**Abstract.** According to modelling studies, ocean alkalinity enhancement (OAE) is one of the proposed carbon dioxide removal (CDR) approaches with large potential, and the beneficial side effect of counteracting ocean acidification. The real-world application of OAE, however, remains unclear as most basic assumptions are untested. Before large-scale deployment can be considered, safe and sustainable procedures for the addition of alkalinity to seawater must be identified and governance established. One of the concerns is the stability of alkalinity when added to seawater. Seawater is already supersaturated with respect to calcium carbonate minerals, and an increase in total alkalinity together with a corresponding shift in carbonate chemistry towards higher carbonate ion concentrations would result in further increase in supersaturation, and potentially to solid carbonate precipitation. Precipitation of carbonate minerals consumes alkalinity and increases dissolved CO<sub>2</sub> in seawater, thereby reducing the efficiency of OAE for CO<sub>2</sub> removal. In order to address the application of alkaline solution as well as fine particulate alkaline solids, a set of six experiments was performed using natural seawater with alkalinity of around 2,400 μmol/kgw. The application of CO<sub>2</sub>-equilibrated alkaline solution bears the lowest risk of losing alkalinity due to carbonate formation if added total alkalinity (ΔTA) is less than 2,400 μmol/kgw. The addition of reactive alkaline solids can cause a net loss of alkalinity if ΔTA > 600 μmol/kgw (e.g., for Mg(OH)<sub>2</sub>). Commercially available Ca(OH)<sub>2</sub> causes in general a net loss in TA for the tested amounts of TA addition, which has consequences for suggested use of slurries supplied from ships. The application of excessive amounts of Ca(OH)<sub>2</sub>, exceeding a threshold for alkalinity loss, resulted in a massive increase in TA (> 20,000 μmol/kgw) at the cost of lower efficiency and resultant high pH values > 9.5.

Our results indicate that using an alkaline solution instead of reactive alkaline particles can avoid carbonate formation, unless alkalinity addition shifts the system beyond critical supersaturation levels. To avoid the loss of alkalinity and dissolved inorganic carbon (DIC) from seawater, the application of reactor techniques can be considered. These techniques produce an equilibrated solution from alkaline solids and CO<sub>2</sub> prior to application. Differing behaviours of tested materials suggest that

35 standardized engineered materials for OAE need to be developed to achieve safe and sustainable OAE with solids, if reactors  
technologies should be avoided.

## 1 Introduction

The impacts of climate warming are increasingly severe (IPCC, 2021). To tackle this problem, the 2°C target was stipulated  
in the 2015 Paris Agreement (UNFCCC, 2015). While many countries claim to have shown efforts to decrease greenhouse gas  
40 emissions since, the overall emissions are still rising (Friedlingstein et al., 2021) and it seems now improbable to reach the  
target by mitigation alone, without the help of negative emission technologies (NETs) (IPCC, 2021). However, most discussed  
NETs or carbon dioxide removal (CDR) technologies are still immature for upscaling or even ready for operation.

Ocean Alkalinity Enhancement (OAE) is one of the CDR strategies being considered (NAS, 2021). However, it is far from the  
application stage because its potential impacts have yet to be understood as well as practicalities of employment, like suitable  
45 monitoring and verification schemes. This is due to the lack of laboratory and field experiments. Consequences of application  
and its optimal deployment need to be determined. There are a number of model studies (Köhler et al., 2010; Ilyina et al.,  
2013; Lenton et al., 2018; Kheshgi, 1995; González and Ilyina, 2016) focusing on the consequences of OAE at the global scale  
or the applicability via (cargo) ships (Caserini et al., 2021). They are, however, based on a series of assumptions, e.g., that  
added alkalinity remains stable, is not lost or negative TA could be a consequence, and that alkalinity can be technically added  
50 to seawater.

One of the key questions to be solved for OAE is the stability of the added alkalinity (Moras et al., 2021). Additional alkalinity  
loss via carbonate phase formation (causing CO<sub>2</sub> leakage), either via inorganic processes or triggered by biological activity,  
should be avoided. The carbonate supersaturation level is a driver for possible formation of new carbonate phases (Koishi,  
2017). After nucleation from a bulk solution and for the growth to proceed, an energy barrier at the interface between the new  
55 phase and the surrounding solution matrix must be overcome (Koishi, 2017; Sear, 2007).

Carbonate formation in seawater, filtered with 0.2 µm filters to remove particles, with a salinity around 35 at 25°C, starts at a  
saturation level of  $\Omega_{\text{calcite}}$  around 19-20 (Morse and He, 1993), which corresponds to an  $\Omega_{\text{aragonite}}$  of around 12.5-13.5. Filtering  
of water is for avoiding nuclei for condensation or providing surfaces for carbonate formation (Wurgaft et al., 2021).

Addition of alkalinity without equilibrating the water with the atmospheric CO<sub>2</sub> causes high saturation levels (due to more  
60 pronounced shifts in the carbonate system). Even under optimal conditions for air-sea gas exchange, CO<sub>2</sub> equilibration in a  
natural system will take weeks to months (Jones et al., 2014). Such a non-equilibrated system would be representative for any  
OAE application where CO<sub>2</sub> uptake is not actively facilitated, or where ocean mixing of waters and ingassing is slow.

In order to test for the stability of alkalinity after simulated OAE application, this study aims to address the following five  
questions:

65

70

- 1) What is the efficiency advantage using preproduced, CO<sub>2</sub>-equilibrated alkaline solutions over non-equilibrated alkaline solutions?
- 2) Do naturally occurring particles in the ocean water affect the stability range of added alkalinity?
- 3) Are fast reacting solid alkaline materials like Ca(OH)<sub>2</sub> or even slower ones like Mg(OH)<sub>2</sub> useful for adding alkalinity to the seawater?
- 4) Does lost alkalinity due to carbonate formation recover due to redissolution to some part?
- 5) At which elevated bulk solution saturation levels can potential loss of alkalinity be expected?

## 2 Methods

In order to understand the consequences of different application procedures, materials and boundary conditions for sustainable application of OAE, a set of six experiments was designed (Table 1) using these basic system setups:

- I A CO<sub>2</sub>-equilibrated system, using an aqueous solution for OAE, testing 4 days.
- II A non-CO<sub>2</sub>-equilibrated system using an aqueous solution for OAE, testing 4 days.
- III A CO<sub>2</sub>-equilibrated system with/without added carbonate particles and, using aqueous solution for OAE, testing a period of ~90 days.
- IV A non CO<sub>2</sub>-equilibrated system, using solid particles of magnesium hydroxide (Mg(OH)<sub>2</sub>) for OAE, testing 4 days.
- V A non CO<sub>2</sub>-equilibrated system, using solid alkalinity of Ca(OH)<sub>2</sub> for OAE and forcing TA loss to study TA recovery potential, testing 10 days.
- VI Adding excessive amounts of alkaline particles to test if TA-loss can be avoided, testing 24 hours.

**Table 1:** Overview on the 6 experiments conducted (I-VI). Abbreviations: abiotic (a), seawater filtered with 0.2 μm filters to remove plankton, and biotic (b), seawater filtered with 55 μm filters to remove larger plankton. The column CO<sub>2</sub> refers to equilibrated to atmospheric CO<sub>2</sub> levels (eq.) or not (neq.). ΔTA is the added alkalinity range per experiment.

#	biotic abiotic	material	CO <sub>2</sub>	setup			ΔTA [μmol/kgw]	concept
				filtered	reactor	storage		
I	a	Na <sub>2</sub> CO <sub>3</sub> / NaHCO <sub>3</sub>	eq.	0.2 μm	0.5 L bottle	dark	0 - 2,400	CO <sub>2</sub> -equilibrated, ΔTA 300 μmol/kgw steps, TA addition with stock solution, runtime 4 days
	b			55 μm	1.2 L bottle	climate chamber	0 - 1,200	
II	a	NaOH	neq.	0.2 μm	0.5 L bottle	dark	0 - 2,400	Non-CO <sub>2</sub> -equilibrated, ΔTA 300 μmol/kgw steps, TA addition with stock solution, runtime 4 days
	b			55 μm	1.2 L bottle	climate chamber	0 - 1,200	
III	b	Carbonate precipitate	eq.	-	8.0 L bottle	harbour	0/2,100/2,400	CO <sub>2</sub> -equilibrated, TA-addition with stock solution, trigger precipitation with seed material, 90 days
IV	a	Mg(OH) <sub>2</sub>	neq.	0.2 μm	1.2 L bottle	climate chamber	0 - 2,400	Non-CO <sub>2</sub> -equilibrated, ΔTA 600 μmol/kgw steps, TA addition with solid alkaline material, runtime 4 days
	b			55 μm			+ 34,288	
V	a	Ca(OH) <sub>2</sub>	neq.	0.2 μm	0.5 L flask	shaking table	5,400	pH/TA development over 10 days, redissolution, solid alkaline material
VI	a	Mg(OH) <sub>2</sub> / Ca(OH) <sub>2</sub>	neq.	0.2 μm	0.5 L flask	shaking table	-	TA loss/gain of various weights of added solid alkaline materials, runtime 1 day

To examine how planktonic organisms and particles naturally occurring in the ocean might affect OAE performance, e.g., by serving as condensation nuclei for mineral precipitation, we performed two separate sets of experiments including and  
90 excluding biogenic particles (termed biotic and abiotic hereafter). For the abiotic approach seawater was filtered through a 0.2  $\mu\text{m}$  PC-filter. Seawater for the 'biotic' approach was filtered through a 55  $\mu\text{m}$  filter to exclude larger and rare organisms (e.g., mesozooplankton), but keep the remainder.

For all experiments **I** to **IV**, oligotrophic coastal seawater ( $\text{TA} \approx 2,411 \mu\text{mol/kgw}$ ,  $\text{S} \approx 36.6$ ,  $\text{T} \approx 23^\circ\text{C}$ ) was taken at 4 metres  
95 depth in the vicinity of the harbour of Taliarte, Gran Canaria, on 2021-09-16 (**I+II+IV**) and 2021-09-30 (**III**). Seawater for the alkalinity recovery test, experiment **V**, was taken from the open North Sea (German Bight, N 54.93 E 6.43). CO2SYS (Pierrot et al., 2006) was used to determine the amount of alkaline solution/solid material needed to increase TA in several steps.

## 2.1 Experiment I and II: Comparing CO<sub>2</sub> equilibrated versus non-equilibrated alkalinity enhancement

For the abiotic **equilibrated system (Ia)** nine batch solutions were prepared adding TA in nine steps of 300  $\mu\text{mol/kgw}$ , starting  
100 at an initial alkalinity value of  $\sim 2,400 \mu\text{mol/kgw}$  (fresh untreated seawater,  $\Delta\text{TA}_0$ ), with a maximum final treatment of  $\sim 4,800 \mu\text{mol/kgw}$  ( $\Delta\text{TA}_{2400}$ ). The TA-enhancement was achieved by adding calculated volumes of 0.5 M  $\text{NaHCO}_3$  and 0.5 M  $\text{Na}_2\text{CO}_3$  solutions using calculations from CO2SYS to ensure equilibrated conditions. While preparing stock solutions with  $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$ , solids dissolved entirely within seconds to several minutes. After taking an initial sample (day 0) from every  
105 batch, the remaining solutions were filled in portions of  $400.0 \text{ g} \pm 0.5 \text{ g}$  into 500 ml Dickson bottles (bottles for seawater TA and DIC standards), each for a duration of 24 h or 96 h. All bottles were stored in the dark, unsealed - open to the laboratory atmosphere and kept at a constant temperature of 24  $^\circ\text{C}$ .

The exact same procedure was followed for the abiotic **non-equilibrated system (IIa)**, except using a 0.5 M NaOH solution for the alkalinity enhancement and preventing gas exchange by filling the bottle to the top ( $\approx 525 \text{ g}$ ) and capping them airtight without headspace.

