0.48 t PO$_4$-P km^{-2} yr^{-1}, whereas the
Warnow exported only 0.36 t DIN-N km^{-2} yr^{-1} and 0.01 t PO$_4$-P km^{-2} yr^{-1}.

However, we also want to shortly address the reasons for the high uncertainty range of our calculated nutrient
540 exports. Firstly, they derive from high fluctuating nutrient concentrations in the surface water within the seasons. This is also
visible in the high standard deviations (Table 2). Therefore, the 95 % confidence level of the nutrient exports is high and
reflects the natural dynamic. Secondly, we conducted default error propagation during the export calculation which leads to
even higher ranges on top of the high natural dynamic.

Compared to the Warnow river, it is noticeable that the range of uncertainties is highly different for the two sources.
545 While our uncertainties are mostly higher and in the same order of magnitude compared to the means, the uncertainties of
the river data are one order of magnitude lower. This is likely due to the different time scales of the two data sets. Our export
data were generated by taking only the first post-rewetting year into account in which the system was still in a transition state
and thus, showed very dynamic nutrient concentrations. The uncertainties of the river exports were generated by using
25 years of data, leading to lower uncertainties than using data from only one year and they were calculated as standard
550 deviation and not as standard error, as was done for the exports of our study site. Therefore, this has to be considered when
their uncertainty ranges are compared directly. Nevertheless, our results highlight the importance of currently still

unmonitored and small, [1]ndependently draining areas along the coastline of the Baltic Sea, in particular those that become intentionally flooded (HELCOM, 2019).

4.2 Assessment of the GHG dynamics

555 #### 4.2.1 CO₂

The carbon system in our study area is governed by a variety of processes (e.g. Wolf-Gladrow et al., 2007; Kuliński et al., 2017; Schneider and Müller, 2018). C_T and A_T were transported with the brackish water from the central bay and ultimately from the Arkona Basin. Additional alkalinity can be added either by a supply of freshwater, which in the southwestern Baltic Sea is characterized by higher alkalinities than the brackish or even saltwater endmember (Beldowski et al., 2010; Müller et

560 al., 2016), or can be introduced by mineralization processes from the seafloor in the inner bay and the flooded peatland. Primary production (i.e., carbon fixation) will decrease C_T, lower the pCO_2 and increase pH during the formation of organic matter. The mineralization of OM from various sources (new primary production, mineralization of the inundated former vegetation and from the underlying peat) will enhance C_T and A_T concentrations, increase pCO_2 and decrease pH. Air-sea exchange during our study is fostered by a pCO_2 that is above atmospheric levels throughout the year, except for a short

565 period in spring in the inner bay and the peatland, where outgassing of CO_2 occurred, resulting in lower pCO_2 and a decrease in C_T.

We observed three main developments in the surface water CO_2 system and air-sea flux pattern: (i) in winter 2019/2020, the CO_2 system hardly differed between the peatland and the inner bay; (ii) from spring to autumn, there were significant differences in the CO_2 system between the peatland and the inner bay, with higher pCO_2, C_T and A_T values and

570 lower pH in the peatland coinciding with an enrichment in chlorophyll a; (iii) overall, the first post-rewetting year showed sustained high, but less variable CO_2 fluxes compared to pre-rewetting conditions. In the following, we will discuss these three observations and set them into context.

(i) Initial post-rewetting CO_2 dynamics

The first weeks after the rewetting were characterized by high nutrient concentrations, a continuous increase in A_T, C_T and

575 pH and a decrease in pCO_2 (Figure 5, Figure 7, Figure 8). The increase in C_T and A_T coincided with a steady increase in salinity (Figure 4), which is in line with a general increase of A_T with increasing salinity known for the western Baltic Sea (e.g. Kuliński et al., 2022).

Still, the A_T values at the given salinity were higher in the inner bay and the peatland than would be expected from a linear A_T/salinity relation found for surface waters in the open Baltic Sea from the central Gotland Sea to the Kattegat

580 (Beldowski et al., 2010; Müller et al., 2016). Thus, the high A_T in the inner bay and peatland were likely associated with [2]ocal carbonate ($CaCO_3$) weathering from terrestrial sources and/or a transport by groundwater (Schneider and Müller, 2018). C_T and A_T values during this period were consistently higher by ~70–80 µmol kg⁻¹ in the peatland than in the inner bay, consistent with enhanced leaching from the recently inundated peat. Besides, local $CaCO_3$ weathering as well as local

Number: 1 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 15:45:52
independent

Number: 2 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 15:51:12
but do you have evidence for this in your area?

anoxic processes, such as SO_4^{2-} reduction may have increased the A_T in the submerged soil and finally contributed to higher
585 A_T values compared to the inner bay.

