

38 **Abstract**

39 The importance of carbon (C)-nutrient interactions to the prediction of future C uptake has long
40 been recognized. The Energy Exascale Earth System Model (E3SM) land model (ELM) version 1
41 is one of the few land surface models that include both N and P cycling and limitation (ELMv1-
42 CNP). Here we provide a global scale evaluation of ELMv1-CNP using International Land Model
43 Benchmarking (ILAMB) system. We show that ELMv1-CNP produces realistic estimates of
44 present-day carbon pools and fluxes. Compared to simulations with optimal P availability,
45 simulations with ELMv1-CNP produces better performance, particularly for simulated biomass,
46 leaf area index (LAI), and global net C balance. We also show ELMv1-CNP simulated N and P
47 cycling are in good agreement with data-driven estimates. We compared ELMv1-CNP simulated
48 response to CO₂ enrichment with meta-analysis of observations from similar manipulation
49 experiments. We show that ELMv1-CNP is able to capture the field observed responses for
50 photosynthesis, growth, and LAI. We investigated the role of P limitation in the historical
51 balance and show that global C sources and sinks are significantly affected by P limitation, as
52 the historical CO₂ fertilization effect was reduced by 20% and C emission due to land use and
53 land cover change was 11% lower when P limitation was considered. Our simulations suggest
54 that introduction of P cycle dynamics and C-N-P coupling will likely have substantial
55 consequences for projections of future C uptake.

100 **1. Introduction**

101 The recent global carbon (C) budget showed that over the last half century global
102 fossil CO₂ emissions have increased from about 3 Pg C/yr in 1960s to about 9.5 PgC/yr in the
103 last decade (Friedlingstein et al., 2019). It has also been shown that land ecosystems play
104 important roles in controlling the fractions of CO₂ emissions that remain in the atmosphere
105 by taking up about 29% of total emissions (Le Quéré et al., 2018). Large uncertainties
106 remain on the net land-atmosphere C exchange, mainly due to difficulties in quantifying the
107 complex C cycle processes such as CO₂ fertilization effects, responses of carbon fluxes to
108 temperature and precipitation variation, and C emissions associated with land use and land
109 cover change (LULCC). These uncertainties will very likely hamper our ability to predict the
110 future trajectories of atmospheric CO₂.

111 One of the important uncertainties relates to our understanding of C-nutrient
112 interactions and nutrient limitation and how they are represented in models. The
113 importance of nitrogen (N) availability to predicted land C storage has been long recognized
114 (Hungate et al., 2003). Although there were only two models in CMIP5 (the fifth phase of
115 the Coupled Model Intercomparison Project) that accounted for N dynamics and N
116 limitation (Thornton et al., 2007; Thornton et al., 2009; Arora et al., 2013), many ESMs
117 participating in CMIP6 (the Coupled Model Intercomparison Project phase 6) are now
118 including N cycle and C-N interactions (Davies-Barnard et al., 2020; Lawrence et al., 2019;
119 Goll et al., 2017a; Smith et al., 2014; Sellar et al., 2019). The comparisons between these
120 models have been summarized in Arora et al. (2020) and Davies-Barnard et al. (2020). In
121 recent years, significant efforts have also gone into understanding phosphorus (P) cycle
122 dynamics and the role of P limitation in land C storage (Jiang et al., 2019; Hou et al., 2020;
123 Reed et al., 2015; Wieder et al., 2015b; Sun et al., 2017). Increasing numbers of models
124 have developed the capability to include P cycle processes and C-N-P interactions (Wang et
125 al., 2010; Goll et al., 2012; Thum et al., 2019; Goll et al., 2017b; Yang et al., 2014; Yang et al.,
126 2019; Sun et al., 2021). It has been shown that considering P cycle dynamics and C-N-P
127 interactions improves process representation and model fidelity compared with
128 observational and experimental data in most models (Goll et al., 2017b; Yang et al., 2014).

129 Model simulations have also demonstrated the importance of P limitation to land C uptake
130 (Zhang et al., 2014; Goll et al., 2012; Yang et al., 2016; Yang et al., 2019; Sun et al., 2021).
131 Using an ensemble of 14 terrestrial ecosystem models to simulate the planned free-air CO₂
132 enrichment experiment AmazonFACE, Fleischer et al. (2019) showed that P availability
133 reduced the projected CO₂-induced C sink by about 50% compared to estimates from
134 models assuming no phosphorus limitation. Taken together, understanding and
135 representation of the role of P cycle dynamics in affecting terrestrial C balance is essential
136 for the prediction of future terrestrial carbon uptake and atmospheric CO₂ concentration.

137 Despite these recent efforts, P cycle dynamics and C-N-P interactions are not yet
138 included in most CMIP6 models. The Energy Exascale Earth System Model(E3SM) is one of
139 the few models that have been developed a coupled C-N-P capability in the land component
140 in CMIP6 (Burrows et al., 2020). The land model in E3SM, herein referred to as ELMv1-CNP,
141 has been first applied in the Amazon region to test its capability and to evaluate the
142 importance of P limitation in this region (Yang et al., 2019). Yang et al. (2019) provides an in-
143 depth evaluation of ELMv1-CNP for the Amazon rainforest using field observational data,
144 with a focus on how the introduction of P cycle dynamics and P limitation improved model
145 simulated spatial variation of productivity. They show that effects of P limitation on C
146 sources and sinks in the Amazon region are significant, reducing simulated CO₂ fertilization
147 of new carbon uptake by as much as 31%.

148 This study expands the analysis in the Amazon region to the global scale and has two
149 main aims: (1) to provide an evaluation of ELMv1-CNP performance on the global scale
150 using both observational and experimental data, and (2) to quantify the role of P cycle
151 dynamics and P limitation in affecting simulated C sources and sinks globally. We first
152 evaluate the performance of ELMv1-CNP using the ILAMB benchmarking system (Collier et
153 al., 2018), which has been widely used in the evaluation of land surface models and ESMs
154 (Lawrence et al., 2019; Bonan et al., 2019; Zhu et al., 2019; Friedlingstein et al., 2019). We
155 then evaluate ELMv1-CNP simulated N and P pools and fluxes with an observation-based
156 dataset. Realizing that the static benchmarking may not help constrain future model
157 projections, we further evaluate ELMv1-CNP using experimental manipulations of

158 atmospheric CO₂. Finally, we take advantage of the P-enabled capability in ELMv1-CNP to
159 quantify the effect of P dynamics on the simulated ecosystem responses to increasing
160 atmospheric CO₂, increasing N deposition, LULCC, and climate change on the global scale.