110 For the biotic **equilibrated system (Ib)** and **non-equilibrated system (IIb)** 1.2-L polycarbonate bottles were used, both filled to the top and capped airtight. Bottles were stored in a climate chamber (24  $^\circ\text{C}$  and 12/12 hours light/dark intervals) over the duration of the experiment to ensure a stable environment for the microbial community. The same seawater, resources and procedures for alkalinity enhancement were utilized as in the abiotic experiments **Ia** and **IIa**. Samples were taken just at the start (day 0) and the end of the experiment (day 4) to avoid headspace in the bottles. Starting with the initial value of seawater  
115 ( $\Delta\text{TA}_0$ ) the alkalinity was increased in eight 150  $\mu\text{mol/kgw}$  steps to 3,600  $\mu\text{mol/kgw}$  ( $\Delta\text{TA}_{1200}$ ).

## 2.2 Experiments III: Testing the role of particles as condensation nuclei for mineral precipitation

We prepared a solution in equilibrium with the atmosphere as described for experiment **I** for the two highest  $\Delta\text{TAs}$ , namely  $\Delta\text{TA}_{2100}$ ,  $\Delta\text{TA}_{2400}$ . Solutions were placed into 8L PET bottles in two treatments: one without adding particles and one with adding previously precipitated carbonates (120 mg wet weight each) as seed material (precipitation nuclei), gained from a

120 preceding experiment. The closed bottles were placed next to the pier in the harbour of Taliarte, Gran Canaria, about 1.5 m  
below the water surface. Samples were taken at days 0, 2, 4, 6, 8, 10. After the 10 days of processing the content of the bottles  
was transferred to 500 ml Dickson bottles and left alone closed to the atmosphere and in the dark for another 80 days. Two  
additional samples were collected at days 46 and 90.

## 2.3 Experiments IV, V and VI: Testing alkalisation with solid $\text{Mg}(\text{OH})_2$ and $\text{Ca}(\text{OH})_2$ .

### 125 2.3.1 Experiment IV: $\text{Mg}(\text{OH})_2$

While for experiments **I** and **II** fast dissolving materials with relatively high solubilities were used to produce an alkaline  
solution, solid materials were used in experiments **IV**, **V** & **VI**. Magnesium hydroxide in experiment **IV** was added as a powder  
directly into the reactor bottles. Because of a lower reactivity the material was not to be expected to dissolve immediately, so  
dissolution took place throughout the experimental duration of four days. Two different  $\text{Mg}(\text{OH})_2$  materials from the  
130 companies (Negative Emissions Materials (brucite I) and Carl Roth (brucite II)) were utilized to compare their behaviour in  
dissolution and generation of alkalinity. Brucite I is a substance derived from the dissolution of olivine rich material, brucite  
II an industrial product prepared for rapid dissolution. Both, abiotic and biotic approaches (distinction 0.2  $\mu\text{m}$  filtration) were  
conducted in 1.2-L PC bottles and followed the same procedure as in **Ib** and **Iib**, filled airtight to the top and kept in the climate  
chamber, after mixing them gently for 5 minutes. The mass of added magnesium hydroxide was calculated to yield the same  
135 increase in alkalinity as in experiments **I** and **II**, assuming total dissolution could be achieved. The target concentrations ranged  
from 12.8 mg/kgw to 666 mg/kgw and representing solid alkalinity addition steps of  $\Delta\text{TA}_{600}$ ,  $\Delta\text{TA}_{1200}$ ,  $\Delta\text{TA}_{1800}$ ,  $\Delta\text{TA}_{2100}$ ,  
 $\Delta\text{TA}_{2400}$ , and  $\Delta\text{TA}_{34,288}$ . The latter high addition was intended to simulate an approach assuming large amounts of particles  
being added, e.g., via ship disposal. In experiment **IV** subsamples were taken at the start of the experiment and after 24 and 96  
hours. The brucite material was dried at 40°C for 72 hours before the experiments.

### 140 2.3.2 Experiment V: Alkalinity recovery after mineral precipitation

This experiment focused on redissolution of alkalinity, initially consumed due to carbonate precipitation after  $\text{Ca}(\text{OH})_2$   
application. 0.2 g  $\text{Ca}(\text{OH})_2$  ( $\Delta\text{TA}_{5400}$ ) were dissolved in 500 ml PC-Erlenmeyer-flasks filled with 300 g of North Sea water  
(0.2  $\mu\text{m}$  filtered) and left open to the laboratory atmosphere. The experiment was conducted in 12 timesteps from 15 min to  
10 days, each time with three replicates and one control flask each without any material. All experimental flasks were  
145 permanently placed on a shaking table (120 rpm). The pH value of the seawater was continuously monitored in 5 minutes  
steps.

### 2.3.3. Experiment VI: Thresholds – the swing from TA loss to TA gain again

The experiment was set up to check if potential threshold values for TA loss/gain after 24 hours exist in case larger amounts  
of solids are dissolved than in the previous experiments, resulting in the loss of TA. A gradient of added solid masses to

150 seawater, using the brucite II (experiment **IV**) and the  $\text{Ca}(\text{OH})_2$  (experiment **V**) were used. For this the same seawater as in  
experiment **V** was used adding up to 13.3 g brucite or 2 g  $\text{Ca}(\text{OH})_2$  per kg of seawater and measuring TA after 24 hours. The  
same bottles (500 ml PC flasks) and experimental setup (shaking table) as in experiment **V** was used.

### 2.3 Measurements

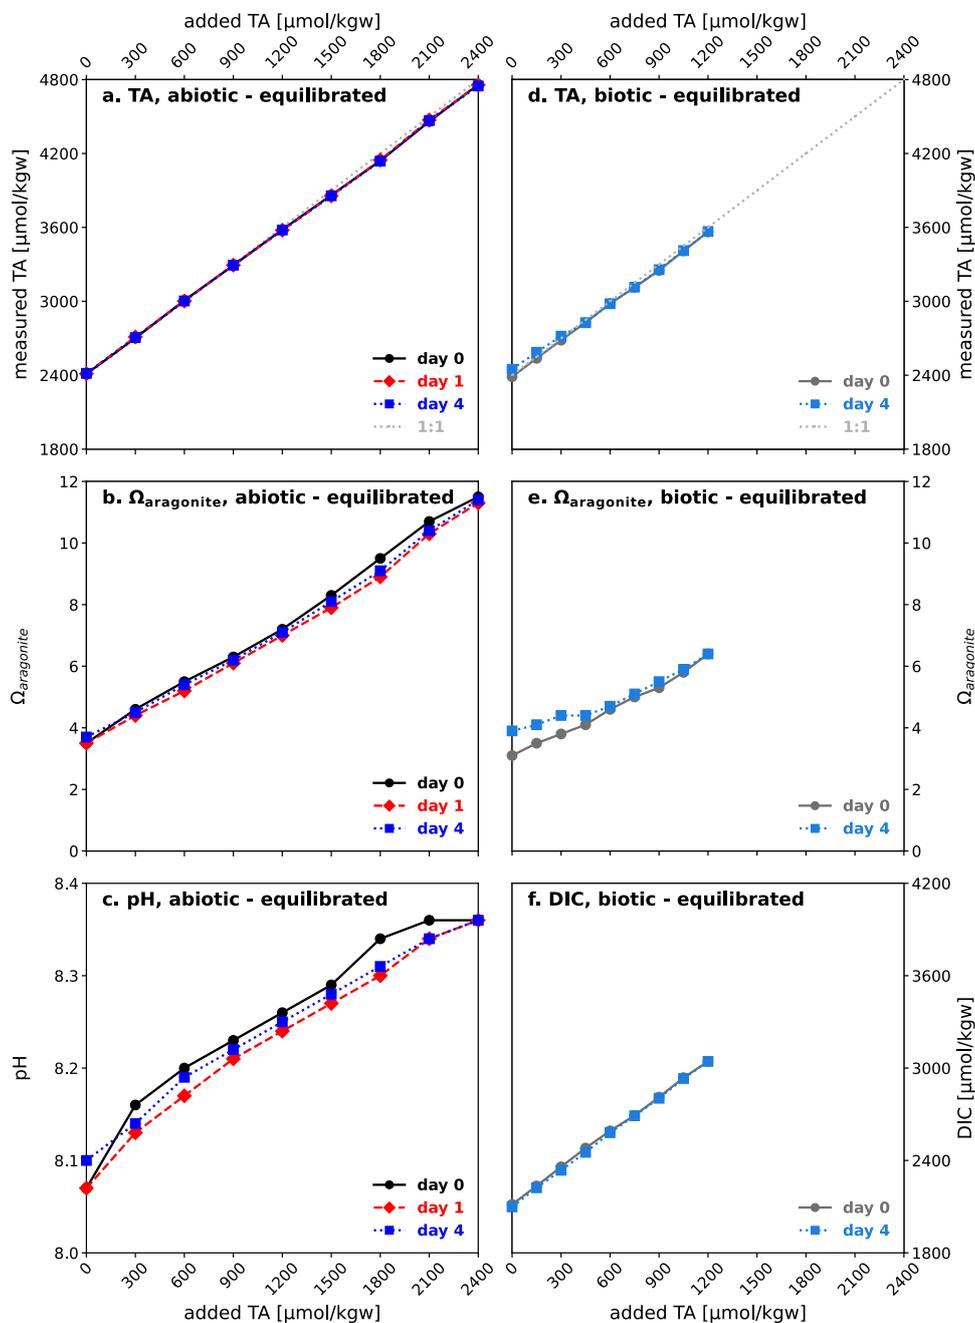

155 Immediately after the end of an experiment each sample was filtered (0.2  $\mu\text{m}$ ) to stop possible further reaction on larger  
particles and remove the biomass from the biotic approaches for further analysis. While filtering, all systems were kept airtight  
as much as possible to prevent gas exchange with the atmosphere. Samples were measured for total alkalinity (TA), pH,  
salinity, conductivity, temperature, and some for dissolved inorganic carbon (DIC). TA was determined by titration with 0.1 M  
sulfuric acid within an 862 Compact Titrosampler (Metrohm) - for samples of day 46 and 90 in experiment **III** and all samples  
of experiment **V** a different titrator (888 Titrand, Metrohm) with a 0.02 M hydrochloric acid was used. DIC was analysed by  
160 infrared absorption, using a LI-COR LI-7000 on an AIRICA system (MARIANDA, Kiel). Calibration of TA and DIC  
measurements was determined against certified reference materials (CRM batches 143 and 190), supplied by A. Dickson,  
Scripps Institution of Oceanography (USA). Measurements were made on two technical replicates for TA and three for DIC.  
Final values are numerical averages of these replicates. To analyse for pH, salinity, conductivity and temperature a WTW  
multimeter (MultiLine® Multi 3630 IDS, pH-probe: SenTix 940 pH-electrode, conductivity: TetraCon 925 cell, Xylem) was  
165 employed. The pH-probe was calibrated with WTW buffer solutions according to NIST/PTB in 4 steps (1.679-9.180 at 25°C)  
For the TetraCon 925 cell 0.01 mol/L KCl calibration standards for conductivity cells (WTW, traceable to NIST/PTB) was used.  
Variables such as  $\text{pCO}_2$  or aragonite saturation state ( $\Omega_{\text{aragonite}}$ ) were calculated using measured values of TA and pH (or DIC  
in case of experiment **I** (biotic) and experiment **II**) with CO2SYS (Pierrot et al., 2006) Excel sheet. The carbonate dissociation  
constants ( $K_1$  and  $K_2$ ) of Lueker et al. (2000) were used.