The oversaturation in pCO_2 and potentially the excess leaching of alkalinity from the soil might have contributed to the decrease in pCO_2 and increase in pH in the peatland in winter 2019/2020. This was apparently reinforced by a short episode of primary production mid/end January, indicated by a steeper decline of the pCO_2 and a steeper pH increase. This coincided with a short increase in chlorophyll a (~30 $\mu g\,L^{-1}$) and a slight intermittent increase of the surface water
590 temperatures (Figure 4). This short, unusually early productive period might have resulted from the high nutrient availability induced by the rewetting of the peatland (Sect. 3.2.1), in particular the high NH_4^+ levels, which simultaneously showed a sharp intermittent minimum.

[1]i) Production and mineralization governance over the productive period (spring to autumn)

In late winter and the first half of spring, pCO_2 continuously decreased in the peatland as well as in the inner bay. Lowest
595 pCO_2 was measured between March and May and coincided with enhanced chlorophyll a concentrations and a high availability of nutrients in the peatland and in the inner bay, which decreased until mid spring. This resulted in a slight CO_2 uptake in the peatland of -0.005 g m^{-2} h^{-1} for a short period of time, so that spring was the only season when pCO_2 was on average below atmospheric concentrations in the inner bay (Figure 9). This finding can be attributed to the onset of the productive period, at still moderate surface water temperatures below 10 °C until mid April. During this period, productivity
600 clearly [2]ominated mineralization, as suggested by the decreasing pCO_2 and increasing pH, despite rising temperatures, as well as increasing O_2 oversaturation in the surface waters. These trends were slightly more pronounced in the peatland than in the inner bay, in accordance to[4] higher nutrient concentrations available for production.

From mid spring until late summer, the peatland was characterized by increased pCO_2 and a variable CO_2 system together with high mean chlorophyll a concentrations of up to 106.0 $\mu g\,L^{-1}$. N-nutrients were very low and the system was
605 clearly nitrogen-limited, with only slightly elevated NH_4^+ concentrations in late summer (Figure 4, Figure 5). Furthermore, the O_2 saturation shifted from over- to undersaturated conditions. These observations suggest that the peatland and the inner bay were characterized by simultaneous production and mineralization processes from mid spring until autumn that kept the N-nutrients (except PO_4^{3-}) low. Mineralization of OM in the water column, sediment and soil clearly dominated over production, leading to the observed high pCO_2, lowered pH, and enhanced A_T and C_T concentrations. Mineralization during
610 this period was clearly more pronounced in the peatland than in the inner bay, leading to the higher pCO_2, A_T, and C_T values in the peatland, and a stronger and more pronounced reduction of the pH. This stronger mineralization, in particular in the warm summer months, also led to higher DOC concentrations in summer, with a maximum in June/July coinciding with maximum surface water temperatures. The enhanced mineralization in the peatland was likely fueled by higher OM availability from high decomposition rates of fresh plant substrate from inundated plant residuals (Glatzel et al., 2008; Hahn-
615 Schöfl et al., 2011),[5]nd also due to the omission of topsoil removal before the rewetting. In addition, aerobic and anaerobic oxidation of CH_4, that was produced in anoxic zones, might have led to increased CO_2 production, especially during increased water temperatures (e.g. Treude et al., 2005; Dean et al., 2018), due to the availability of SO_4^{2-} and O_2.

seems like a counter-factual suggestion

The calculated A_T (from C_T and pH) in the peatland was consistently lower than the measured A_T with a difference in the range of 55–122 µmol kg^{-1} and thus of 2.7–4.7 % (data not shown). This difference was higher than in the Baltic Sea, where the contribution of organic A_T is estimated to be 1.5–3.5% (Kuliński et al., 2014). Due to closer vicinity to the coast and the high amount of degradable OM, this higher contribution of organic A_T was to be expected. The highest discrepancy between measured A_T values and those calculated from pH and C_T occur in early summer, simultaneously to the highest values in DOC, in particular in the peatland (Figure 4). This suggests that the organic A_T related to the occurrence of DOC (and thus [1]OM), contributed to the excess of A_T. The higher DOC formation in summer in the peatland might partly explain the difference in A_T between the inner bay and the peatland.

[2]ii) Sustained high CO_2 fluxes but less variability caused by brackish water flooding

The amplitude of the CO_2 fluxes from formerly drained parts of the study area decreased after rewetting with brackish water, while the amplitude of CO_2 fluxes from the ditch (inundated after flooding but with deeper, probably incompletely exchanged water) did not differ strongly before and after rewetting (Figure 9). An increased water table is the main driver for the reduction of CO_2 emissions on formerly drained locations. A similar scenario has been reported for terrestrial sites (Bubier et al., 2003; Strack, 2008). In a nearby coastal peatland, both photosynthesis and ecosystem respiration were strongly reduced after rewetting (Koebsch et al., 2013). [3]he rewetting of our study area probably caused a die-back of the highly productive grassland vegetation at a rate faster than that occurring after freshwater rewetting (Hahn-Schöfl et al., 2011), which in turn would have led to a reduction of the CO_2 flux amplitude.