161

162 **2. Method**

163 **2.1 Model Overview**

164 ELMv1-CNP is based on the Community Land Model version 4.5 (CLM4.5), which
165 includes coupled C-N biogeochemistry from CLM4 (Thornton et al., 2007) and
166 improvements to canopy photosynthesis, soil biogeochemistry and representation of
167 nitrogen cycle dynamics (Koven et al., 2013; Bonan et al., 2011; Oleson et al., 2013).
168 Recognizing the critical role of the tropical forests in the global carbon cycle and C-climate
169 interactions and the important role of P cycle dynamics and P limitation in tropical forests,
170 we implemented a fully prognostic P cycle and C-N-P interactions into ELMv1-CNP, enabling
171 ELMv1-CNP to be one of the few land surface models that include both N and P cycle
172 dynamics and limitation. The main model features include (1) a fully prognostic P cycle
173 tracking various soil inorganic P pools, vegetation P pools, litter and soil organic P pools (2)
174 the representation of P limitation on plant productivity and litter and soil organic matter
175 decomposition based on a supply-demand approach (3) resolving N vs P limitation using
176 the Liebig law (4) the vertically-resolved soil inorganic and organic P dynamics (5) the
177 decoupling of P cycle from C and N cycle during decomposition due to phosphatase activity
178 (6) the representation of adsorption-desorption dynamics based on soil order.

179 Besides the P cycling processes, the other important difference of ELMv1-CNP from
180 CLM4.5 is the removal of instantaneous downregulation of photosynthesis from nutrient
181 limitation. Instead, longer-term downregulation of productivity is enabled through the
182 implementation of C, N, and P nonstructural vegetation storage pools. In CLM4.5, nutrient
183 limitation is calculated at each time step as a function of potential GPP, stoichiometry of
184 plant tissues, and nitrogen uptake. Any “excess” carbon due to nitrogen limitation is
185 immediately released to the atmosphere through instantaneous downregulation. This
186 nutrient limitation can be highly variable over time and affects diurnal and seasonal cycles

187 of gross primary productivity, which is not consistent with flux tower observations (Ghimire
188 et al., 2016) or with short-term elevated CO₂ experiments that were done with and without
189 nutrient fertilization (Metcalfe et al., 2017). In the current model, competition for available
190 nutrients and plant uptake still occur every timestep given instantaneous demand that is a
191 function of plant GPP and microbial nutrient immobilization (Oleson et al.,
192 2013). However, nutrients taken up by plants are now first allocated to non-structural N
193 and P storage pools instead of directly to structural pools. Nutrient limitation to allocation
194 is determined by comparing plant nutrient demand (given GPP and stoichiometry) and the
195 nutrient availability from the non-structural nutrient pools, which is a function of the pool
196 size in relation to long-term demand. The “excess” carbon flux, which cannot be allocated
197 due to nutrient limitation, is directed to the non-structural plant carbon (NSC) pool instead
198 of downregulating GPP. This pool respire to the atmosphere with a given turnover time.
199 Details about the representation of NSC can be found in the supporting information (Text
200 S1)

201 The model version used in this study is the publicly released ELM v1 and can be
202 downloaded along with all the parameter files at <https://github.com/E3SM-Project/E3SM>.
203 We also provide the key model parameters in Table S1 (PFT specific) and Table S2 (soil
204 order specific).

205 **2.2 Simulations**

206 The simulations presented here were first spun up to bring C, N, and P pools to
207 equilibrium by recycling the GSWP3 (Global Soil Wetness Project Phase 3) climate forcing
208 data (<http://hydro.iis.u-tokyo.ac.jp/GSWP3/>) between 1901-1920, along with constant
209 atmospheric CO₂, N deposition and land cover type at year 1850. Spinup was accomplished
210 through two steps: accelerated decomposition (AD) spinup and regular spinup. We ran the
211 model for 250 years in the AD spinup mode. The purpose of the AD spinup is to accelerate
212 the decomposition process and speed up the spinup process of the carbon and nutrient
213 cycles. The AD spinup procedure was modified from that originally described by Thornton
214 and Rosenbloom (2005), which used spatially invariant acceleration factors to accelerate
215 decomposition in soil organic matter (SOM) pools. Here we updated the AD spinup by

216 including the impacts of temperature and soil moisture on the acceleration factor. This
217 resulted in higher acceleration factors in cool and/or dry climates, which are typically slower
218 to achieve steady state. In addition, vegetation dead stem and coarse root mortality
219 were accelerated by a factor of 10 to achieve steady state biomass more quickly. In the
220 AD spinup, supplemental soil mineral P was applied for the entire simulation such that there
221 was no P limitation on C and N dynamics. During the transition between AD spinup and
222 regular spinup, we initialized the soil inorganic pools using global P maps developed by
223 (Yang et al., 2013). Since the P cycle involves both biological and geochemical processes
224 that occur on geological time scales, the initialization of P pools provides some reasonable
225 estimates of soil P pools without running the model for millions of simulated years. We
226 then ran normal spinup for 600 years with active C, N, and P coupled biogeochemistry until
227 C, N, and P pools reached equilibrium. The criteria for equilibrium are for global total NEE
228 less than 0.1 PgC/yr averaged over 100 years, the threshold recommended for the C4MIP
229 (Jones et al., 2016). We also ran a control simulation between 1850-2010 as a continuation
230 of the normal spinup. We added the time series of labile P, secondary mineral P and
231 occluded P for the control simulation (Fig. S1). There are very little changes in the inorganic
232 P pools during the 161 years control simulation suggesting that these pools can be
233 considered in equilibrium for the time scale of our interest.