## 170 3 Results

### 3.1 Experiment I: Equilibrated alkalisation

By adding defined amounts of a  $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$  solution,  $\text{CO}_2$ -equilibrated TA addition in steps of  $300 \mu\text{mol/kgw}$  for abiotic and  $150 \mu\text{mol/kgw}$  for biotic approaches was achieved, yielding a range from  $\Delta\text{TA}_0$  ( $\text{TA}=2,411 \mu\text{mol/kgw}$ ,  $\Omega_{\text{aragonite}}=3.5$ ,  $\text{pH}=8.07$ ) up to  $\Delta\text{TA}_{2400}$  ( $\text{TA}=4,750 \mu\text{mol/kgw}$ ,  $\Omega_{\text{aragonite}}=11.4$ ,  $\text{pH}=8.36$ ) for the abiotic and  $\Delta\text{TA}_{1200}$  ( $\text{TA}=3,567 \mu\text{mol/kgw}$ ,  $\Omega_{\text{aragonite}}=6.4$ ,  $\text{pH}=8.15$ ) for the biotic experiment (Fig. 1). The alkalinity enhancement has taken place almost in a linear manner close to ideal ('1:1' dotted-grey line in Fig. 1a and d). As the solution was initially  $\text{CO}_2$ -equilibrated with current atmospheric conditions, DIC,  $\Omega_{\text{aragonite}}$  and pH-value increased proportionally. Neither in the abiotic ( $0.2 \mu\text{m}$  filtered) nor in the biotic ( $55 \mu\text{m}$  filtered) treatment, including living planktonic organisms, a detectable loss in TA could be observed after 1 and 4 days.  $\Omega_{\text{aragonite}}$  values remained with its highest value of 11.4 just below the critical threshold of around 12.5 for  $\Omega_{\text{aragonite}}$  at salinity of 36.5 (corresponding to  $\Omega_{\text{calcite}} \sim 19$  as identified by Morse and He (1993)), and prevented a potential loss of alkalinity due to precipitation. The pH-value followed a quasi-linear trend with added TA, and increased to 8.36 for the abiotic  $\Delta\text{TA}_{2400}$  (Fig. 1c). For the investigated time period of 4 days a doubling of the original TA of filtered natural ocean water up to  $4,750 \mu\text{mol/kgw}$  could be realised, while carbonate chemistry remained stable in all TA treatments.

185 **Figure 1: Temporal development after CO<sub>2</sub> equilibrated alkalisation:** (a, b, c) abiotic set-up, (d, e, f) biotic set-up; (a, d) added vs. measured alkalinity; (b, e) aragonite saturation state ( $\Omega_{\text{aragonite}}$ ) in relation to added alkalinity; (c) pH in relation to added alkalinity; (f) DIC in relation to added alkalinity. Black/grey symbols correspond to start of the experiment, red after 1 day and blue after 4 days. Initial conditions of used seawater:  $\Delta\text{TA}_0 \approx 2,411 \mu\text{mol/kgw}$ ,  $\Omega_{\text{Ar}} = 3.5$ , pH = 8.07.

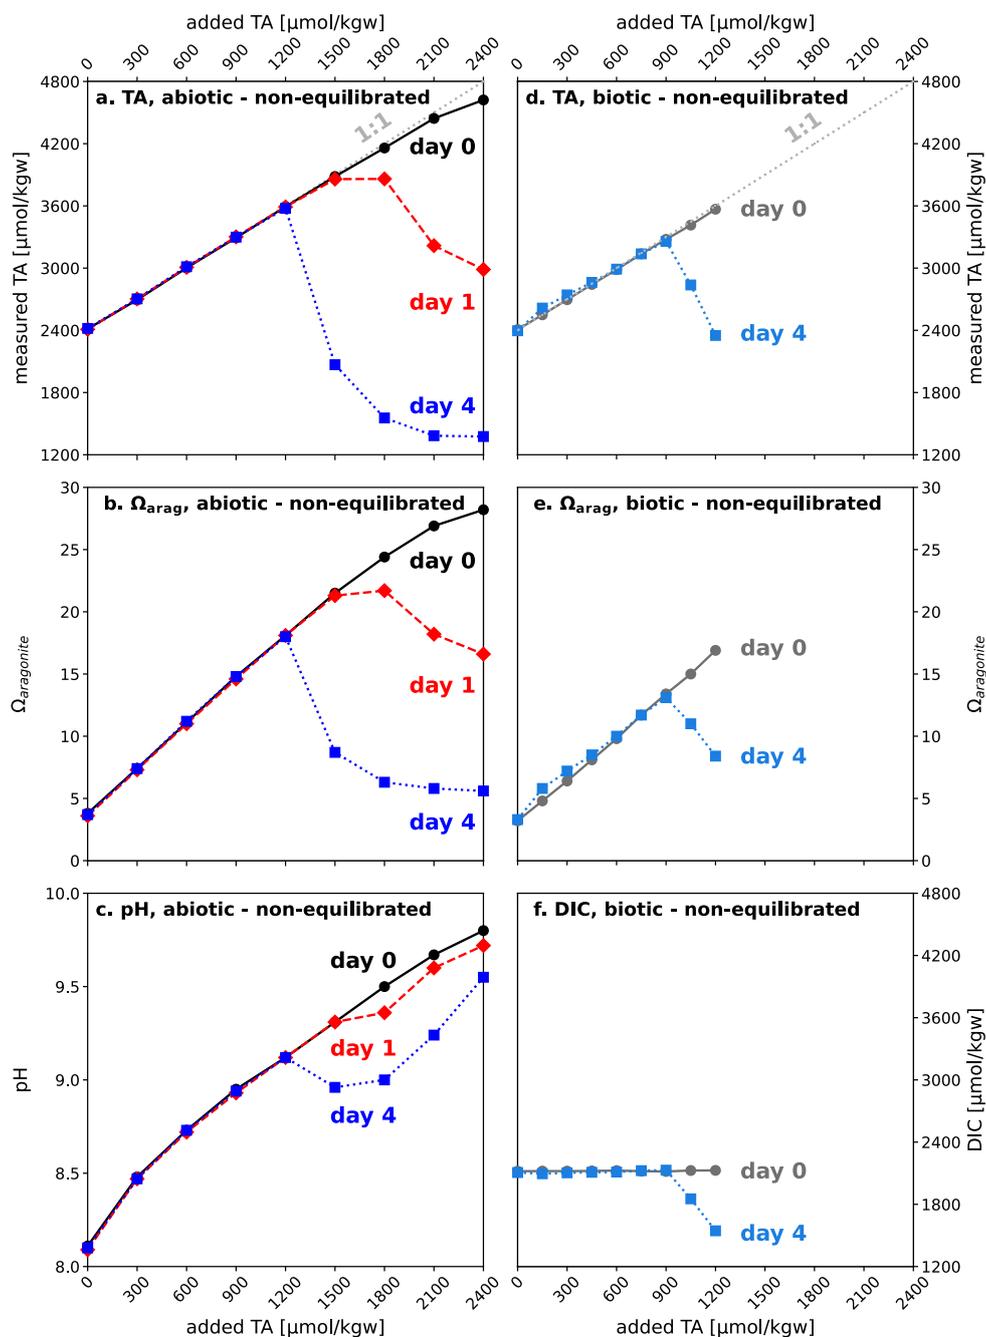

### 3.2 Experiment II: Non-equilibrated alkalinisation

190 In the non-equilibrated experiments **II**, solely TA was increased by using a 0.5 M NaOH stock solution while DIC remained at the initial seawater level of 2,120  $\mu\text{mol/kgw}$ . Equilibration with the atmosphere was inhibited by closing the sample containers air-tight. TA increased at the highest level ( $\Delta\text{TA}_{2400}$  with target level  $\sim 4,800$   $\mu\text{mol/kgw}$ ) to only 4,622  $\mu\text{mol/kgw}$  in the abiotic approach, with  $\Omega_{\text{aragonite}} \sim 28$  and a pH of 9.80. An immediate precipitation of 0.1-2 cm long mineral needles was observed floating in the abiotic reactor bottles just seconds after TA addition, suggesting nucleation happens in the water.

195 Precipitation on the wall of the vessel was not visible by eye. This is also reflected by a slight deviation from the idealised TA-addition line in Fig. 2a ('1:1' dotted-grey line), which indicates a noticeable decrease for the two highest TA additions ( $\Delta\text{TA}_{2100}$  and  $\Delta\text{TA}_{2400}$ ).  $\Delta\text{TA}_0$  to  $\Delta\text{TA}_{1800}$  maintained their intended alkalinity in both the abiotic and biotic treatments on day 0. After 1 day alkalinity loss can also be observed for  $\Delta\text{TA}_{1800}$ . The decline in TA for the three highest TA additions was now accompanied by visible precipitation on the inner wall of the reactors, suggesting that at this stage wall surfaces of the vessel

200 acted as nucleation points. Alkalinity loss continued and on day 4 was also detected in the next lower treatment. At this stage the alkalinity in the four highest treatments dropped below values prior to alkalinity addition, marking a net loss of alkalinity compared to the initial seawater water level. Associated to this,  $\Omega_{\text{aragonite}}$  declined to values of 5.6 to 6.3 on day 4 (Fig. 2b), approaching the initial value of  $\sim 3.5$ . pH, on the other hand, remained comparatively high, with only small decreases of 0.3-0.4 units down to values of 9-9.5 (Fig 2). In the abiotic treatments  $\Delta\text{TA}_0$  to  $\Delta\text{TA}_{1200}$  alkalinity was stable and no precipitation

205 was observed within the first four days. In contrast, in the biotic setup alkalinity loss already occurred in  $\Delta\text{TA}_{1050}$  and  $\Delta\text{TA}_{1200}$  treatments at least on day 4, i.e. at lower alkalinity additions than in the abiotic treatments (Fig. 2d), with corresponding declines in  $\Omega_{\text{aragonite}}$  and DIC (Fig. 2e and f).