Average summer/autumn CO_2 fluxes after rewetting had a mean of 0.26 ± 0.29 g m^{-2} h^{-1} and remained thus relatively high compared with those fluxes from 2019. They were also higher than the fluxes determined in studies of shallow coastal or near-shore waters in the northwestern Bornholm Sea of up to 0.01 g m^{-2} h^{-1} (Thomas and Schneider, 1999) or the Bothnian Bay of around ~0.0007 g m^{-2} h^{-1} (Löffler et al., 2012). In a nearby coastal fen recently influenced by brackish water inflow, ecosystem respiration was [4] orders of magnitude lower (Koebsch et al., 2020) compared to our study site, where the ongoing decomposition [5]f submerged substrate from plant residuals and the fresh soil may have fueled the continuously high CO_2 fluxes in the first year after rewetting (Hahn-Schöfl et al., 2011). The mineralization of OM from primary production driven by the high initial nutrient availability, as well as aerobic and anaerobic oxidation (Dean et al., 2018) of easily degradable substrates or CH_4, might have additionally contributed to these CO_2 fluxes. We expect that CO_2 emissions will further decrease, likely because substrates become exhausted and a novel ecosystem will be established (Kreyling et al., 2021), with developing algae fostering CO_2 fixation.

4.2.2 CH_4

We observed three main developments in surface water methane concentrations and flux patterns: (i) a short-term, very moderate increase in CH_4 concentrations directly after rewetting in winter 2019/2020; (ii) an increase in the CH_4 concentrations mainly from spring to autumn, that was significantly higher and more variable in the peatland than in the

certainly, and also high CH4 fluxes could be expected from this management

650 inner bay and correlated with water temperature; (iii) in the first year after rewetting, much lower CH_4 fluxes than reported for nearby peatlands rewetted by freshwater. These three observations are discussed and set into context in the following.

(i) Short-term, moderate increase in the CH_4 concentrations in the winter after rewetting

[1]The measurements in winter, immediately after rewetting, showed a short-term increase in the CH_4 concentrations, although remaining low (Figure 8). Rewetting with brackish water inundated both the degraded peat and the remaining vegetation.
655 While this implies the instant availability of labile OM, the intensity of methanogenesis depends not only on the total amount but also on the quality of the OM (Heyer and Berger, 2000; Parish, 2008). Inundated plant material and its subsequent die-back provide high-quality OM, so that in our study the availability of OM was not a limiting factor. Nevertheless, the CH_4 concentration remained low and was associated with low temperature, which is an important factor controlling microbial processes and CH_4 production. A study in a nearby shallow coastal area of the Baltic Sea, between the islands of Rügen and
660 Hiddensee, showed that water temperature was the primary driver of the temporal variability in CH_4 emissions, with low rates associated with low temperatures (Heyer and Berger, 2000).

The rewetting with brackish water transported water with a salinity of 6–7.4 into the peatland such that there were no significant differences in salinity compared to the inner bay in winter (same as for temperature; Table 2). Thus, sulfate reached the peatland immediately after rewetting. As a terminal electron acceptor (TEA), SO_4^{2-} promotes the ~~establishment~~[2]
665 of sulfate-reducing bacteria (SRB), which outcompete methane-producing microorganisms (methanogens) for substrates (Segers and Kengen, 1998; Jørgensen, 2006; Segarra et al., 2013). This process was shown to play an important role in flat brackish water systems (e.g. Heyer and Berger, 2000). The availability of other TEAs, such as NO_3^- that had high concentrations in our study of $\sim 100 \pm 58\ \mu mol\ L^{-1}$, could have further suppressed methanogenesis (Table 2) (Jørgensen, 2006). Beside competitive mineralization, aerobic and anaerobic CH_4 oxidation may have reduced the CH_4 concentrations
670 (Heyer and Berger, 2000; Reeburgh, 2007; Knittel and Boetius, 2009; Steinle et al., 2017), supported by the effective exchange of water masses. Overall, the rewetting with brackish water during the cold winter season apparently inhibited methanogenesis [3]and/or effective oxidation, resulting in low CH_4 concentrations and a small CH_4 flux into the atmosphere.

(ii) [4]ncreased and variable CH_4 concentrations during the vegetation period

The increasing temperature from spring to autumn was accompanied by an enhanced and albeit variable CH_4 concentrations.
675 [5]emperature is crucial in controlling CH_4 cycling in shallow coastal/near-shore waters as well as in wetlands, and a distinct relationship between temperature and CH_4 concentrations has been reported for brackish shallow water systems (Bange et al., 1998; Heyer and Berger, 2000) and for the organic-rich sediments in the North Sea (e.g. Borges et al., 2018). Similar relationships describe the CH_4 exchange in permanently inundated wetlands (e.g. Koebsch et al., 2015) and in a peatland close to our study site during the first year after rewetting (Hahn et al., 2015). Moreover, CH_4 concentrations in the peatland
680 ($r_s = 0.75$, n = 74, $p < 0.05$) and the inner bay ($r_s = 0.55$, n = 29, $p < 0.05$) correlated significantly and positively with temperature. In the study of Heyer and Berger (2000) the temperature range influenced the temporal variability in CH_4 emissions, which were highest in late spring. [6]ince the temperature range in the peatland of our study was variable (e.g.,

[1]maximum difference of ~6 °C between samplings), with the highest values between spring and autumn (7.4–23.1 °C), this variability may have contributed to the observed CH_4 dynamics.