234 After the model was spun up, we ran the global historical transient simulations (1850–
235 2010) at 0.5 degree spatial resolution using GSWP3 v2 climate forcing data, along with
236 historical transient atmospheric CO₂ concentration, N deposition, land use and land cover
237 change that are part of the CMIP6 protocols (<https://luh.umd.edu/data.shtml>). Input data
238 and references are summarized in Table S3. We also ran a suite of single-factor simulations
239 to examine the individual effects of changing environmental factors. In addition to the ELM
240 v1 simulations with a fully active P cycle, we also performed historical transient and single-
241 factor simulations with P limitation switched off (supplementing P availability to fully meet
242 demand at each grid cell and for each timestep). We denoted the default ELM v1
243 simulations that have an active P cycle as the CNP configuration (ELMv1-CNP) and

244 simulations assuming P saturation (e. g. no P limitation on plant productivity or
245 decomposition) as the CN configuration (ELMv1-CN).

246 We also performed one additional simulation where we initiated a global step increase
247 of atmospheric CO₂ concentration, by +200ppm, starting from 2001 and continuing through
248 2010. These simulations are designed to mimic the Free Air CO₂ Enrichment (FACE)
249 experiments (Ainsworth and Long, 2005). To quantify model sensitivities to elevated CO₂,
250 we calculated the effect size (treatment divided by control) over the 10 years of simulation
251 (2001-2010). We then evaluated model sensitivities to elevated CO₂ against meta-analysis
252 from FACE experiments (Ainsworth and Long 2005).

253 All of the simulations are summarized in Table 1.

254

255 **2.3. ILAMB**

256 We used the International Land Model Benchmarking system (Collier et al., 2018; Luo et al.
257 et al., 2012; Hoffman et al., 2017) to assess the model performance. The ILAMB package is a
258 powerful tool for systematic evaluation of land model performance through comparison
259 with observational data for biogeochemistry, hydrology, radiation and energy, and climate
260 forcing. It was designed to use a wide array of observational data to constrain model
261 results, including various land carbon pools and fluxes, inferred CO₂ concentration
262 variability, and functional relationships. For each variable, ILAMB scores model performance
263 for period mean, bias, root-mean-square error (RMSE), spatial distribution, interannual
264 coefficient of variation, seasonal cycle, and long-term trend. These scores are aggregated
265 into an overall score representing multiple aspects of model performance for each variable.
266 These aggregated absolute scores are then used to calculate the relative score, which
267 indicates the relative performance of each model with respect to other models used in the
268 same analysis. ILAMB offers a variety of graphical diagnostics and tabular data to assist the
269 user in understanding when, where, and to what degree model results deviate from
270 observational data. The observational datasets used for the evaluation of carbon cycle in
271 ILAMB are listed in Table S4.

272 In order to understand how the implementation of P cycling dynamics affects model
273 performance, we evaluated the performance of both ELMv1-CNP and ELMv1-CN. In order to
274 provide a context in terms of model performance in ILAMB, we provide the ILAMB
275 evaluation of several other land models included in the Land Surface, Snow and Soil
276 moisture Model Intercomparison Project (LS3MIP) as part of CMIP6 (<https://www.wcrp-climate.org/wgcm-cmip/wgcm-cmip6>). LS3MIP includes a collection of model experiments
277 including both offline land model experiments and coupled experiments (Van Den Hurk et
278 al., 2016). We used the results from the offline land model experiments. Like our
279 simulations, these experiments were performed at 0.5by0.5 spatial resolution and using the
280 GSWP3 forcing data. Other model configurations in LS3MIP are identical to that used in
281 CMIP6 historical simulations, which we used for the simulations in this study.
282

283

284 2.4. GOLUM-CNP

285 Since there is no nutrient cycle metrics in ILAMB, we also compared major N and P pools
286 and fluxes along with nutrient use efficiencies from ELMv1-CNP with the data-driven
287 estimates of N and P pools and fluxes from the Global Observation-based Land-ecosystems
288 Utilization Model of Carbon, Nitrogen, and Phosphorus (GOLUM-CNP) (Wang et al., 2018).
289 GOLUM-CNP combines data-driven estimates of N and P inputs and outputs and observed
290 stoichiometric ratios with a steady-state diagnostic model, providing global steady-state N
291 and P pools and fluxes for large biomes. Despite large uncertainties and the steady-state
292 assumptions, GOLUM-CNP provides a global data-driven product that can be used to test
293 nutrient cycles in land surface models.

294

295 3. Results

296 3.1 Evaluations of ELM v1 using ILAMB

297 ILAMB includes many metrics that cover water, energy, and carbon pools and fluxes on
298 both regional and global scales. Fig. 1 shows ILAMB benchmarking scores for ELMv1-CNP
299 and ELMv1-CN, along with several other land models in CMIP6, which are provided to
300 contextualize ILAMB scores for ELMv1-CNP. The relative model performance scores are

301 shown in Fig. 1, indicating which model version performs better with respect to others. The
302 full results produced by the ILAMB package can be found at [https://compy-
303 dtn.pnl.gov/yang954/build/](https://compy-dtn.pnl.gov/yang954/build/).

304 Fig. 1 shows that the performance of ELMv1-CNP is comparable to other land models in
305 CMIP6. ELMv1-CNP exhibits performance similar to CLM5 (CESM2) in terms of aggregated
306 scores for carbon cycle metrics, while CLM5 shows better performance with respect to
307 overall functional relationships, mainly due to a better score for functional relationship of
308 burned area. The performance of each model varies for different variables. For example,
309 ORCHIDEE land surface model in IPSL-CM6A-LR performs relatively well in inferred
310 atmospheric carbon dioxide, leaf area index and GPP relationships.

311 Fig.1 also shows the comparison between ELM v1-CNP and ELM v1-CN, allowing us to
312 quantify the impacts of including a prognostic P cycle and realistic P availability on model
313 performance. For metrics in Fig. 1 that show the greatest differences between ELMv1-CNP
314 and ELMv1-CN, the CNP version always has a higher score than CN. This is reflected in the
315 relatively higher aggregated scores for carbon cycle variables and functional relationships
316 in ELMv1 -CNP.

317
318 Fig. 2 shows the Global Net Ecosystem Carbon Balance metric in ILAMB for ELM v1-CNP
319 and ELM v1-CN. The observational data sets for this metric are from the Global Carbon
320 Project (Fig. 2a)(Le Quéré et al., 2016) and from the inversion-based estimate (Hoffman et
321 al., 2014), both providing global totals of land carbon accumulation but for different
322 historical time period (1850-2010 for Hoffman et al., 2014 and 1959-2010 for Le Quere et l.,
323 2016). The simulated global C balance by both ELMv1-CNP and ELMv1-CN are in the range
324 of uncertainty of observational estimates, with ELMv1-CNP simulated historical global
325 carbon accumulation being a better match with mean observational estimates, particularly
326 after 1950. ELMv1-CN estimated a net accumulation of land carbon of 22 Pg C over the
327 period 1850-2010, which is much higher than the mean observational estimate of - 8Pg C.
328 ELMv1-CNP estimated land carbon accumulation of 7 Pg C.