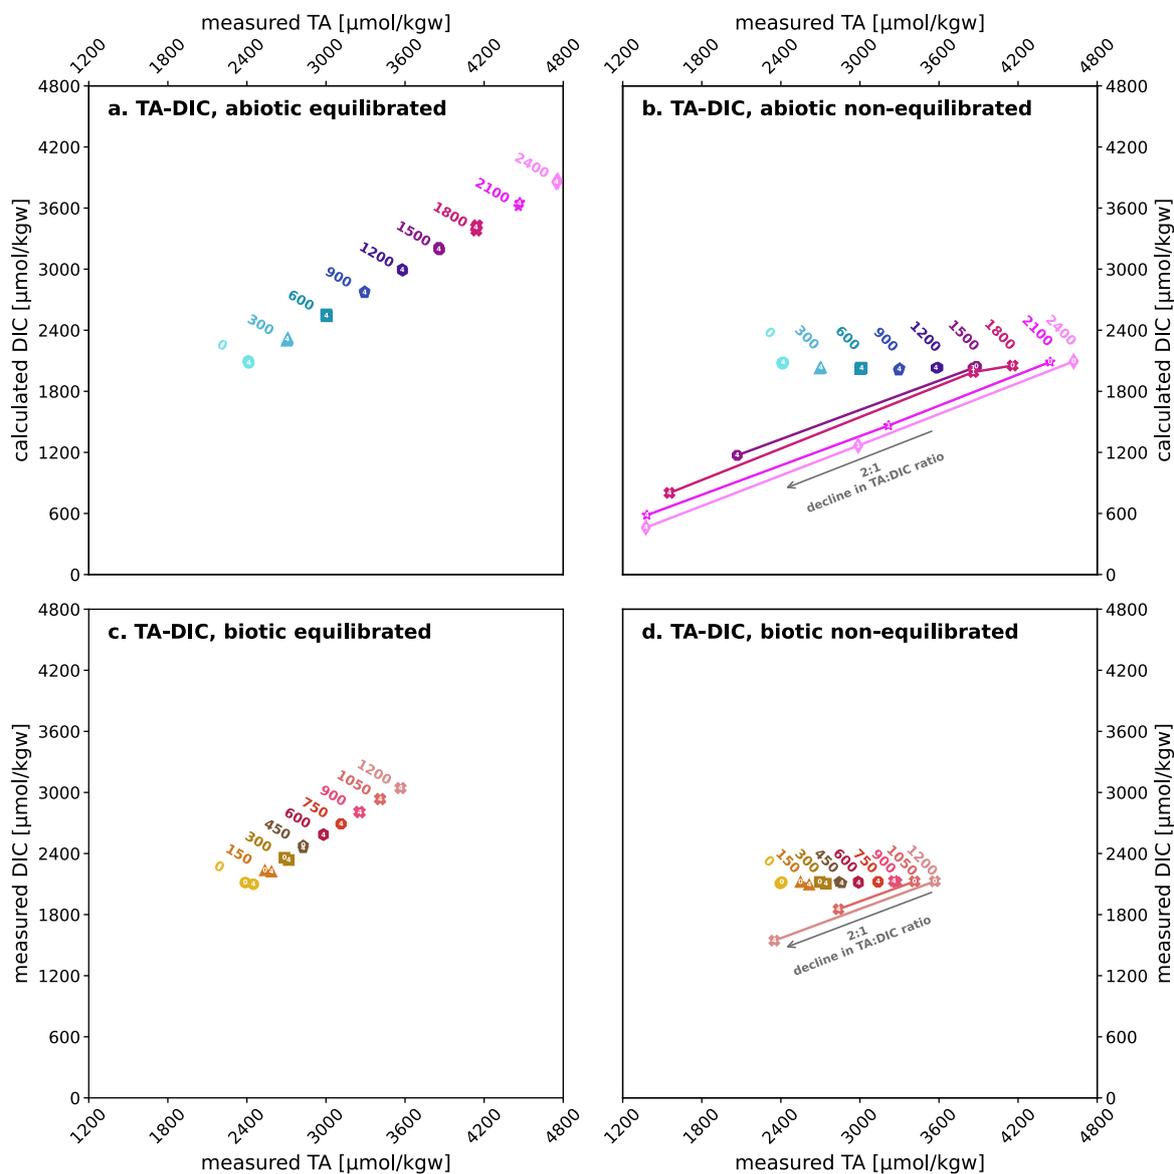

210 **Figure 2: Temporal development after non-equilibrated alkalisation:** (a, b, c) abiotic set-up, (d, e, f) biotic set-up; (a, d) added vs. measured alkalinity; (b, e) aragonite saturation state ( $\Omega_{\text{aragonite}}$ ) in relation to added alkalinity; (c) pH in relation to added alkalinity; (f) DIC in relation to added alkalinity. Black/grey symbols correspond to start of the experiment, red after 1 day and blue after 4 days. Note the different ranges of added alkalinity in the abiotic and biotic set-up. The slightly higher start  $\Omega_{\text{aragonite}}$  for the biotic treatment at day 4 compared to day 1 is because  $\Omega_{\text{aragonite}}$  was calculated by TA and DIC, while for the abiotic experiment using TA and pH.

### 3.3 Experiments I & II: TA/DIC development in equilibrated versus non-equilibrated alkalisation

215 While in the experiment simulating equilibrated alkalisation TA and DIC were added (as  $\text{NaHCO}_3$  and  $\text{Na}_2\text{CO}_3$ ) in proportions (Fig. 3a, c) to maintain close to atmospheric  $\text{CO}_2$  levels, in the non-equilibrated alkalisation experiment only TA was added (as  $\text{NaOH}$ ) (Fig. 3b, d), simulating alkalisation without any  $\text{CO}_2$  equilibration. Whereas the former yielded comparatively moderate changes in seawater carbonate chemistry, with  $\Omega_{\text{aragonite}}$  values remaining below the critical threshold of around 12.5 (identified by Morse and He, 1993), the non-equilibrated approach caused strong changes in the carbonate system with  $\Omega_{\text{aragonite}}$  values above 20 for  $\Delta\text{TA}_{1500}$  to  $\Delta\text{TA}_{2400}$  and between 15 and 17 for  $\Delta\text{TA}_{1050}$  to  $\Delta\text{TA}_{1200}$ , i.e. well above the critical threshold. Consequently, while precipitation was absent in the abiotic and biotic set-up in the equilibrated treatment, strong alkalinity loss through precipitation occurred in the non-equilibrated experiment. While in the biotic set-up precipitation was observed at  $\Delta\text{TA}_{900}$  and  $\Delta\text{TA}_{1200}$  (starting  $\Omega_{\text{aragonite}}$  15 and 18, Fig. 2b), in the abiotic set-up precipitation only occurred at and above  $\Delta\text{TA}_{1500}$ , with no detectable precipitation at  $\Delta\text{TA}_{1050}$  and  $\Delta\text{TA}_{1200}$  (starting  $\Omega_{\text{aragonite}}$  15 and 17, Fig. 2e). The loss-ratio in TA:DIC was about 2:1 (Fig. 3b, d) in all treatments, indicating the loss of alkalinity due to the precipitation of carbonates. Loss-ratio in TA:DIC for the abiotic set-up were 2.1 for  $\Delta\text{TA}_{1500}$ , 2.1 for  $\Delta\text{TA}_{1800}$ , 2.0 for  $\Delta\text{TA}_{2100}$ , and 2.0 for  $\Delta\text{TA}_{2400}$  and for the biotic set-up 2.1 for  $\Delta\text{TA}_{1050}$  and 2.1 for  $\Delta\text{TA}_{1200}$ .

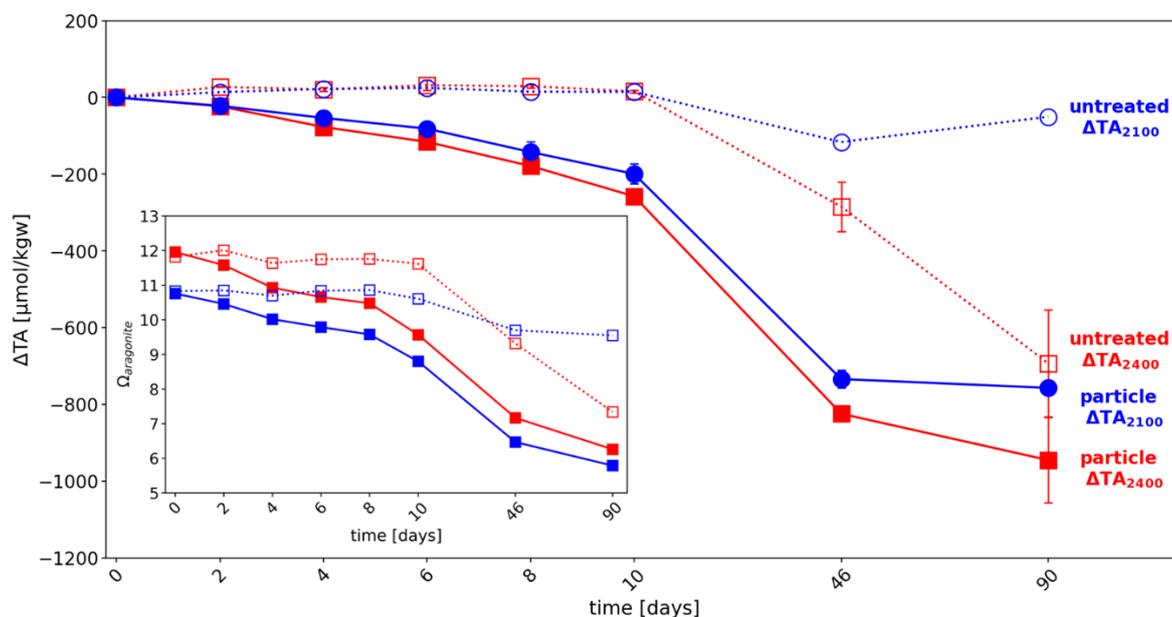

230 **Figure 3: TA versus DIC at the start of the experiment and after precipitation;** (a-b) abiotic after 0, 1 and 4 days, (c-d) biotic after 0 and 4 days, equilibrated alkalisation (left), non-equilibrated alkalisation (right). The  $\Delta\text{TA}:\Delta\text{DIC}$  change ratio of 2:1 indicates that alkalinity loss was due to carbonate precipitation. Sampling days (0, 1 and 4) are written on top of each datapoint marker. Due to overlapping in case of no change in data, the marker description is set up to down.

### 3.4. Experiment III: Long-term stability of added alkalinity in CO<sub>2</sub> equilibrated approach

Experiment III was an extension of experiment I, testing for the long-term (up to 90 days) stability of added alkalinity in the two highest treatment levels (abiotic,  $\Delta TA_{2100}$  &  $\Delta TA_{2400}$ ), where for  $\Delta TA_{2400}$  the start  $\Omega_{\text{aragonite}}$  is 11.9, close to the critical  $\Omega_{\text{aragonite}}$ , while for  $\Delta TA_{2100}$   $\Omega_{\text{aragonite}} \sim 10.8$ . Without adding extra particles for the treatment  $\Delta TA_{2100}$  just 50  $\mu\text{mol/kgw}$  TA were lost after 90 days, while the loss is significantly higher in case of the treatment  $\Delta TA_{2400}$  (693  $\mu\text{mol/kgw}$  TA loss), which was closer to the  $\Omega_{\text{aragonite}}$  of about 12.5, identified as being critical for using filtered seawater. While untreated approaches have shown stable values in the first 10 days of runtime, an immediate and persistent decline in TA could be observed for the treatments with added precipitates from previous experiments, functioning as seed material.  $\Delta TA_{2100}$  with particles decreased by 199  $\mu\text{mol/kgw}$  after 10 days and 757  $\mu\text{mol/kgw}$  after 90 days, while the  $\Delta TA_{2400}$  treatment dropped by 258  $\mu\text{mol/kgw}$  after 10 days and 945  $\mu\text{mol/kgw}$  after 90 days, see Fig. 4a.

As in experiment II precipitation at the walls of the reactors were observed. As the treatments here are close to the supersaturation level where naturally carbonate formation starts, it cannot be ruled out a wall effect caused in the setup with  $\Delta TA_{2400}$  without extra particles the higher loss compared to  $\Delta TA_{2100}$ . Nonetheless experiments in the free water would not face such a wall-effect problem but might be facing a comparable fate due to other surfaces abundant.

**Figure 4: Long-term stability of added alkalinity in CO<sub>2</sub> equilibrated approach:** development of alkalinity loss ( $\Delta TA$ ) over time in the two highest alkalinity treatments of experiment I,  $\Delta TA_{2400}$  (red) and  $\Delta TA_{2100}$  (blue), in untreated mode (dotted lines) and with particle addition (solid line) over time. Insert: Development of  $\Omega_{\text{aragonite}}$  in the above treatments. Error bars denote standard deviations of two measures, except for untreated  $\Delta TA_{2100}$  where only one measurement was taken due to technical problems.