685   The peatland and the inner bay were clearly influenced by the same hydrographic conditions, evidenced by their very similar salinities and temperatures. However, the peatland showed higher CH_4 concentrations from spring to late autumn, likely due to the high availability of OM as described by Heyer and Berger (2000) and Bange et al. (1998). Incubation experiments of a degraded fen grassland demonstrated the accumulation of fresh plant litter in a new sediment layer after flooding that resulted in high rates of CH_4 and CO_2 production (Hahn-Schöfl et al., 2011). A further potential

690   driver of OM availability is the sedimentation of freshly produced OM originating from primary production, as described for shallow areas in the Baltic Sea (Bange et al., 1998) and for a shallow bight in the North Sea, which in the latter led to a yearly peak in the seasonal CH_4 cycle (Borges et al., 2018). Although our observations were not made in OM-poor sediments, an impact of primary production on enhanced CH_4 concentrations in the OM-rich Drammendorf peatland is likely, given [2]he significant positive correlation of the surface CH_4 concentrations and the chlorophyll a concentration

695   ($r_s = 0.41$, n = 56, $p < 0.05$). [3]urthermore, aerobic CH_4 production cannot be excluded, as its occurrence has been reported in oxic freshwater (Bogard et al., 2014) and during NO_3^- limitation and PO_4^{3-} availability (Damm et al., 2010), conditions that also prevailed in spring and summer at our study site.

(iii) Brackish water rewetting and low CH_4 emissions

Despite high surface water CH_4 concentrations in the peatland and their inter-seasonal and spatial variability, rewetting with

700   brackish water resulted in CH_4 emissions considerably lower than those from temperate fens rewetted with freshwater, where CH_4 emissions strongly increased (Augustin and Chojnicki, 2008; Couwenberg et al., 2011; Hahn et al., 2015; Franz et al., 2016; Jurasinski et al., 2016).

At our study site, although average CH_4 fluxes on formerly terrestrial locations increased significantly by 1 [4,5]rder of magnitude after rewetting, the overall increase from 0.13 ± 1.01 to 1.74 ± 7.59 mg m^{-2} h^{-1} (Figure 9) was lower than that

705   reported for freshwater rewetted fens under similar climatological boundary conditions (e.g. Hahn et al., 2015; Franz et al., 2016). Even several years after rewetting, the annual CH_4 budgets of a shallow lake on a formerly drained fen varied between 4.0 and 91.0 g m^{-2} yr^{-1} (Franz et al., 2016), corresponding to 11.0–249.3 mg [6]m^{-2} h^{-1}. Our CH_4 fluxes were also lower than the emissions reported from coastal-near shallow waters of the Baltic Sea, where fluxes of 39.9–104.2 mg m^{-2} h^{-1} were measured in June/July (Heyer and Berger, 2000). For the same months, mean CH_4 fluxes at the formerly dry stations in

710   our study site were 0.5–4.9 mg m^{-2} h^{-1}. However, compared to CH_4 fluxes from continental shelves (0.015–0.024 mg m^{-2} h^{-1}; adapted from Bange et al., (1994)), the fluxes of our study site were 2 orders of magnitude higher. Despite low average fluxes, emission peaks could be distinguished with the highest flux from the now inundated ditch of 149.2 mg m^{-2} h^{-1} in September 2020 and 108.3 mg m^{-2} h^{-1} in October 2020. While these values were still lower than the maximum value of 243.0 mg m^{-2} h^{-1} reported by Heyer and Berger (2000), it is important to stress that our study site was a

715   source of CH_4 already in its drained state, especially within the drainage ditch, where CH_4 fluxes were comparable to the ~0.2 mg m^{-2} h^{-1} reported from undrained fens (Danevčič et al., 2010).

No - these recalculations is per day (not per h)

The lower CH_4 emissions of the brackish rewetted Drammendorf peatland can be attributed to the availability of TEAs, especially SO_4^{2-}, which (1) may have contributed to a suppression in methanogenesis by competitive inhibition (Segers and Kengen, 1998; Jørgensen, 2006; Segarra et al., 2013) or (2) fostered the anaerobic oxidation of methane (AOM)

720 as an effective pathway to reduce CH_4 emissions, and by (3) fast aerobic CH_4 oxidation mediated by oxygen-rich water. Significant CH_4 production rates in marine and brackish water settings have been reported only where SO_4^{2-} is depleted, such as in the porewater of an inundated and degraded fen (Hahn-Schöfl et al., 2011) or below the SO_4^{2-} penetration zone in marine settings (e.g. Boetius et al., 2000; Reeburgh, 2007). At our study site, the depth of SO_4^{2-} penetration was propably low due to the short impact of the brackish water. Moreover, AOM is sensitive to the introduction of O_2 mediated by wind-