329 Fig. 3 shows the spatial distribution of vegetation biomass for the benchmark data and
330 model bias in ILAMB. Overall both ELMv1-CN and ELMv1-CNP tend to overestimate
331 biomass, compared to this specific global product of biomass (GEOCARBON). The high bias
332 in the tropical region is much reduced in ELMv1-CNP simulations (Fig. 3a, 3b and 3c). The
333 better performance of ELMv1-CNP is also reflected in the spatial Taylor diagram for
334 biomass (Fig. 3d).

335 Another important benchmark in ILAMB is the functional relationships between two
336 variables, for example the relationship between GPP and precipitation and the relationship
337 between LAI and precipitation. An accurate simulation of these relationships in addition to
338 individual benchmarks is an indication that the models are representing the underlying
339 processes correctly. ELMv1-CNP produces a better functional relationship compared to
340 ELMv1-CN. For example, for the relationship between LAI and precipitation ELMv1-CN
341 overestimated LAI, particularly in regions with high precipitation, while the ELMv1-CNP
342 configuration shows an improved relationship (Fig. 4). The improvement of the functional
343 relationship is mainly due to the improvement in high precipitation regions, e.g. lowland
344 tropical forest regions. In these regions, inclusion of P dynamics and P limitation reduced
345 simulated bias in GPP and LAI, therefore leading to better match with the observations.

346

347 3.2. Evaluation of N and P cycling in ELMv1-CNP

348 We evaluated simulated nutrient use efficiencies against that from GOLUM-CNP product
349 on the biome level. Here we define nutrient use efficiency as the ratio between annual NPP
350 and annual nutrient uptake (for both N and P), with NUE for nitrogen use efficiency and
351 PUE for phosphorus use efficiency (Finzi et al., 2007). ELMv1-CNP simulated NUE is higher
352 in temperate and boreal forests and lower in grassland, which is consistent with GOLUM-
353 CNP (Fig. 5a). However, ELMv1-CNP predicted higher NUE in tropical lowland forests than
354 GOLUM-CNP. ELMv1-CNP simulated PUE is also generally consistent with GOLUM -CNP
355 (Fig. 5b). However, ELMv1-CNP simulated PUE in tropical forests is much lower than that
356 from GOLUM-CNP.

357 We also evaluated ELMv1-CNP simulated N and P pools and major fluxes on the global
358 scale for the period of 2001-2010 with the observationally derived products in GOLUM-
359 CNP. Fig. S2 shows the comparison of N and P uptake from ELMv1-CNP and GOLUM-CNP at
360 the biome level. ELMv1-CNP simulated plant N and P uptake is in agreement with GOLUM-
361 CNP, with higher uptake fluxes in tropical forests and lower uptake in temperate and boreal
362 forests. ELMv1-CNP simulated N uptake is lower in the tropical forests, compared to
363 GOLUM-CNP (Fig. S2a). Conversely, simulated P uptake is higher than GOLUM-CNP
364 estimates across the tropics (Fig. S2b).

365

366 **3.2 Evaluations using CO₂ manipulation experiment**

367 Relative to the control simulation, increasing atmospheric CO₂ concentration by 200ppm
368 increased gross primary productivity by 23% (global mean) over the 10 years of simulation
369 (2001-2010). Nearly all PFTs showed more than a 10% increase in productivity, with more
370 significant increases occurring in tropical regions and middle latitudes (Fig. 6a). The
371 modeled response ratio of NPP is also showing widespread increases, and on the global
372 scale our results showed a 25.8% increase in NPP in response to CO₂ enrichment (Fig. 6b).
373 The simulated increases in GPP and NPP also showed, to a large extent, translated into
374 increases in vegetation carbon (Fig 6c), with a global average response ratio of 18%. The
375 modeled response ratio of LAI is much smaller, a 5% increase globally (Fig 6d). The globally
376 aggregated simulated effect size of CO₂ enrichment from ELMv1-CNP on GPP, NPP, LAI and
377 NSC compare well to the observations from the meta-analysis (Fig. 7), particularly for GPP
378 and LAI. ELMv1-CNP overestimated the responses of NPP. Both observations and
379 simulations show large sensitivity of NSC to CO₂ enrichment, with larger variability in the
380 model simulations.

381

382 **3.3. Carbon, nitrogen and phosphorus pools and fluxes**

383 **3.3.1 Carbon budget**

384 Major components of the global land C budget for present day (mean of 2001–2010) in
385 ELMv1-CNP are shown in Fig 8a. These are from historical simulations with transient climate

386 forcing, atmospheric CO₂ concentration, land use and land cover change, and N deposition.
387 For the present day, model simulated total ecosystem C is 2588.73 Pg C, with about 22%
388 stored in vegetation (575.45 Pg C), about 5% stored in litter and coarse wood debris (122.5
389 Pg C), and 73% stored in soil organic matter (1890.78 Pg C). Model simulated vegetation C is
390 within the range of inventory-based estimates from IPCC AR5 (450–650 Pg C). Our simulated
391 vegetation C is also comparable to or slightly higher than observational estimates from the
392 literature: 455Pg C (GEOCARBON, (Avitabile et al., 2016; Santoro et al., 2015), 550±100 Pg C
393 (Houghton, 2003), 560±94 Pg C (Defries et al., 1999), and 450 Pg C (Erb et al., 2018). Model
394 simulated total soil C is within the range of estimates from IPCC AR5 (1500-2400 Pg C) and
395 that from Jobbágy and Jackson (2000) (1750±250 PgC). Model simulated total soil C is lower
396 than several other observational estimates from the literature: 2376-2456 (Batjes, 2014),
397 3000 Pg C (Köchy et al., 2015). As for the top 1m soil carbon, model simulated values are
398 within the range of estimate reported by Todd-Brown et al. (2013) (890-1660 Pg C), but
399 lower than the observational based estimate of 1462–1548 Pg C from Batjes (2014) and
400 1325 Pg C from Köchy et al. (2015). Model simulated litter C (22.9 Pg C) is lower than the
401 observational based estimate: 68 Pg C (Matthews, 1997) and 43±3 Pg C (Pan et al., 2011).
402 Model simulated coarse wood debris C stock (99.6 Pg C) is higher than the observational
403 based estimate: 75 Pg C (Matthews, 1997) and 43±3 Pg C (Pan et al., 2011).