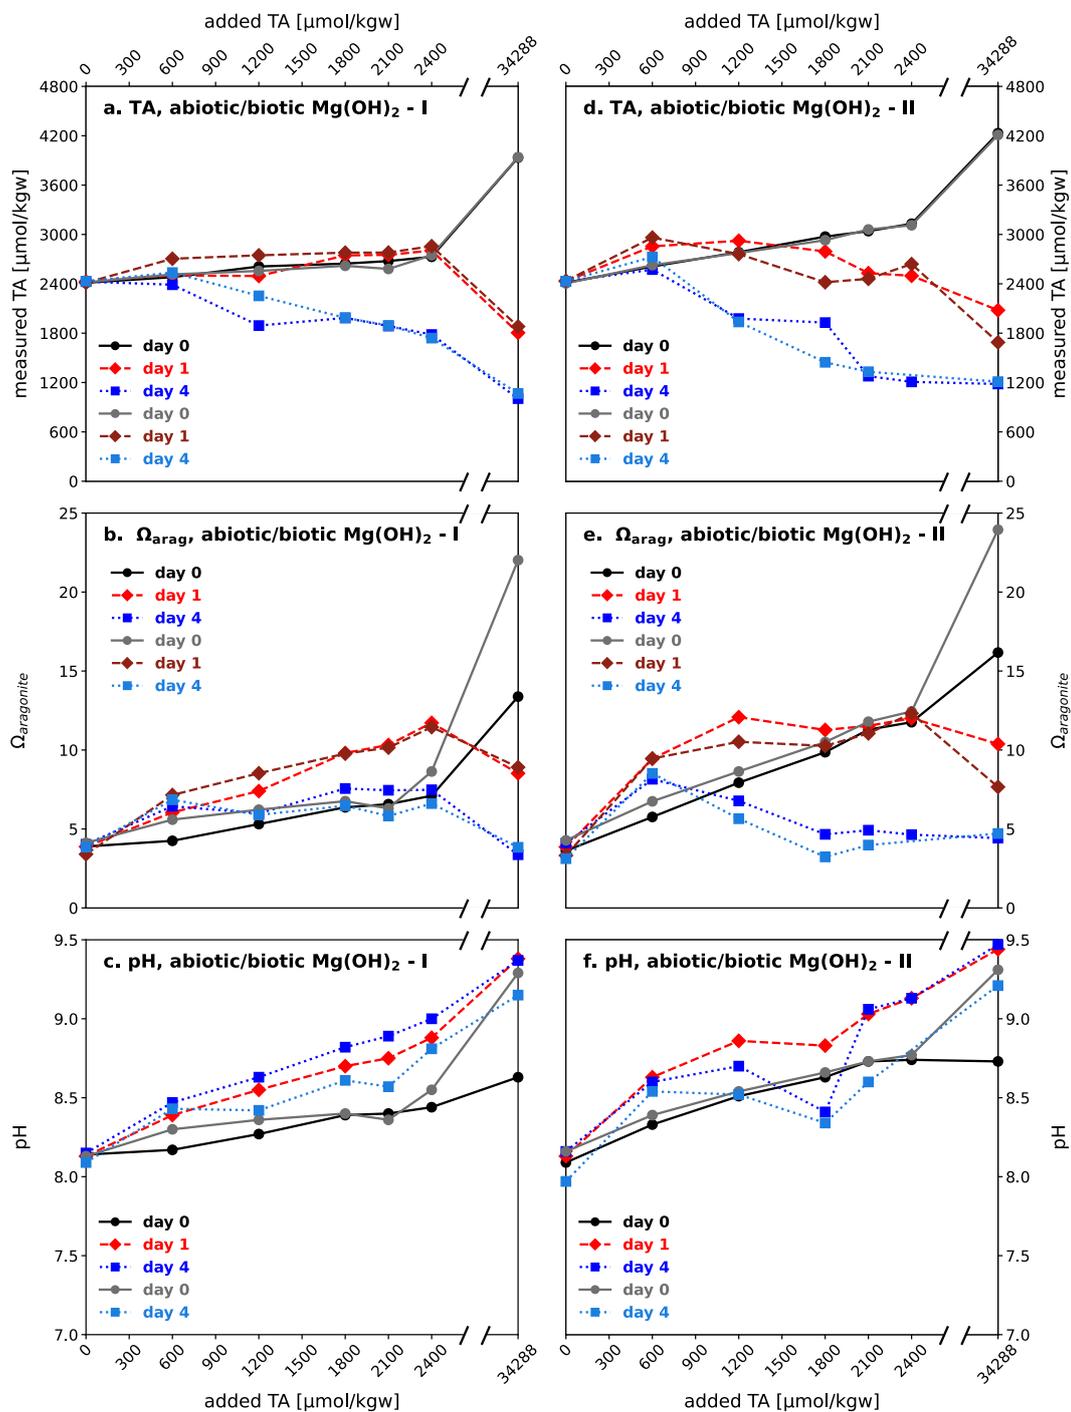

### 3.5 Experiment IV: Alkalinity addition with brucite

255 Unlike in the equilibrated and non-equilibrated experiments **I** and **II**, in which an alkaline solution was applied, brucite ( $\text{Mg}(\text{OH})_2$ ) was added as a solid to enhance alkalinity. While  $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$  (equilibrated) and  $\text{NaOH}$  (non-equilibrated) were fully dissolved in the stock solutions after seconds to several minutes,  $\text{Mg}(\text{OH})_2$  dissolved relatively slowly. Due to a comparatively moderate reactivity in seawater it never reached the point of full dissolution, with the exception of the  $\Delta\text{TA}_{600}$  treatment, which is relatively close to the theoretical solubility of brucite in seawater (determined using PHREEQC, equilibrating seawater with atmospheric conditions) that corresponds to an increase of  $\Delta\text{TA}_{500}$  (Fig. 5d). The consequences were transparent to increasingly blurry suspensions, dependent on the added amounts of material. Except from the  $\Delta\text{TA}_{600}$  each reactor had visible residua at the bottom, right after the addition of the solid material. Consequently, the aspired  $\Delta\text{TA}$  steps have not been reached like in the equilibrated and non-equilibrated treatments in experiments **I** and **II**. This also counts for the highest dosage of 1,000 mg, corresponding to  $\Delta\text{TA}$  of 34,288  $\mu\text{mol}/\text{kgw}$ , see Fig. 5a and d.

260 Excluding the highest dosage, after the addition of brucite I, TA reached only 2,746  $\mu\text{mol}/\text{kgw}$  ( $\Delta\text{TA}=335 \mu\text{mol}/\text{kgw}$ ) for the target of  $\Delta\text{TA}_{2400}$  at day 0, while for brucite II maximum increase in TA was achieved at day 1 for  $\Delta\text{TA}_{600}$ . After 1 day of runtime no treatment achieved the target  $\Delta\text{TA}$  (Fig. 5a). TA collapsed in all reactors below or close to the initial seawater level at day 4 with exception of biotic treatment  $\Delta\text{TA}_{600}$ . The decline of TA occurred in the form of a ‘runaway precipitation’ as labelled by Moras et al. (2021), meaning carbonate formation causes lower TA-levels than the initial values. This process led to lower TA values with higher amounts of added brucite at the end of the experiments.  $\Omega_{\text{aragonite}}$  was enhanced moderately up to a maximum of 7.1 in the bulk solution in the abiotic  $\Delta\text{TA}_{2400}$  reactor at day 0, then increased to 11.7 after day 1, and finally declined to relative stable values of 6.0-7.5 after 4 days. pH-values also just experienced a slight increase up to 8.4 at day 0, reached values of 8.4-8.6 in regular steps after 1 day and continued rising in the same stable proportions to 8.5-9.0 (also see Fig. 5c.).

275 While brucite I formed aggregates of particles being insoluble for the duration of the experiment, brucite II (a commercial product for industrial use optimized) did not form aggregates and dissolved more efficiently, leading to higher TA-levels at day 0. Comparably to brucite I, TA levels for brucite II declined in the following four days well below start TA for treatments  $> \Delta\text{TA}_{600}$ , declining to  $\sim 1,200 \mu\text{mol}/\text{kgw}$  for  $\Delta\text{TA}_{1800-2400}$ , while  $\Omega_{\text{aragonite}}$  for the same range consistently reached values of  $\sim 5$ , or lower. Only  $\Delta\text{TA}_{600}$  remained slightly above the initial seawater TA level after 4 days, but also declined significantly compared to day 0. For experiment **IV** all treatments showed the same general trends, independent of treatment (abiotic, biotic) or type of brucite.

280 The high  $\Delta\text{TA}$  approach using 1,000 mg brucite (corresponding to a theoretical solid material TA addition of 34,288  $\mu\text{mol}/\text{kgw}$ ) reached TA values above 4,000  $\mu\text{mol}/\text{kgw}$  at day 1, an  $\Omega_{\text{aragonite}}$  of 20 and pH-values of 9.6. Immediate precipitation at the base of the bottles was observed. The total TA increase on day 0, however, is on the same general trend.

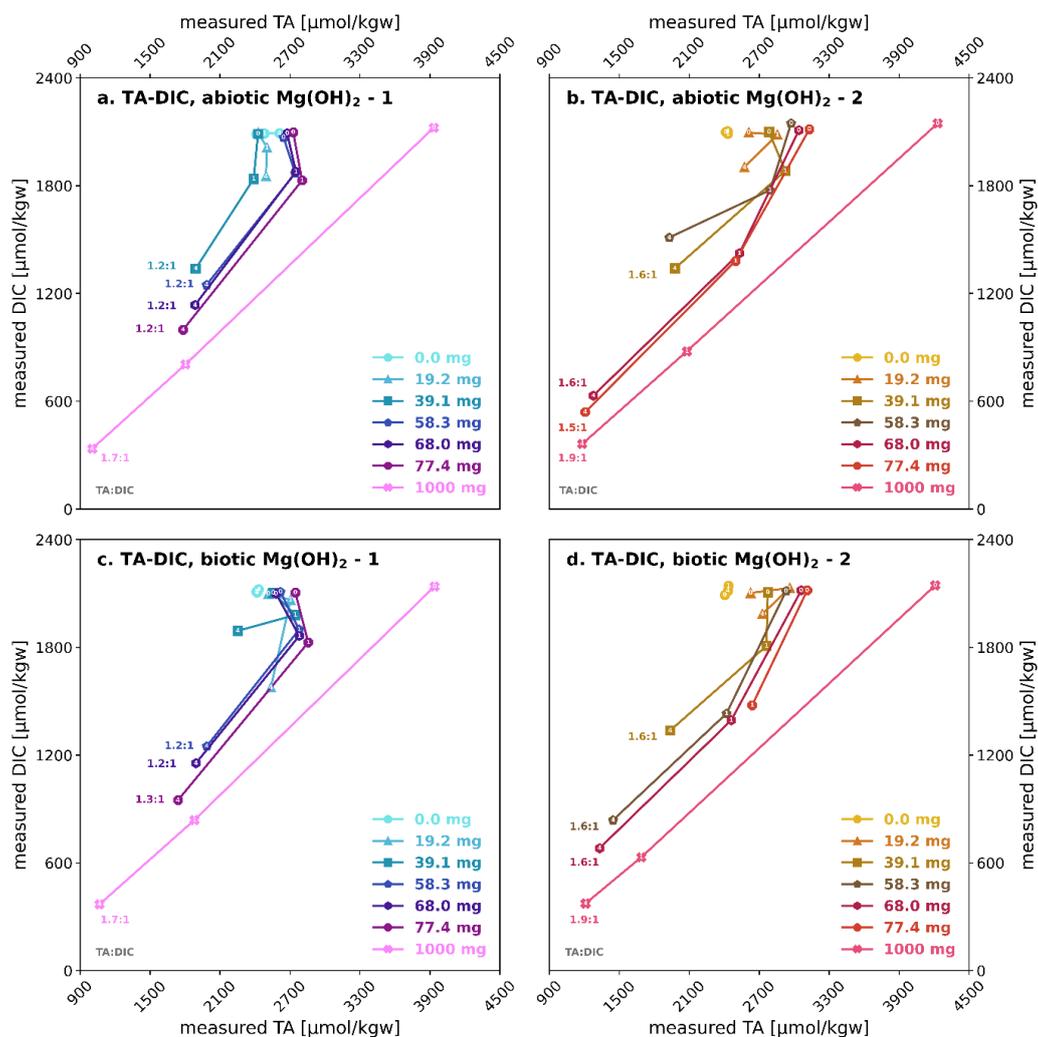

**Figure 5: Dissolution of particulate brucite (types I and II) over time;** (a, d) development of alkalinity (TA), (b, e) aragonite saturation state ( $\Omega_{\text{aragonite}}$ ) and (c, f) pH immediately after addition (day 0 – black/grey), 1 day (red) and 4 days after (blue); abiotic treatments – solid lines, biotic – dotted lines. Brucite additions range from 19.2 mg ( $\Delta\text{TA}_{600}$ ) to 1,000 mg ( $\Delta\text{TA}_{34,288}$ ). Comparable trends are observed in all treatments, independent of substrate type (brucite I and II) and set-up (abiotic/biotic).

285

### 3.6 Experiment IV: TA/DIC evolution brucite

Although for some treatments the  $\Delta\text{TA}:\Delta\text{DIC}$  development from day 0 to 1 shows some TA increase, loss in DIC is the general pattern (Fig. 6). Towards day 4 a loss of TA and DIC can be observed in most treatments. The TA:DIC change ratio thereby differs from that observed in experiment II, where a ratio of 2:1 indicated pure carbonate precipitation, in this case it ranges between 1.2:1 and 1.9:1, clearly showing that in parallel to carbonate precipitation brucite dissolution was still ongoing. In all four treatments there is a tendency of higher  $\Delta\text{TA}:\Delta\text{DIC}$  change-ratios with higher brucite addition, indicating alkalinity loss due to carbonate precipitation to increase relative to the alkalinity gain due to brucite dissolution. The higher  $\Delta\text{TA}:\Delta\text{DIC}$  ratios for brucite II (1.6:1 to 1.9:1) compared to brucite I (1.2:1 to 1.7:1) indicate higher carbonate precipitation for the former.