725 driven resuspension (Treude et al., 2005). Since our study area was shallow and likely experiences regular wind-driven resuspension, spatially and temporally dynamic AOM can be assumed. However, the CH_4 fluxes suggested that an effective aerobic and anaerobic oxidation of CH_4 was more likely. Moreover, higher CH_4 concentrations in the peatland compared to the inner bay in combination with the high lateral water exchange due to frequent changes in the water level (Figure 3) should have driven a net advective export of CH_4-enriched water to the inner bay. This would have further contributed to the

730 low peatland CH_4 emissions and the observed high variability.

While CH_4 production and emission were likely prevented by rewetting with oxygen-rich, sulfate-containing brackish water, the possibility remains that the total CH_4 release was underestimated by unsufficient accounting for ebullition. In the marine environment, bubble-mediated transport is attributed to gassy sediments and an effective mechanism of vertical CH_4 migration (e.g. Borges et al., 2016). Although neither of the methods used to determine CH_4

735 fluxes specifically account for ebullition, we estimated that 6.9 % of all analyzed chamber-based fluxes were partly bubble-influenced. We observed further that in another 9.6 % of the chamber-based flux measurements the CH_4 concentration patterns indicated ebullition, but these were not accounted for in the final calculations of diffusive flux. Thus, given that only 16.5 % of the chamber-based flux measurements indicated bubble-mediated CH_4 transport and in almost half of those cases, the resulting perturbation was small and was included in the flux amplitude, the magnitude of the ebullition-driven

740 underestimation of our flux estimates is considered to be small.

In summary, the increase in CH_4 concentrations after rewetting in winter was small, short-lived and associated with the die-back of plants. CH_4 fluxes in the first year after rewetting remained relatively low and were lower than typical for post-rewetting conditions. They also followed a seasonal pattern common for shallow organic-rich systems, with a strong correlation with temperature in spring and summer. The ongoing depletion of OM after the initial post-rewetting shock and a

745 new start of the ecosystem will likely lead to a decrease in CH_4 emissions.

4.2.3 N_2O

The rewetted peatland was a source of N_2O in the first year after rewetting, although the mean annual N_2O flux of $7.02 \pm$ 0.07 mg m^{-2} h^{-1} was very low (Figure 9). This was expected since permanent inundation leads to anoxic conditions in the peat, preventing the production of N_2O (e.g. Succow and Joosten, 2001; Strack, 2008). However, the range of post-rewetting

seems, if extrapolated, to correspond to 1.1 kg N2O-N ha-1 yr-1, which is actually quite high for a rewetted peatland

Number: 8 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 17:00:53
you need to clarify your argument. If NO3 is available, anoxic conditions (and fresh OM) will rather faclilitate denitrification and N2O production.

But the limitation could generally be availability of NO3, since NH4 oxidation may be impeded

750 N$_2$O fluxes in the first 3 months (winter) was clearly much larger than during the rest of the year, which indicated that N$_2$O was strongly and immediately affected by the rewetting, as shown elsewhere (Goldberg et al., 2010; Jørgensen and Elberling, 2012). The highest N$_2$O flux (0.4 mg m^{-2} h^{-1}) and the highest NH$_4^+$ concentration (78.0 µmol L^{-1}) was measured one week after rewetting and a significant positive correlation between these two variables was found in winter. Additionally, correlations of NO$_2^-$/NH$_4^+$ and NO$_3^-$/NO$_2^-$ were found in the peatland and in the inner bay (Figure D1). These

755 results suggested that N$_2$O was produced as a side product of nitrification, either in the surface water or in the peat. The accumulation of N$_2$O, but also of NO$_2^-$ and NO$_3^-$ in winter can be interpreted as a result from shifting O$_2$ conditions in the freshly inundated ecosystem, such that incomplete process chains of e.g. nitrification and denitrification were favored (Rassamee et al., 2011).

During late spring and early summer, undersaturation of the surface water with N$_2$O, compared to the atmosphere,
760 pointed to consumption within suboxic/anoxic zones of the peat. Consumption in the surface water was unlikely because anoxic conditions were never found near the peat surface. The undersaturation of N$_2$O a few months after rewetting evidenced the change in O$_2$ conditions in the peat, from oxic to hypoxic/anoxic, turning the rewetted peatland into an N$_2$O sink, at least temporarily. This change was likely driven by the higher availability of fresh OM (measured as chlorophyll a) in the peatland compared to the inner bay, finally leading to significantly lower N$_2$O concentrations in the peatland in
765 summer ($p < 0.001$, Table 2).