404 Model simulated present day GPP(134.15 Pg C/yr) is slightly higher than observational
405 based estimate: 123±8 Pg C/yr (Beer et al., 2010), 119±6 Pg C/yr (Jung et al., 2011) and 123
406 PgC/yr (IPCC AR5), and lower than 150-175 Pg C/yr from Welp et al. (2011) that is derived
407 based on oxygen isotopes of atmospheric CO₂. A recent study based on satellite data
408 suggested a global GPP of 140 Pg C/yr for year 2007 (Joiner et al., 2018). The comparisons
409 between simulated carbon pools and fluxes and available observations are also included in
410 Table 2.

411

412 3.3.2. Nitrogen budget

413 The ELMv1-CNP estimated N budget for the present day (2001–2010) is summarized in
414 Fig 8b. Compared to the C cycle, there are fewer observational estimates for N pools and

415 fluxes. Most of the literature values are from other model simulations. Although not
416 appropriate for direct model evaluation, these modeling estimates from the literature
417 provide a broad context for us to evaluate our simulated pools and fluxes.

418 Model simulated vegetation N is 4.36 Pg N, which is comparable to the estimates from
419 some other modeling studies: 3.8 Pg N (Zaehle et al., 2010; Xu and Prentice, 2008), 5.3 Pg N
420 (Xu and Prentice, 2008) and lower than the estimates of 16 Pg N (Lin et al., 2000) and 18 Pg
421 N (Yang et al., 2009). Model simulated total soil organic matter N is 188.79 Pg N, which is
422 reasonable considering the observational based estimate for 1m of 95 Pg N (Post et al.,
423 1985) and 133–140 Pg N (Batjes, 2014). ELMv1-CNP estimated biological nitrogen fixation
424 (BNF) of 89 TgN/yr is within the range of estimates from literature. Vitousek et al. (2013)
425 estimated that global BNF ranges between 40–100 TgN/yr using a mass-balance approach.
426 A meta-analysis by Davies-Barnard and Friedlingstein (2020) suggested that global inputs of
427 BNF in natural ecosystems range between 52 and 130 TgN/yr, with a median global value of
428 88 TgN/yr. For the purpose of comparison, BNF estimates from CLM5 is 96.4 TgN/yr, slightly
429 higher than our estimate. The comparisons between simulated N pools and fluxes and
430 available observations are also included in Table 2.

431
432

433 **3.3.3 Phosphorus budget**

434 The ELMv1-CNP estimated P budget for the present day (2001–2010) is summarized in
435 Fig 8c. Very few observational data are available for P on the global scale. The only
436 observation-based global product is the global P maps developed by (Yang et al., 2013).
437 Model simulated vegetation P is 0.36 Pg P, which is comparable to the estimates from other
438 modeling studies ranging from 0.23 to 3 Pg P (Goll et al., 2012; Wang et al., 2010; Jahnke,
439 1992). Model simulated soil organic P is 3.75 Pg P, which is slightly lower than previous
440 studies 5.74 Pg P (Goll et al., 2012), 5–10 Pg P (Smil, 2000), and 8.6 Pg (Yang et al., 2013).
441 Model simulated soil mineral P for the top 40cm and 60cm is 63.24 and 81.32 respectively,
442 which are generally comparable to the estimate of 45 Pg P for top 50cm soil from Yang et al.
443

444 (2013). The comparisons between simulated P pools and fluxes and available observations
445 are also included in Table 2.

446

447 **3.4. The effects of P limitation on historical carbon cycle**

448 ELMv1-CNP calculates the extent of both N and P limitation for plant growth on the
449 global scale (Figs. 9a and 9b). Generally speaking, P is a more limiting nutrient in tropical
450 evergreen forests and savannas in South America and Africa, while N is more limiting in
451 temperate regions (Fig. 9a). The ratio between the P limitation factor and N limitation
452 factor illustrates the degree of N-P colimitation (Fig. 9b). In many parts of the world, both
453 N and P are limiting productivity.

454 Fig. 10 shows the effects of P dynamics on historical land carbon accumulation.
455 The introduction of P dynamics leads to a 19.5% reduction in C storage due to CO₂
456 fertilization between 1850 and 2010. The consideration of P dynamics also leads to a lower
457 estimate of land use emissions (143.89 PgC vs 161.21 PgC) as CNP simulations generally
458 show lower initial vegetation biomass. Increasing N deposition generally leads to a small
459 carbon accumulation between 1850 and 2010 in both CN and CNP simulations. With P
460 limitation, however, the carbon accumulation from N deposition is reduced by about a
461 third. Climate, although responsible for the large seasonal and interannual variability of
462 carbon fluxes, has only minor impacts on historical carbon accumulation on the global
463 scale for both CN and CNP simulations. When changes of all environmental factors are
464 considered, the impact of P dynamics on carbon accumulation is the balance between a
465 smaller CO₂ fertilization effect and lower land use emissions, with the net effect being
466 slightly lower historical carbon accumulation.

467 Fig. 11 shows the simulated spatial patterns of productivity and carbon storage and
468 how they are affected by P dynamics and limitation. P dynamics strongly control land
469 carbon uptake and storage, particularly in tropical regions. Globally NPP is highest in
470 tropical evergreen forests and lower in middle to high latitude regions. Plant growth in
471 tropical regions, however, is generally limited by P availability, particularly in the central
472 and eastern Amazon basin and tropical Africa. The reduced productivity due to P limitation

473 translates into reduced vegetation carbon storage and soil carbon storage, with the
474 exception of tropical savannas, where fire dynamics also play an important role in
475 vegetation and soil carbon storage.