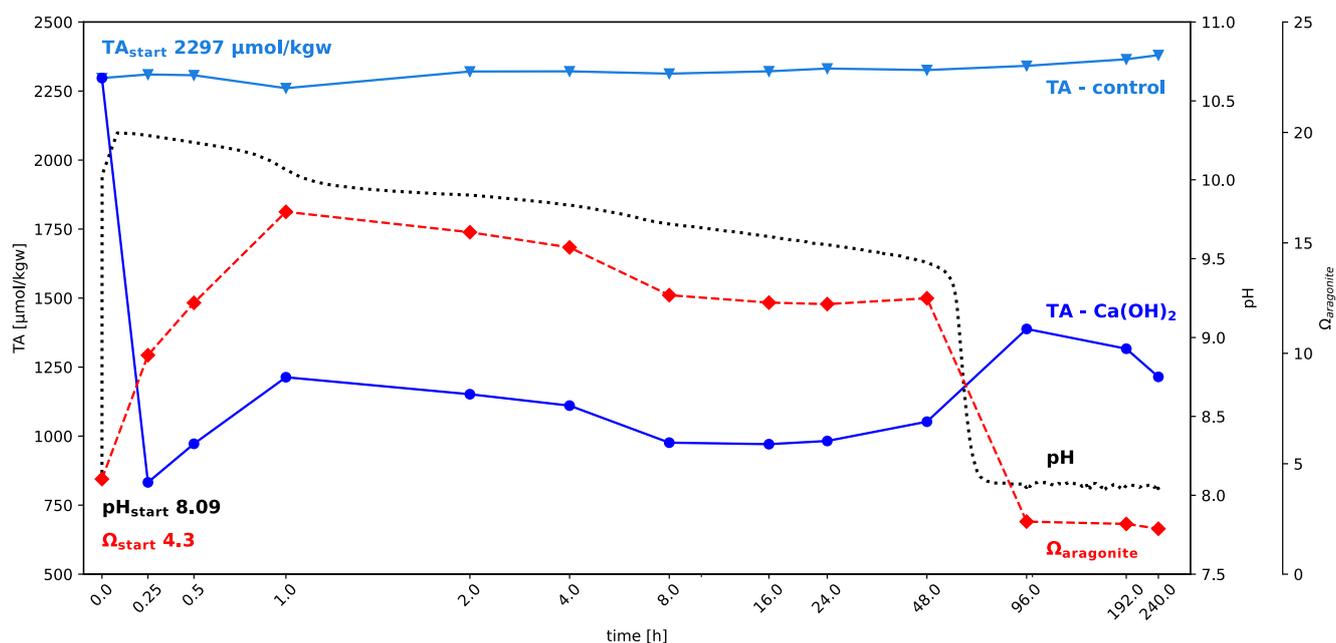

295 **Figure 6: Development of TA versus DIC during brucite dissolution;** (a, b) abiotic after 0, 1 and 4 days, (c, d) biotic after 0 and 4 days. The day of sampling (0, 1 and 4) are written on top of each data point marker.  $\Delta\text{TA}:\Delta\text{DIC}$  change ratios for brucite I (1:1.2) and brucite II (1:1.6) are indicating simultaneous precipitation and dissolution, while their difference could be described by their differing dissolution characteristics.

### 3.7. Experiment V: Alkalinity recovery after mineral precipitation in the presence of CO<sub>2</sub> equilibration

300 This experiment was intended to test for possible recovery of alkalinity after its loss due to mineral precipitation. Addition of 0.66 g/kgw Ca(OH)<sub>2</sub> and its fast dissolution led to an immediate collapse of alkalinity down to 832 μmol/kgw within 15 minutes, losing more than half of the initial seawater alkalinity (Fig. 7). At the same time pH increased to above 10 and Ω<sub>aragonite</sub> to about 9.5. In the following hour part of the alkalinity recovered, while Ω<sub>aragonite</sub> further increased, accompanied by a steady decline in pH, caused by invasion of CO<sub>2</sub> into the water. After an hour Ω<sub>aragonite</sub> and TA started to decline for the next 48 hours.

305 After that a shift in the carbonate system causes a drastic decline in pH (inflection point at hour 60.4 at pH 8.988) and slight increase in TA, indicating that despite declining Ω<sub>aragonite</sub> some lost alkalinity recovers, which is likely due the redissolution of carbonate forms, not crystallized yet into stable calcite or aragonite. The results show that it is possible to recover, on a time scale of days, some of the lost alkalinity, but despite using a shaking bath to accelerate CO<sub>2</sub> invasion, even after 10 days about half of the initial alkalinity remains lost and the Ω<sub>aragonite</sub> levelled off below the start values.

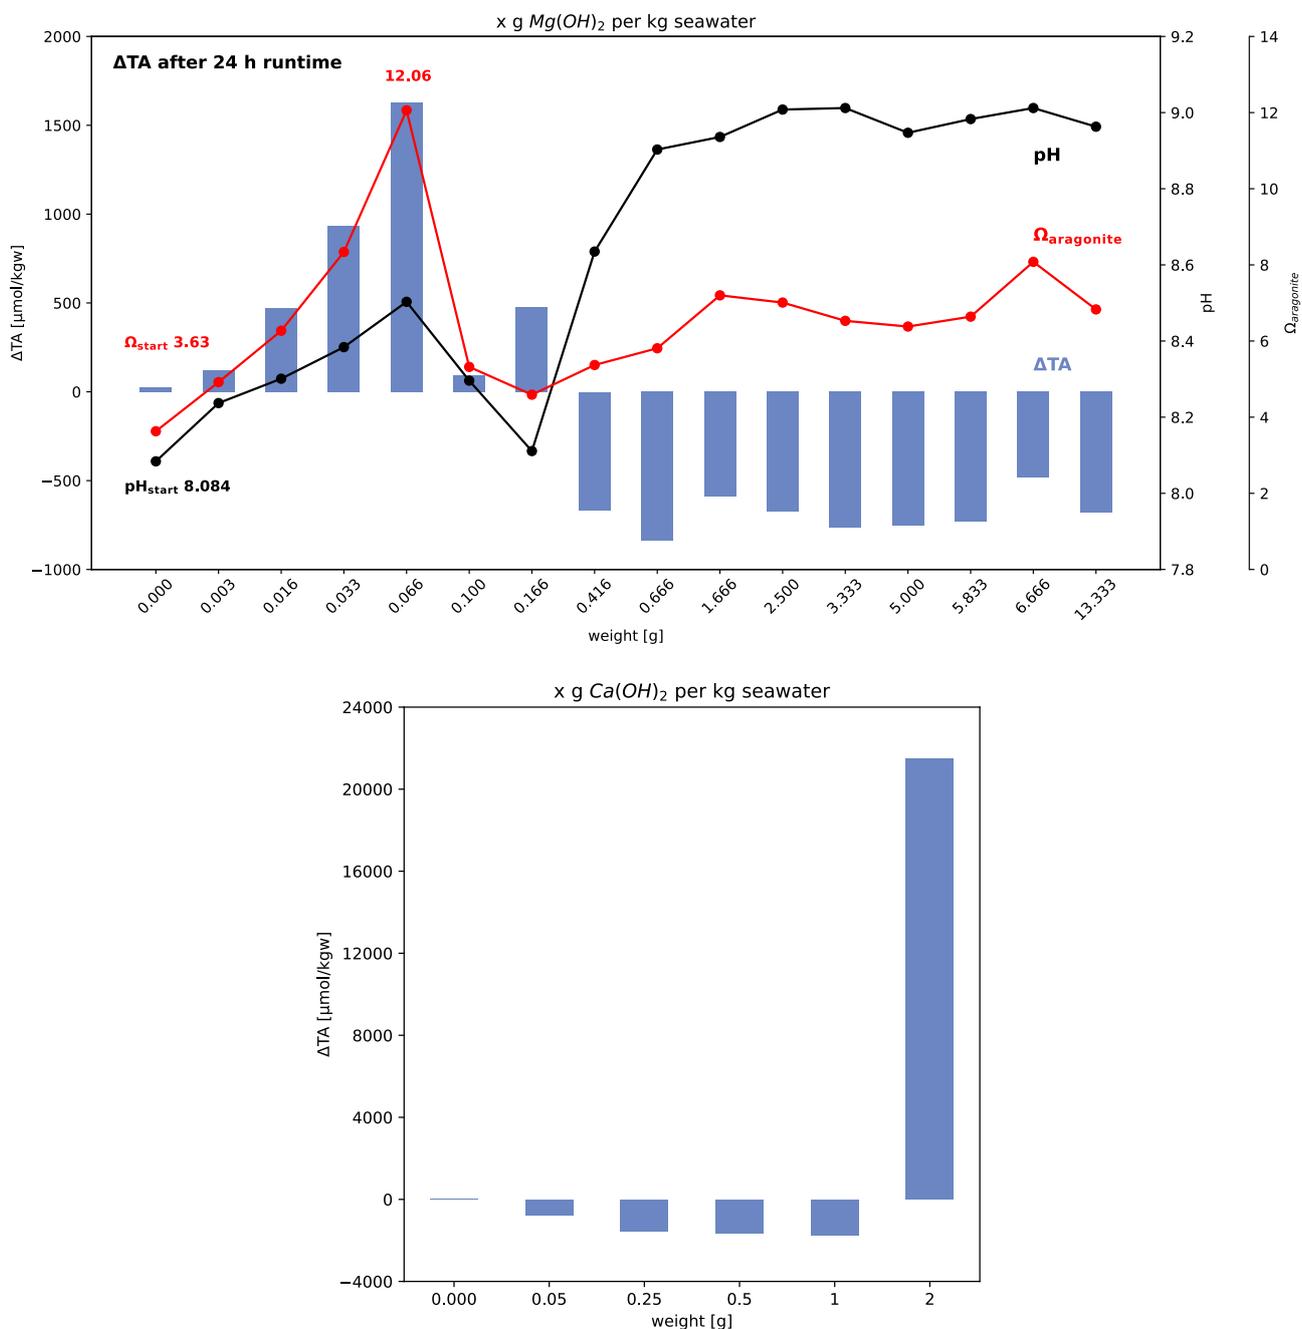

310 **Figure 7: Partial recovery of alkalinity after carbonate precipitation;** Change in alkalinity, pH and Ω<sub>aragonite</sub> after adding 0.66 g Ca(OH)<sub>2</sub> / kgw to North Sea water in a shaking bath (simulating wave processes to allow accelerated air-water-CO<sub>2</sub>-exchange). Ca(OH)<sub>2</sub> dissolution is so fast, that it is hard to track. While the water gradually equilibrates with the atmosphere, a series of loss and gain of alkalinity can be observed.

### 3.8 Experiment VI: Threshold of alkalinity addition to avoid carbonate precipitation

315 The addition of increasingly larger amounts of  $\text{Mg}(\text{OH})_2$  confirms that the increase in added TA after 24 hours stops at  $\Omega_{\text{aragonite}}$   
close to 12.5 (Fig. 8a). For larger additions net loss of alkalinity was generated, which would subsequently lead to  $\text{CO}_2$  evasion.  
In the case of  $\text{Ca}(\text{OH})_2$  (Fig. 8b) the net loss switches to alkalinity gain at the highest addition. However, the measured increase  
in alkalinity ( $\sim 21,000 \mu\text{mol/kgw}$ ) is less than expected, based on the mineral addition ( $\sim 27,000 \mu\text{mol/kgw}$ ), suggesting a lower  
efficiency and therefore higher costs of application. In later experiment, the highest dosage of added  $\text{Ca}(\text{OH})_2$ , shows that still  
320 a gain in TA can be achieved. Therefore, two threshold types are demonstrated with this experiment and experiment **IV**: one  
showing that a threshold level for losing alkalinity after adding a certain amount of solid alkalinity exist, based on material  
quality, and one gaining at higher levels TA by adding excess solid alkalinity to seawater with a high enough dosage.  
Interestingly, this effect is not visible using  $\text{Mg}(\text{OH})_2$  at given higher amounts added, suggesting material specific behaviour  
with different outcome for OAE application. In case of brucite, an important difference to experiment **IV** is the use of a shaking  
325 bath, likely making the influence of particle surface processes less effective due enforced advection of water around the particle  
surfaces. In addition, the shaking conditions causing faster exchange of  $\text{CO}_2$  with the atmosphere do not reflect water bodies  
below the wave line.