Previously reported N$_2$O fluxes in drained peatlands range from 0.002 to 0.45 mg m^{-2} h^{-1}, with a clear trend towards higher fluxes in fertilized or naturally N-rich areas (Flessa et al., 1998; Glatzel and Stahr, 2001; Augustin, 2003; Strack, 2008; Minkkinen et al., 2020). Augustin et al. (1998) examined multiple degraded fens in Mecklenburg-Vorpommern and Brandenburg (Germany) and calculated N$_2$O fluxes of 0.04 to 0.10 mg m^{-2} h^{-1} in extensively and intensively used fen
770 grasslands, respectively (Augustin et al., 1998). N$_2$O fluxes in drained peatlands result from low water levels which allows the penetration of oxygen into the peat to fuel N$_2$O producing processes (Martikainen et al., 1993; Regina et al., 1999). As the water level in our study site was permanently below the soil surface before rewetting, it is likely that it was a source of N$_2$O. The mean post-rewetting N$_2$O flux determined in our study area (0.02 ± 0.07 mg m^{-2} h^{-1}) is in the lower range of fluxes from drained peatlands. Therefore, as shown in other studies (Succow and Joosten, 2001; Minkkinen et al., 2020), the rewetting
775 very likely led to a reduction of N$_2$O fluxes.

In general, the N$_2$O fluxes in rewetted peatlands are in the same range as fluxes from pristine ones (Minkkinen et al., 2020), indicating that rewetting is a very effective measure to reduce N$_2$O emissions to natural levels. Literature values range from up to 0.01 and 0.02 mg m^{-2} h^{-1} for rewetted and undrained boreal peatlands (Minkkinen et al., 2020), respectively, to 0.08 mg m^{-2} h^{-1} for a rewetted riparian wetland near a freshwater meadow (Kandel et al., 2019). Although it
780 is difficult to compare the N$_2$O fluxes determined in this study to those of other sites with different salinities, hydrologies and also histories of usage, our mean annual post-rewetting value lies in the lower range of N$_2$O fluxes previously reported for rewetted and pristine peatlands.

what was a source of N2O? not clear from this sentence

Number: 5 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 17:22:09
so you compare data from rewetted and drained conditions here ?

Number: 6 Author: au30574   Subject: Comment on Text   Date: 04-12-2022 17:38:13
It seems Minkinen et al report that "The range at rewetted sites was similar to undrained peatlands: annual emissions varied from 0.022 to 0.191 g N_2O m^{-2} a^{-1}."

recalculation of these rates to hourly values gives: 0.0025- 0.022 mg N2O m-2 h-1. So this would indicate that your values are in the high end ?

5.   Conclusions

The effects of rewetting a drained coastal peatland with brackish water in winter and the subsequent formation of a permanently inundated area were studied over one year.

We found a strong pulse of DIN leaching out of the peat followed by the transport of DIN into the inner bay, leading to a high export especially in winter compared to the Warnow, a nearby river. However, due to a rapid decrease of nutrient concentrations in spring, the nutrient export after a rewetting in spring or summer would likely be lower compared to rewetting in winter, at least during the first few months thereafter.

Further, CO_2 concentrations and emissions seem to remain relatively high after the rewetting with brackish water compared to the dry conditions before rewetting. This was likely driven by the high OM availability from the residual vegetation but also by the high rate of primary production in the water column. However, the flux amplitude decreased after rewetting and thus, peak emissions during the vegetation period were prevented. The lack of a strong increase of CH_4 emissions in the first year after rewetting with brackish water, in contrast to nearby areas rewetted with freshwater, suggests that especially during the colder months, rewetting with brackish water or seawater would minimize CH_4 emissions and thus maximize the effect on integrated GHG emission reduction. Moreover, a rapid elevation of the water level, as occurred at our study site, will promote the oxidation of peat-derived CH_4 in the water column. Future CH_4 emissions will depend on processes, such as the development of vegetation and will likely decrease. According to literature, it is likely that the peatland was a rather large source of N_2O before rewetting due to its drainage for agricultural use. However, the permanent inundation initialized a rapid decrease of N_2O emissions and converted the peatland into a N_2O sink during summer, with fluxes similar to pristine peatlands.

With the ongoing formation of salt grass meadows, livestock farming at our study area can and will continue. However, the area's use has not hindered its positive development towards an ecosystem with the potential to eventually become a carbon and nutrient sink in the future. We expect that both the nutrient export and GHG emissions will slowly decrease due to a shrinking reservoir of substrates. Nonetheless, because degraded peat is both nutrient- and OM-enriched, this decrease will occur slowly, given that the topsoil was not removed prior to flooding to diminish nutrients and OM, as was demonstrated by other studies. Whether or not the area will act as a C sink in the future depends on the success and speed of the establishment of vascular vegetation and its burial in the anoxic parts of the sediment.

Nutrient export from peatlands and the re-establishment of the nutrient and C-sequestration functions of highly degraded coastal peatlands after rewetting are complex processes whose elucidation requires long-term investigations. The pronounced seasonal dynamics highlight the need for approaches that include a high temporal resolution, such as achieved with sensor-based or eddy-supported measurements.