476

477 **4. Discussions**

478 **4.1. ILAMB benchmarking**

479 This study presents a global assessment of the ELMv1-CNP. Yang et al. (2019) evaluated
480 the performance of ELMv1-CNP in the Amazon region using plot-level observations from the
481 RAINFOR network and found that the model captures well the observed productivity and
482 biomass gradient across the Amazon basin. Here we further evaluate the global model
483 performance using the ILAMB benchmarking system – an open source land model
484 evaluation system that is designed to assess model performance at site level, regional, and
485 global scales in an integrated and comprehensive way.

486 We include several other land models in CMIP6 in our ILAMB analysis with the goal of
487 providing a context for the performance of ELMv1-CNP. We found that ELMv1-CNP exhibits
488 similar performance to other models. It is challenging to demonstrate a clear improvement
489 or degradation for complex land surface models in ILAMB. For example, our analysis
490 indicates that ELMv1-CNP performance is comparable to CLM5 in terms of the overall
491 carbon cycle. Both ELMv1-CNP and CLM5 have a common ancestor CLM4.5, but they took
492 very different approaches for further development. CLM5 had significant efforts undertaken
493 in improving the representation of nitrogen cycle, while ELMv1-CNP was more focused on
494 implementing a prognostic phosphorus cycle and C-N-P interactions. Model development
495 activities in both models helped improved model performance through the lens of ILAMB
496 but the sources of improvements are quite different. This highlights the need to include
497 more process-level evaluations in ILAMB for the purpose of evaluating the impact of specific
498 model improvements.

499 Although CLM5 and ELM-CNP perform similarly in terms of ILAMB scores, it is worth
500 noting the unique role of P cycle dynamics in affecting C cycling and the importance of
501 including P cycle limitation in earth system models for better prediction of carbon-climate

502 feedbacks. The important role of soil P availability in affecting plant growth in tropical
503 forests residing on highly weathered soils has long been recognized (Walker and Syers,
504 1976; Vitousek et al., 2010; Butler et al., 2018; Elser et al., 2007). Recent work has also
505 explored how increasing demand for P may attenuate predicted increase in NPP
506 conceptually by comparing potential demand with potential nutrient available in the 21st
507 Century (Wieder et al., 2015b; Sun et al., 2017). Increasing numbers of land models have
508 incorporated P cycle dynamics and P limitations (Sun et al., 2021; Nakhavali et al., 2021).
509 Although both N and P limitation acts through reducing NPP, it is critical to include P cycling
510 explicitly in models since P cycle dynamics are very different from the N cycling dynamics.
511 The primary input for P is through rock weathering, which make it a very much non-
512 renewable nutrient for the terrestrial ecosystems, whereas N fixation, the primary input for
513 N, is more biologically driven. P cycling involves the transformation of various forms of P
514 through a series of biological, enzymatical and geochemical processes with the turnover
515 time ranging from seconds to millions of years. N cycle dynamics are relatively simpler, with
516 two inorganic forms and mostly biological and enzymatical processes involved. In addition,
517 the interactions between N and P cycling also points to the need to include P cycle explicitly
518 in land models. Increasing numbers of studies have shown that biological N fixation could
519 be constrained by soil P availability (Hungate et al., 2004; Reed et al., 2013; Barron et al.,
520 2008; Edwards et al., 2006; Crews et al., 2000). On the other hand, studies have also shown
521 that increases in N availability can promote phosphatase activity and enhance biochemical
522 mineralization and therefore accelerate P cycling (Mcgill and Cole, 1981; Wang et al., 2007;
523 Houlton et al., 2008; Olander and Vitousek, 2000; Treseder and Vitousek, 2001; Marklein
524 and Houlton, 2012). We will continue refine and improve the representation of the C-N-P
525 interactions in the future development of ELM.

526 Also, ILAMB, despite being a comprehensive benchmarking tool for land surface models,
527 is limited in scope in terms of the benchmarking data included. For example, Quesada et al.
528 (2012) found that the decreasing west-east gradient in productivity is mostly related to total
529 soil P. Yang et al. (2019) show that consideration of soil P availability improved model
530 simulated productivity, enabling the model to capture the productivity gradient from west

531 to east across the Amazon basin. The problem is that this productivity gradient across the
532 Amazon basin is not captured in ILAMB benchmark data so the “failure” of a CN model
533 would not be captured by ILAMB.

534 We show that the model performance generally improved with realistic P availability
535 through the implementation of a prognostic P cycle in ELM. Compared to ELMv1-CN,
536 ELMv1-CNP simulated biomass has lower bias across the tropical regions as P limitation
537 leads to lower productivity and hence lower biomass. ELMv1-CNP produces better ILAMB
538 scores on the functional relationships between GPP, LAI and other forcing variables, mainly
539 due to improved estimate of GPP and LAI in tropical regions. ELMv1-CNP also produces
540 higher ILAMB scores for the integrated benchmarks such as global net ecosystem carbon
541 balance and carbon dioxide concentration. We note that satisfactory performance for these
542 two integrated metrics is most critical to a land model in ESMs as they are most relevant to
543 the coupling between land ecosystems and radiatively-forced climate change.

544
545 Although the ILAMB benchmarking system is very useful for evaluating model
546 performance from different aspects simultaneously, interpretation of ILAMB scores
547 deserves extra caution with known observational bias considered. For example, ILAMB uses
548 LAI estimated from remote sensing observations from the Moderate Resolution Imaging
549 Spectroradiometer (MODIS) as benchmarking data, while studies have suggested that
550 MODIS LAI may be biased low due to reflectance saturation in dense canopies in the
551 tropical forests (Shabanov et al., 2005; Huete et al., 2002; Kobayashi and Dye, 2005).
552 Another example is the observational data for biomass. There are significant differences
553 between the “tropical” and “GlobalCarbon” datasets and the “GeoCarbon” dataset for
554 tropical biomass, but they were given about the same default weight in the ILAMB scoring
555 system. Mitchard et al. (2014) investigated the marked differences between different
556 estimates of Amazon biomass and suggested the regional biases in some remote sensing
557 products might be due to the lack of consideration of ecological variation in tree wood
558 density and allometry. Further investigation of these datasets is needed to ensure the
559 quality of biomass benchmarking data.