**Figure 8:** Change in alkalinity after adding Mg(OH)<sub>2</sub> or Ca(OH)<sub>2</sub> to North Sea water in a shaking bath (simulating wave processes to allow accelerated air-water-CO<sub>2</sub>-exchange). (a) Net loss occurs when alkalinity addition exceeds the critical saturation level of aragonite, while in (b) it is shown, using Ca(OH)<sub>2</sub> that for high added amounts of solid the TA-loss can be turned into a gain. Note for data in 8b no pH values are available for calculation of aragonite saturation levels.

## 4 Discussion

### 335 4.1 General discussion

Results show that the way alkalinity is added to the ocean is crucial to have sustained elevated alkalinity values, and more importantly, to avoid an alkalinity net-loss through carbonate precipitation. Major controlling factors are (i) the type of mineral used, (ii) whether TA is introduced in solid form or as a solution, (iii) in the case of a solution, if it is already enriched with DIC for pCO<sub>2</sub>-equilibrium with the atmosphere or not, and (iv) the presence of biogenic or mineral particles in seawater, affecting 'runaway precipitation' of carbonate (Moras et al., 2021) and associated loss of TA.

In the approach using alkaline solutions equilibrated with atmospheric CO<sub>2</sub> (experiment **I**) no TA loss was observed after 4 days, even at high delta TA. The reason is that the carbonate system (based on  $\Omega$  of the bulk solution) stayed within boundaries to avoid mineral precipitation for the duration of 4 days. In contrast, application of a solution with elevated alkalinity not equilibrated with atmospheric CO<sub>2</sub> (experiment **II**; compare Figs. 1 and 2) caused already at the first day a sustained loss of alkalinity, for the high alkalinity addition of 2,400  $\mu\text{mol/kgw}$  (Fig. 2). The reason is that, for the same  $\Delta\text{TA}$ , perturbations of the carbonate system that affect mineral precipitation are much stronger in this non-equilibrated scenario. Consequently, treatments with non-equilibrated conditions in experiment **II** reflect water bodies not being able to equilibrate in time before a loss due critical oversaturation happens, likely to be close below the seawater surface given the slow equilibration with the atmosphere (Jones et al., 2014). This would indicate that usage of reactors to prepare suitable CO<sub>2</sub>-equilibrated alkaline solutions should be considered for large scale OAE (see section below).

Relevant losses for the biotic treatment in experiment **II**, simulating non-equilibrium conditions, after four days were visible already for treatments with additions > 900  $\mu\text{mol TA/kgw}$  (Fig. 2). Results of experiment **II** indicate that a lack of condensation nuclei in the filtered abiotic treatments prevented the start of precipitation at lower TA additions. The difference between biotic and abiotic treatments in experiment **II** is additional potential seed surface due to particles and plankton >0.2  $\mu\text{m}$  and < 55  $\mu\text{m}$ , which may act as nucleation sites ('seed') for precipitation. In fact, this has resulted in loss of TA at lower  $\Delta\text{TA}$  levels in the biotic treatment. The loss ratio of TA and DIC ( $\Delta\text{TA}:\Delta\text{DIC}$ ) of 2:1 (Fig. 3b, d) indicates that the precipitate is composed of carbonates. Comparable observations were made using quartz particles in Moras et al. (2021), because the abundance of potential surface nucleation sites lowers the threshold for alkalinity loss via precipitation.

Notably, once carbonate precipitation is initiated (Fig. 2), TA-loss does not stop at  $\Omega_{\text{aragonite}}$  levels of 12.5-13.5 (corresponding to  $\Omega_{\text{calcite}}$  levels of 19-20), which were reported (Morse and He, 1993) as threshold levels above which spontaneous carbonate formation occurs (in filtered seawater at 25°C and salinity of 35). Once the process of carbonate formation is triggered it continues until a certain specific thermodynamic equilibrium is reached, which may not have been reached considering the duration of the experiments. Experiment **III** demonstrates that the loss of alkalinity can start without particles also at lower

365 than the described critical  $\Omega_{\text{aragonite}}$  for filtered seawater if time is longer than 10 days and that the presence of carbonate precipitates from former experiments accelerated this process (Fig. 4). Precipitation of minerals at the surface of the walls of the experimental vessel without adding particles underlines the relevance of surfaces added and their quality as can be seen by the difference between adding carbonate precipitates and not (Fig. 4).

Experiment **IV** differs from experiments **I** to **III**, using alkaline solids  $\text{Mg}(\text{OH})_2$  to produce alkalinity in the seawater while providing at the same time a reactive surface area. Carbonate formation and TA loss started in this experiment at  $\Omega_{\text{aragonite}}$  well  
370 below 12.5 of the bulk solutions. Dissolution-precipitation processes at the surface of the particles happen at the same time (Figs. 5 and 6), as indicated by the  $\Delta\text{TA}:\Delta\text{DIC}$  change ratios in the bulk water between 1.2:1 and 1.9:1, clearly lower than 2:1 as expected for carbonate formation alone (compare experiment 2, Fig. 3). The differences in  $\Delta\text{TA}:\Delta\text{DIC}$  change ratios for brucite I (1:1.2) and brucite II (1:1.6) for moderate solid TA-additions up to  $\Delta\text{TA}_{2400}$  indicate significant product specific differences in simultaneous mineral dissolution and carbonate formation characteristics at their surfaces. This result calls for  
375 detailed product specific evaluation of solid alkaline materials before application, and quality control in case a certain material might be identified as being useful. In addition, this finding suggests that simple modelling of alkalinity addition based on a given mineral type provides no realistic insights into real world ocean alkalinity enhancement applications. Not only particle surface processes on added solid alkaline particles are to be considered. As shown in the equilibrated approach of experiment **III** with an added solute alkalinity instead of reactive particles, on longer time scales (here up to 90 days) also the presence of  
380 potential nucleation sites, in the form of suspended particles or other exposed surfaces, affect the stability of added alkalinity and hence have to be considered for OAE applications. Importantly, alkalinity loss processes identified in these laboratory scale experiments need to be investigated in field trials for further verification and quantification.

#### 4.2 Loss of alkalinity, carbonate formation, temporal stability and potential recovery of alkalinity

The question of potential recovery of lost alkalinity is even more complicated (experiment **V**, Fig. 7) and is a critical aspect  
385 for OAE application: If lost alkalinity recovers after a certain time and target TA is reached, then such transient losses could be accepted. The simple experiment **V** with  $\text{Ca}(\text{OH})_2$ , lasting 10 days, illustrates that alkalinity consumed via carbonate formation may partly be released again. Here probably facilitated by accelerated ingassing of  $\text{CO}_2$  using a shaking bath (Fig. 7), as indicated by the decline in pH after  $\sim 2.5$  days. This shaking bath experiment may not be representative for open ocean application, but shows the problem to face, a net loss of TA under certain conditions. Future experiments should gain insights  
390 under which conditions a temporal loss of alkalinity can be accepted if a net increase would be the result. This was not achieved in experiment **V**, but could be given different application scenarios or dilution in time (c.f. Moras et al., 2021).

In general, amorphous calcium carbonate (ACC) with variable proportion of Mg contents precipitates from water as a precursor prior to the crystallisation of minerals like aragonite or calcite via transformation processes (Rodriguez-Blanco et al., 2017). Direct calcite or aragonite precipitation from water occurs only at high supersaturation levels (Rodriguez-Blanco et al., 2017),  
395 which were exceeded in some of the experiments here.

The precursor ACC leading to an alkalinity loss via nucleation is not stable and can redissolve (Mergelsberg et al., 2020; Brečević and Nielsen, 1989; Clarkson et al., 1992), with reported solubilities more than 100 times larger than for calcite in pure water. Under which conditions ACC precursors formed during OAE can redissolve, to avoid longer-term alkalinity loss, and how fast mixing with untreated water has to be to avoid permanent loss of TA, is - based on few existing data (c.f. Moras et al., 2021) - difficult to assess for OAE. Further experiments in context of OAE are therefore needed. A good understanding of mixing rates of treated and untreated water at OAE application sites is therefore critical to avoid permanent TA loss.

The observations from the threshold experiment **VI** (Fig. 8) are making the application more non-trivial, as an excess application of alkaline solids could cause an addition of TA instead of a loss, but with for now unknown consequences for ecosystems due temporal high pH-values above 9.5 for longer time (c.f. Fig. 7 using lower doses compared to excess addition in experiment **VI**).

In addition, solid particles of different quality, react differently if high application amounts per volume of seawater are used (Fig. 8). In the case of the used  $\text{Ca}(\text{OH})_2$  a gain in TA could be observed (Fig. 8b) using high dosages of material (2 g/kgw versus 1 g/kgw, which lead to a TA loss). For the brucite instead, even adding 13 g/kgw lead not to a positive TA after 24 hours. This simple experiment **VI** suggests that TA-loss must not be necessarily the case using excess amounts of fast dissolving minerals at the costs of high pH-levels, local critical oversaturation levels, and lower efficiency. As long as consequences of such excess treatment of seawater are not well enough understood for sustainable OAE management, the combination of results from the experiments **I** to **IV** suggest that adding alkalinity to the ocean should be undertaken such that the rate of increase in TA is equal to or less than the rate of re-equilibration of atmospheric  $\text{CO}_2$  to avoid critical oversaturation levels. Such control seems to be difficult to achieve with the direct addition of tested fine solids or highly alkaline liquids not in equilibrium with the atmosphere. It is possible to obtain greater control if a reactor is used to prepare a pre-equilibrated solution with elevated alkalinity without triggering precipitation ( $\Omega_{\text{aragonite}} < \sim 12.5$ , c.f. experiment **I** in Fig. 1b).

Before starting open ocean experiments, detailed model approaches are needed to assess these problems identified here: stability of added alkalinity, possible redissolution of temporary lost alkalinity, and excess application causing a net TA increase with co-precipitation of carbonates and possibly concerning duration of high pH-values. This in turn needs more laboratory or mesocosm scale experiments to determine which role particles, present in natural waters, play by lowering the threshold level for potential TA loss (c.f. experiment **IIa** and **IIb**, abiotic with biotic particles, or Wurgraft et al., 2021) to parameterize models. By now, there are simply not enough reliable data existing to allow for reliable, realistic model calibration. A serious aspect considering that models are used to assess global and regional potential of OAE, which in turn is used to discuss which CDR-methods are to be considered for future global CDR-schemes.

Considering that temporally unstable precursors of carbonate minerals form during the application of OAE, as indicated by experiment **V** (Fig. 7), knowledge about the structure and behaviour of such unstable carbonate species formed is essential for discussing further the application scenarios of OAE. It is relevant to know the fraction and quality of formed unstable carbonate phases which might redissolve under given local and seasonal conditions, as well as application scenarios, because the question of a net-TA loss or gain depend on it, and if a TA loss is only transient for a given acceptable time. Understanding which

430 quality of particle surfaces, and surface area amounts per volume of water, trigger TA-loss is further to investigate. It is known  
for a few particles, only. E.g., it is a common laboratory routine to ‘seed’ water with solid carbonates for the initiation of  
carbonate precipitation (Wurgaft et al., 2021; Morse et al., 2003; DeBoer, 1977). The abundance of suitable surfaces allow  
carbonate formation and alkalinity loss at lower bulk water saturation levels than used to artificially precipitate carbonates  
from filtered seawater as shown by Wurgaft et al. (2021) and supported by results from Molnár et al. (2021), and experiment  
435 **III** (addition of precipitates from previous experiments). In addition, biotic processes may support carbonate formation at the  
small scale, via photosynthesis, modulating the local carbonate system via uptake of inorganic carbon (Wolf-Gladrow and  
Riebesell, 1997). Experiment **II** indicate that ocean-based particles lead to carbonate formation at lower  $\Delta$ TA levels compared  
to filtered water, despite that in this specific seawater only little particles were present.

Because triggered carbonate precipitation aids or boosts further precipitation in seawater, it is in the context of an OAE  
440 application scenario essential to understand under which conditions alkalinity loss can be avoided, given the large variety of  
possible combinations of particles and biota in the world’s ocean. The continued loss of alkalinity well below critical values  
of  $\Omega_{\text{aragonite}}$  once triggered was labelled ‘runaway precipitation’ by Moras et al. (2021). This aspect needs further understanding  
based on the few experiments available, as TA-loss may stop under certain conditions and a possible regain of TA might  
happen (Fig. 7), which would be a relevant aspect of OAE-management.