Appendix C: Comparability of two independent approaches to atmospheric flux determination

Since the gas transfer velocity k model (Sect. 2.5.3) requires a water-air interface and thus cannot be applied to dry conditions, atmospheric flux measurements obtained by manual closed-chambers along a representative transect (Figure 2b) were available to determine pre-rewetting GHG fluxes (CO_2 and CH_4). After rewetting, data from manual closed-chambers

830 (transect) and from surface water sampling for the k model (transect and peatland stations) were used. The two methodologies were applied at the same locations along the transect only after rewetting (Table C1).

Table C1. Overview of the methods used to determine the atmospheric GHG fluxes

Pre-rewetting	Post-rewetting	
transect (Figure 2b)	transect (Figure 2b)	peatland area (Figure 2a)
chamber-based	chamber-based [1,2]	k model [2]
	k model [1,2]	

This page contains no comments

To evaluate the inter-comparability of the flux estimates obtained with the two methods, the results from station BTD7 were compared for each post-rewetting season (Figure C1). Data from this station were chosen because it was permanently flooded after rewetting and thus assured a valid baseline for comparison. The dynamics of the CO_2 fluxes determined by the two methods were the same and thus did not differ significantly in any of the seasons (Kruskal-Wallis test, $p > 0.05$).

CH$_4$ fluxes also did not differ significantly, except in autumn (Kruskal-Wallis test, $p < 0.001$), when the average flux calculated according to the two methods differed by a factor of 2.7. However, the data of the k model had less impact, due to the smaller number of measurements ($n = 6$). Given the smaller data set compared to that of the closed chambers ($n = 17$), the same statistical analysis was conducted without a seasonal division. The results showed no significant differences in the two methods for CH$_4$ fluxes (Kruskal-Wallis test, CO_2 and CH$_4$). Therefore, it was deemed appropriate to combine the flux-estimation methods for each GHG into one post-rewetting data set, as this allowed the consideration of a broader range of possible flux amplitudes. In addition, the post-rewetting data acquired along the transect were pooled with data distributed throughout the peatland area. Although the area covered by the transect was smaller than the covered by the k-model data from the peatland, such that pooling of the post-rewetting-data risked spatial bias, two positive effects of pooling were identified: (1) The transect stations were representative of the entire area after flooding, because they covered a water-level-gradient (several cm to > 2 m in the ditch) that coincided with the conditions of the peatland stations. (2) The transect stations represented a large heterogeneity in the peatland before rewetting that decreased post-rewetting. This was also evident from the CO_2 flux measurements, which showed a high variability (data not shown) at each station before rewetting. After rewetting, there was less variability such that the stations became more similar in their atmospheric C-exchange patterns, likely due to the mixing patterns triggered by lateral exchange with the Baltic Sea (Sect. 3.1). Largely similar conditions were therefore assumed at all stations within the peatland.

The pooled post-rewetting flux values were compared with the pre-rewetting values to investigate the direct effect of rewetting on CH$_4$ and CO_2 fluxes.

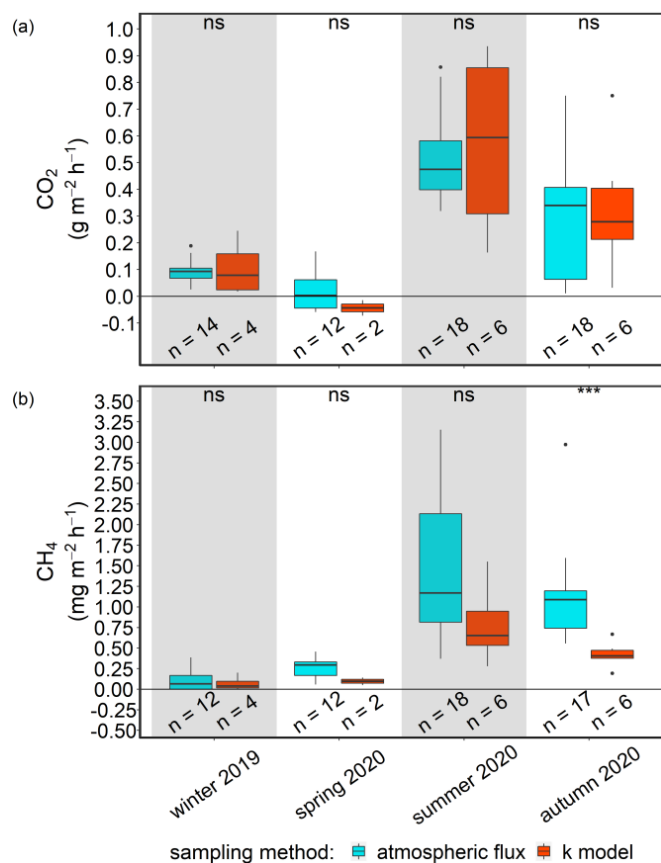
This page contains no comments


Figure C1. Seasonal post-rewetting fluxes of (a) CO_2 and (b) CH_4 at station BTD7 which is part of the GHG flux transect. Chamber-based atmospheric GHG fluxes are shown in blue and air-sea GHG fluxes from the k model in red. The methodological comparisons within seasons are based on a significance level of $p < 0.05$. ns: not significant; *** $p < 0.001$).