560

561 The current version of ILAMB includes analysis of 28 variables using more than 60
562 datasets or data products. None of these variables, however, are directly related to nutrient
563 cycles. As more land surface models are implementing N and P dynamics, it is becoming
564 increasingly important to include metrics for nutrient stocks and fluxes. Davies-Barnard et
565 al. (2020) assessed five nitrogen-enabled land surface models in CMIP6 and called out the
566 need to have better constraints of nitrogen cycle processes. The need is equally urgent, if
567 not more, to synthesize more observations to better constrain the P cycle processes, as less
568 synthesized data are available for P. Encouragingly, recent studies have started to develop
569 observational datasets based estimate of N and P cycling on the global scale for model
570 evaluation, such as the GOLUM-CNP dataset we used in this study. We hope to highlight the
571 need and engage the broader community in developing additional nutrient datasets that
572 can be included in ILAMB.

573 Other metrics that would be useful are the responses from N and P addition
574 experiments. As Yang et al. (2014) showed, fertilization experiments at sites along the
575 Hawaii chronosequence provided a useful evaluation testbed to assess model simulated
576 responses to N and P fertilization effects. FACE experiments are useful for model evaluation
577 as shown here (section 4.2) and in other studies (Wieder et al., 2019; Davies-Barnard et al.,
578 2020). Warming studies that include an explicit focus on nutrient cycle responses will be
579 another good evaluation opportunity (Melillo et al., 2002). An existing challenge is to
580 provide a common protocol to use these types of experiments in the ILAMB benchmarking
581 system.

582

583 4.2 Evaluations using GOLUM-CNP

584

585 On the biome level ELMv1-CNP simulated nutrient use efficiencies are consistent with
586 the observation-based estimates from GOLUM-CNP. This indicates that the representation
587 of N and P cycling and C-N-P coupling is reasonable in ELMv1-CNP. In terms of nutrient
588 uptake, both show the highest N and P uptake in tropical forests, due to the high N and P
589 demand associated with high productivity. ELMv1-CNP predicted lower N uptake in the

590 tropics, compared to GOLUM-CNP. Nutrient uptake in ELMv1-CNP is a function of nutrient
591 availability and nutrient demand, with demand being determined by available carbon for
592 allocation, allocation fractions to different plant tissues and plant tissue stoichiometry. The
593 simulated NPP at the biome level matches well with NPP from GOLUM-CNP (Fig. S3). The
594 differences in nutrient uptake is therefore likely due to the different C:N and C:P
595 stoichiometric ratios for different vegetation tissues used in ELMv1-CNP and GOLUM-CNP.
596 C:N ratios of leaf, wood, and fine root in GOLUM-CNP are all lower than ELMv1-CNP (21,
597 126, and 40 in GOLUM vs 30, 500, and 42 in ELMv1-CNP). This suggests for given amount of
598 carbon allocation, N uptake would be lower in ELMv1-CNP. C:P ratios of leaf, wood, and
599 fine root in GOLUM-CNP also differ quite significantly from those in ELMv1-CNP (410, 5429,
600 and 1250 in GOLUM vs 600, 3000, and 1000 in ELMv1-CNP). The relatively higher P uptake
601 in ELMv1-CNP can be attributed in large part to the difference in dead wood C:P ratios.
602 Differences in allocation factors could also be contributing to the differences in nutrient
603 uptake between ELMv1-CNP and GOLUM-CNP. For example, the mean allocation fraction to
604 fine root is higher in GOLUM-CNP compared to ELM-CNP, while allocation fraction to leaf is
605 lower in GOLUM-CNP, particularly in forest ecosystems (Fig. S4 and S6). GOLUM-CNP also
606 has higher NPP allocation fraction to woody biomass in boreal forests (Fig. S5)

607

608 **4.3. Evaluations using CO₂ manipulation experiments**

609 Our simulated large increase in GPP with CO₂ enrichment (23%) is in agreement with
610 field observations that photosynthetic assimilation increased 28% under elevated CO₂
611 (Ainsworth and Long, 2005). Our simulated 26% increase in NPP is higher than the 17%
612 increase in observed increase in dry matter production in the FACE experiments (Ainsworth
613 and Long, 2005; Wieder et al., 2019). Our simulated 18% increase in biomass is higher than
614 the estimates from Terrer et al. (2019), which provides a data-driven estimate of global CO₂
615 fertilization effect on biomass and show a relative increase in biomass of 12±3% for a 250
616 ppm CO₂ increase. A meta-analysis of woody plants responses to elevated CO₂ shows a
617 mean effects of 22.3% on biomass (Baig et al., 2015). Among CLM4, CLM4.5 and CLM5,
618 ELMv1-CNP is more comparable to CLM5 with a strong simulated response of GPP, NPP, and

619 vegetation carbon in response to CO₂ enrichment, while CLM4 and CLM4.5 showed very
620 weak CO₂ effects (Wieder et al., 2019).

621 The much stronger sensitivity of photosynthesis to elevated CO₂ in ELMv1-CNP is due to
622 the removal of instantaneous downregulation of photosynthesis as a response to nutrient
623 limitation. The instantaneous downregulation assumption in CLM4 and CLM4.5 has been
624 shown to be inconsistent with experimental results (Metcalf et al., 2017). Despite large
625 uncertainty, it is encouraging that simulated NSC response to elevated CO₂ is largely
626 consistent with the observational data (Fig. 7). The low sensitivity of LAI in ELMv1-CNP is
627 also consistent with field observations. Our results suggest the assumption we made
628 regarding the fate of photosynthate is reasonable. Yang et al. (2016) showed that enhanced
629 phosphatase enzyme production response to increasing CO₂ could have important impacts
630 on P availability and sustain forest productivity under elevated CO₂. In simulating the
631 planned free-air CO₂ enrichment experiment AmazonFACE, ELMv1-CNP simulated
632 phosphatase activity increased about 20% over 15 years (Fleischer et al., 2019). Here we
633 show that introduction of NSC pools further improve the response of vegetation processes
634 to changes in P availability and P limitation.

635
636 Our findings are consistent with field studies that show the strong increase of NSC under
637 eCO₂, particularly when nutrient availability is low (Wong, 1990; Körner et al. (2005)).
638 Several studies evaluating CLM4.5 using carbon isotope data also suggested that model
639 performance would be better with the introduction of an NSC pool (Mao et al., 2016;
640 Raczka et al., 2016; Duarte et al., 2017). Further synthesis of field measurements on NSC in
641 CO₂ enrichment experiments are needed to evaluate and constrain the representation of
642 NSC in models.