445 Specifically, the question about the time window until an amorphous carbonate cluster can redissolve when mixed with  
untreated seawater is essential for OAE treatment plans and management, considering that sustainable techniques for the  
application of OAE and monitoring are still missing. Essential global and regional data on stability of TA are still missing and  
need to be collected at large scale, if OAE should be a practical CDR technology, which is one day emerging from the method  
idea to a real-world application technology.

### 450 **4.3 Consequences for application strategies**

Model assessments on the global potential of OAE for long-term CO<sub>2</sub> removal do not consider the risks of alkalinity loss  
through increased carbonate precipitation (Khashgi, 1995; Köhler et al., 2013; González and Ilyina, 2016; Burt et al., 2021;  
Ilyina et al., 2013).

Global modelling studies so far assumed very idealized conditions of OAE, e.g., a spatially and temporally homogenous  
455 increase in TA over years or decades. In reality, OAE will likely be achieved via point source release of solid or liquid TA,  
leading to spatially and temporally much stronger perturbations of the carbonate system, which may in turn trigger carbonate  
precipitation and TA loss. This process might be further facilitated by the presence of particles in seawater, an aspect not  
considered in models so far.

Results from our study, as well as those from Moras et al. (2021) and Wurgaft et al. (2021) suggest that homogenous or  
460 heterogenous nucleation should be avoided to prevent TA loss.

The loss of alkalinity in unfiltered water with elevated alkalinity in disequilibrium with the atmosphere after the addition of a  
solution without particles (Fig. 3, experiment **II**) starts at lower alkalinity additions than in filtered water. The water used in

the experiments **I** to **III** is representative for oligotrophic ocean regions, which are low in particle abundance, but it cannot be ruled out that few suspended sediment grains are affecting the results due the close distance to the coast. Wurgaft et al. (2021) showed that particles from river plumes can trigger alkalinity and DIC loss via carbonate precipitation at lower alkalinity levels than used here ( $\sim 2,400 \mu\text{mol/kgw}$ ) (Figs. 1 and 2). This observation suggests that without further investigation, application of OAE in such areas should be avoided.

Caserini et al. (2021) modelled ship application of OAE simulating addition of a slurry of  $\text{Ca}(\text{OH})_2$ . In their model results, pH levels of 9.2 to 9.5 are reached in open water. Even if these high pH levels would be reached for only a short time (minutes to hours), results here suggest (Figs. 5 to 7) that ship OAE application procedures could result in critical saturation levels, triggering alkalinity loss (c.f. experiment **V** and Moras et al. (2021)). Experiment **VI**, however, showed that at the expense of high pH, application of high doses, exceeding the second threshold identified here, results in a net TA gain, but no loss. But, in that case not all added solid alkalinity is transferred into liquid TA in seawater (Fig. 8: efficiency of 78% after 24 hours for the highest dose).

The addition of unequilibrated alkaline liquid from a ship would have to be in a way that the saturation state remains below critical thresholds at the site of release. The distribution of the alkaline liquid might be operated via large nets with a network of distributed pressure-nozzles causing small point turbulences for effective mixing of treated water with untreated. Slow point addition rates would increase the ship time needed to deliver a cumulative amount of alkalinity change to the ocean. This would increase the cost, and, where fossil bunker fuel is used, reduce the overall effectiveness of OAE, if ship  $\text{CO}_2$ -emissions are not used to produce alkaline solutions added to the ocean. The rate of the ship-based TA-addition would likely be constrained by the rate of  $\text{CO}_2$  resupply to the treated seawater (in general the air-sea gas exchange), and the dilution rate of treated water with untreated.

To avoid that added solid particles act as seeds for carbonate precipitation, it may therefore be feasible to add engineered solid particles with sufficiently slow dissolution rate at the particle surface to prevent critical changes in seawater carbonate chemistry, while sink velocity is slow enough to allow for full dissolution close to the sea surface.

An alternative to open ocean addition is the use of reactors to produce equilibrated solutions for the addition into the sea (as shown by experiment **I**). Reactors for alkalinity production have been proposed for various purposes. For example, Kirchner et al. (2021) demonstrated on land that it is possible to produce alkaline solutions using limestone and seawater to scrub flue gases of a coal power plant. An alkalinity reactor at the industrial scale for counteracting water acidification in lakes after mining brown coal was built and operated in the Lausitz area, Germany (Koch and Mazur, 2016; LMBV, 2017). The pilot plant to this reactor was able to use solid  $\text{CaO}$ ,  $\text{Ca}(\text{OH})_2$  or  $\text{CaCO}_3$  and pure  $\text{CO}_2$  for alkalinity production.

A further alternative is suggested by experiment **I**.  $\text{Na}_2\text{CO}_3$  and  $\text{NaHCO}_3$  dissolve quickly due to their high solubility in seawater. Results here (Figs. 1 and 3) show that the combination of  $\text{Na}_2\text{CO}_3$  and  $\text{NaHCO}_3$  to produce a targeted alkaline solution equilibrated with atmospheric conditions give the best outcome for a potentially sustainable alkalinity addition. The application of solid  $\text{Na}_2\text{CO}_3$  was already suggested by Kheshgi (1995), but also discarded for global application due to limited natural resources.

It might therefore be worthwhile to study the production of  $\text{Na}_2\text{CO}_3$  and  $\text{NaHCO}_3$  from  $\text{CO}_2$ ,  $\text{NaCl}$  and  $\text{H}_2\text{O}$  for OAE using solar thermal energy (Forster, 2014) or possibly as a product of electrochemical approaches (House et al., 2007; Rau et al., 2013). A review on  $\text{NaHCO}_3$  production techniques showed that this topic is under-researched (Bonfim-Rocha et al., 2019), opening up the possibility for improvements in terms of cost and energy demand. In addition, new concepts for  $\text{Na}_2\text{CO}_3$  production (Forster, 2012, 2014; Wu et al., 2019) provide energetically improved and environmentally friendly production schemes. Such improvements are relevant, in context of needed energy resources.

Wu et al. (2019) suggest an energy demand of 5.32 GJ per tonne  $\text{Na}_2\text{CO}_3$ , a decrease by 61% compared to standard Solvay process production. Using solar thermal energy for  $\text{Na}_2\text{CO}_3$  (Forster, 2014) and  $\text{NaHCO}_3$  (Bonfim-Rocha et al., 2019) has the advantage that production is not a burden to the electrical energy grid. Energy costs would be in the range of other discussed CDR approaches, like 4 to 12 GJ/tonne  $\text{CO}_2$  for direct air capture (NAS, 2021; Shayegh et al., 2021), or 3 – 6 GJ/tonne  $\text{CO}_2$  for other methods of OAE (Renforth and Henderson, 2017). If the Na-carbonate solids were produced from  $\text{NaCl}$  solutions (e.g., through electrochemistry), methods for disposing of the waste  $\text{HCl}$  acid, or the evolved  $\text{Cl}_2$  gas would need to be found (NAS, 2021). However,  $\text{HCl}$  could also be a resource to other processes, like the extraction of needed elements for the global energy-transformation from rocks.

#### 4.4 Consequences of alkalinity leakage and impacts of OAE on biota

Model studies indicate that adding alkalinity to the ocean could remove between 3 and 10 Gt of carbon dioxide per year from the atmosphere, while at the same time counteracting ocean acidification (Feng et al., 2017; Harvey, 2008). However, the potential impact of adding alkaline materials on marine organisms and ecosystems is still largely unknown. Most of the alkalinity enhancement experiments carried out to date have used calcium or sodium hydroxides as alkaline substances (D'Olivo and McCulloch, 2017; Lenton et al., 2018; Albright et al., 2016; Cripps et al., 2013), and have been tested on a small number of calcifying organisms, like mollusks (Cripps et al., 2013; Waldbusser et al., 2014), corals (Comeau et al., 2012; Albright et al., 2016), and calcifying algae (Gore et al., 2018). In most cases, adding alkaline materials led to enhanced calcification in response to increased calcite and aragonite saturation states. The only in situ experiment in marine waters was carried out in a coral reef, leading to the restoration of calcification of corals that were affected by the decline in carbonate saturation state caused by acidification (Albright et al., 2016).

Other compounds (like iron, silica or heavy metals) occurring in alkaline rocks that could be added to the water might stimulate or inhibit organism growth, potentially benefiting some organism over others, thereby changing community structure. For instance, a shift towards diatoms and diazotrophic phytoplankton might occur if silica and iron-rich olivine is used as an alkaline agent. On the contrary, the use of alkaline solutions could benefit calcifying plankton, like coccolithophorids (Köhler et al., 2013; Bach et al., 2019), although diverse adaptations within this group may lead to different responses to OAE (Langer, 2009). Moreover, the addition of technical and natural mineral products may also release trace metals, like nickel in case of olivine dominated dunite (Montserrat et al., 2017).

Overall, the side effects of OAE on organisms, and more importantly on ecosystems, is largely unknown and deserves research  
530 at the experimental levels to provide a better knowledge in order to make informed decisions on whether or not alkalinity  
enhancement is a feasible mitigation strategy.

## 5 Conclusion

From the inorganic geochemical perspective, the amount of potentially formed carbonate phases, their stability (potential re-  
dissolution), and the subsequent loss of alkalinity after OAE application determines the sustainability of OAE. Understanding  
535 these processes and their management will be crucial for the decision-making process regarding OAE application and its  
subsequent potential for CO<sub>2</sub> sequestration.

For a given environmental setting, the risk of triggering the loss of alkalinity after OAE is determined by the carbonate  
saturation state, its temporal evolution and particle surface processes, with the possibility of being steered by the surface area  
per volume of water as well as the quality of such a surface. To avoid the loss of alkalinity and maximize alkalinity addition,  
540 the application of an alkaline solution in CO<sub>2</sub>-equilibrium with the atmosphere and/or solutions with saturation levels that  
avoid loss of alkalinity is favourable over the application of tested solid materials. Reactor solutions preparing alkaline  
solutions have been developed for other purposes, like counteracting lake acidification or scrubbing CO<sub>2</sub> from flue gas, and  
their design could be a blueprint for OAE-reactors.

Formation and redissolution of (temporally) instable carbonate phases are not well understood from the viewpoint of OAE  
545 management. This knowledge gap includes natural mixing processes of alkalinity-enhanced water with untreated water,  
therefore diluting potentially critical conditions in time before permanent secondary precipitation occurs. A pre-application  
assessment as part of OAE-management, requires therefore detailed information on the hydrodynamics and advection of CO<sub>2</sub>  
into the water at the site of OAE application.

In addition, a broad spectrum of the effects of duration and degrees of oversaturation levels on permanent carbonate formation  
550 (Fig. 7) needs to be studied, including the effect of temperature affecting nucleation kinetics, which was not addressed here. It  
is likely that in colder waters than tested here, carbonate formation triggered by OAE is delayed via slower kinetics, offering  
more time for dilution with untreated water. A public database with increasing information on tested materials and gained  
parameters for OAE application might help in the future to refine OAE assessments on potentials and risks. Such database  
should include knowledge on the ecosystem response to TA and pH changes, one aspect being understudied.

555 In conclusion, this study outlined some of the relevant aspects where knowledge on applicability of OAE must be refined  
before safe and sustainable application boundary conditions and management procedures for OAE can be established.

### **Data availability**

Data will be made available on a publicly available repository upon final publication.

### 560 **Author contributions**

JHA, NS and JT designed the experiments. NS performed the experiments with partial help of JT, CL und JS. JHA wrote the text with the help of all co-authors.

### **Competing interests**

The authors declare that they have no conflict of interest.

### 565 **Acknowledgements**

Peggy Bartsch (UHH) and Tom Jäppinen (UHH) are thanked for supporting the preparation and conduction of the experiments. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 869357 (project OceanNETs, Ocean-based Negative Emission Technologies - analyzing the feasibility, risks, and cobenefits of ocean-based negative emission technologies for stabilizing the climate) and by the Deutsche  
570 Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – EXC 2037 'CLICCS - Climate, Climatic Change, and Society' – Project Number: 390683824, contribution to the Center for Earth System Research and Sustainability (CEN) of Universität Hamburg.