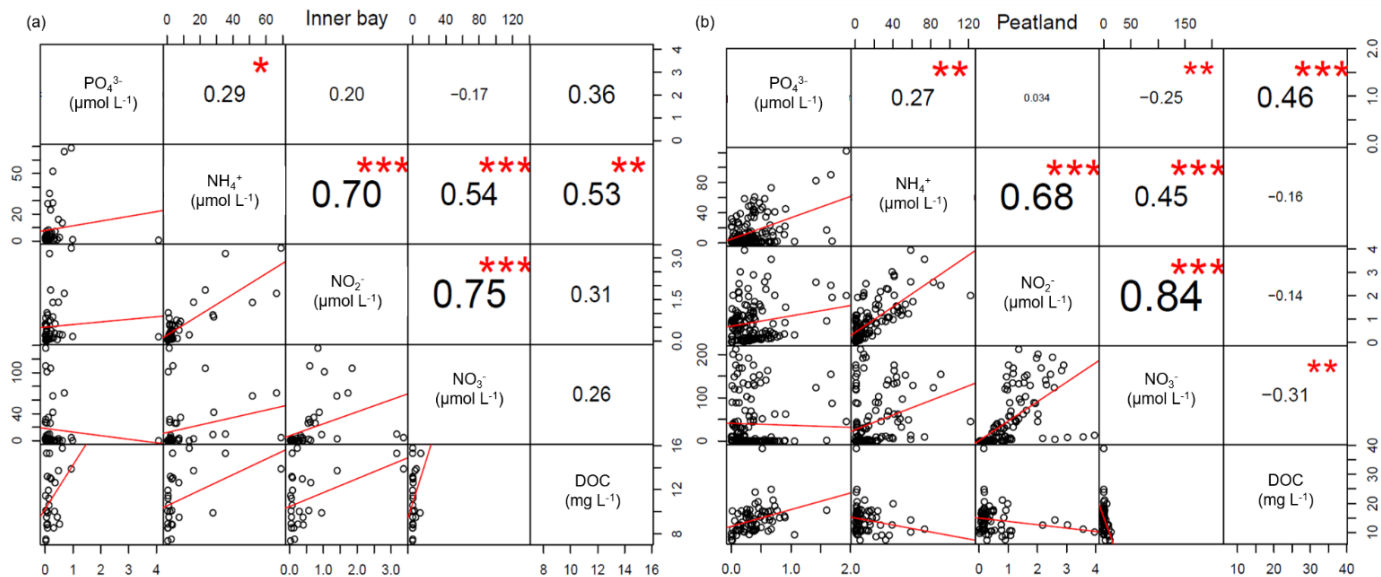
860 **Appendix D: Nutrient cross plots**

Cross plots with linear regression analyses were generated for nutrients (NH_4^+, NO_3^-, NO_2^-, PO_4^{3-}) and DOC concentrations across all seasons to investigate potential correlations (Figure D1). Significant correlations are shown with red asterisks ($p < 0.05$).

This page contains no comments


865 **Figure D1.** Cross plots of the measured nutrient (NH_4^+, NO_3^-, NO_2^-, PO_4^{3-}) and DOC concentrations in (a) the inner bay and (b) the peatland across all seasons. Significant correlations are indicated by asterisks.

Data availability. The raw data used in this study are archived at http://doi.io-warnemuende.de/10.12754/data-2022-0003. The calculated GHG emission data used in this study are archived at http://doi.io-warnemuende.de/10.12754/data-2022-
870 0004.

Author contributions. All authors designed the concept of the study. DLP, AB and CNG conducted the field work, data analysis, and interpretation. DLP and AB wrote the first draft of the manuscript. DLP created the figures and organized the data. AB conducted the statistical analysis. CNG wrote sections of the manuscript. All authors contributed to manuscript
875 revision and approved the submitted version.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. The authors would like to thank Cindy Hoppe and Henning Sack for their great support during the field
880 work; Lara Prelle, Petra Mutinova and the Biologische Station Zingst (all University of Rostock) for providing and measuring some additional nutrient data; Christian Burmeister, Dr. Stefan Otto (both IOW) and Dr. Stefan Köhler (University of Rostock) for their technical laboratory assistance; Dr. Joachim Dippner, Dr. Marvin Lorenz and Dr. Christiane Hassenrück (all IOW) for their help on the nutrient export calculation and statistical analyses, respectively. Dr. Bita Sabbaghzadeh and Dr. Oliver Schmale (both IOW) provided valuable feedback on the manuscript. We are grateful to the
885 Ostseestiftung and especially to Rasmus Klöpper, who guided the cooperation required for the project and provided valuable