643 Our simulated strong sensitivity of photosynthesis to CO₂ enrichment is consistent
644 with recent studies that show large GPP growth during the twentieth century (Campbell et
645 al., 2017; Haverd et al., 2020; Ehlers et al., 2015). Ellsworth et al (2017) also showed a large
646 increase of photosynthesis in response to elevated CO₂ in a temperate forest FACE
647 experiment.

648 The increased sensitivity of GPP and NPP to CO₂ enrichment in ELMv1-CNP, compared
649 with the predecessors CLM 4 and CLM4.5, will very likely reduce the bias in the atmospheric
650 fraction of human CO₂ emissions in previous coupled simulations as noted by Hoffman et al.
651 (2014). In fact, CO₂ concentration metrics in ILAMB, which translate model simulated NEE
652 into atmospheric CO₂ signal using an atmospheric transport model (Collier et al., 2018), is
653 intended for the evaluation of this sensitivity. The inferred atmospheric CO₂ concentration
654 from ELM v1 is very reasonable compared with observed NOAA flask data (Fig. S8 and S9).

655

656 **4.4. Model estimated carbon, nitrogen, and phosphorus pools and fluxes**

657 Global C, N, and P pools in our ELMv1-CNP simulation are in good agreement with
658 recent independent global estimates, indicating that ELMv1-CNP is capable of simulating
659 the contemporary C, N and P cycles. In Yang et al. (2019) it was shown that introduction of
660 more realistic mortality processes improved the model representation of longitudinal
661 spatial patterns of biomass across the Amazon basin. Here we show that an overall high
662 bias in biomass production is corrected through limits of vegetation production in response
663 to P availability, without compromising the improved spatial gradients obtained through
664 the mortality mechanism. It is worth mentioning that our understanding of nutrient stocks
665 and fluxes is much less advanced in comparison with the global C cycle. This has been
666 increasingly acknowledged for the global N cycle as increasing numbers of land surface
667 models have incorporated N cycle dynamics and C-N interactions (Zaehle et al., 2010;
668 Wieder et al., 2019; Davies-Barnard et al., 2020; Smith et al., 2014; Sellar et al., 2019; Goll
669 et al., 2017a; Gerber et al., 2010). Biological N fixation and N-use efficiency have been
670 identified as the key processes that need to be better constrained for land surface models
671 (Davies-Barnard et al., 2020).

672 Our understanding of P stocks and fluxes are even less advanced than that for the N
673 cycle, as shown in this study and other modeling studies that include P as a limiting
674 nutrient. This is mainly due to: (1) various forms of P with different level of availability for
675 plants and microbes, (2) geochemical processes in conjunction with biological processes
676 controlling P availability, and (3) technical challenges in measuring soil P. For example,

677 Hedley fractionation data provide a comprehensive picture of different P forms in soils and
678 has been used for model evaluation and/or initialization in all the land surface models that
679 include a prognostic phosphorus cycle (Wang et al., 2010; Goll et al., 2012; Yang et al.,
680 2014; Yang et al., 2019). However, this extraction method is time-consuming and
681 challenging, and not many routine measurements have been made using this technique.
682 As such, observational estimates of P pools and fluxes are extremely limited. Although
683 recent global Hedley database development (Yang and Post, 2011; Hou et al., 2018) has
684 been helpful in global model development and evaluation, more observational data on P
685 stocks and fluxes are needed to better constrain P-enabled models.

686

687

688 **4.5. Effects of accounting for the P cycle dynamics on simulated carbon balance**

689 **4.5.1. Spatial variation of nutrient limitation**

690 Our simulated nutrient limitation pattern broadly agrees with the findings from Elser et
691 al. (2007) which supports the generally accepted notion that tropical ecosystems residing
692 on highly weathered soils are P limited (Walker and Syers, 1976; Lebauer and Treseder,
693 2008). A recent study that predicted spatial patterns of N and P limitation using the ratios
694 of leaf N and P resorption efficiencies also found a shift from P limitation to N limitation
695 with increasing latitude (Du et al., 2020). Lebauer and Treseder (2008) showed that N
696 limitation is widespread, even in tropical regions. This is consistent with our model
697 simulations which show that although P is more limiting in tropical forests, N is also a
698 limiting nutrient. The geographic distribution of nutrient limitation is generally in
699 agreement with that from Goll et al. (2012) and Wang et al. (2010). Goll et al. (2012)
700 suggests that P limits C uptake mainly in low latitude regions and high latitudes, while N is
701 the limiting nutrient in temperate regions. It is worth mentioning that in Goll et al. (2012) N
702 and P limitation generally have distinct geographic occurrence while this study suggests NP
703 co-limitation occurs in many parts of the world. Wang et al. (2010) also showed that
704 productivity in tropical forests and savanna is limiting by P, while most other biomes are
705 limited by N. This is broadly consistent with our results but with a few key differences.

706 Wang et al. (2010) suggests that P is the limiting nutrient for savannas, whereas our results
707 show savannas are more limited by N. This may have to do with the lack of representation
708 of fire disturbance in Wang et al. (2010). Savannas are subject to regular wildfires, which
709 could have significant effects on nutrient cycle dynamics and nutrient limitation. For
710 example, it has been suggested that while combustion causes significant gaseous losses of
711 N from burned ecosystems, P is largely retained as ash (Herbert et al., 2003). Braakhekke et
712 al (2017) also showed that there are strong losses of N due to fire. Furthermore, Wang et
713 al. (2010) suggested that tropical forests are limited only by P, not by N, whereas our
714 results indicate that N and P both limit tropical forest productivity, although P limitation is
715 more dominant in most of the lowland tropical forests. This is consistent with a recent
716 meta-analysis of nutrient fertilization experiments in tropical forests (Wright et al., 2018).

717

718 **4.5.2. The implications for global carbon cycle and climate**

719 Historical C accumulation is a result of many complex and sometimes counteracting
720 processes controlling C fluxes and stocks (Lawrence et al., 2019), including accumulation of
721 carbon on land due to CO₂ fertilization, accumulation due to nitrogen deposition, carbon
722 fluxes due to climate variability and climate change, and losses and gains due to land cover
723 conversion and regrowth following historical land cover changes (LULCC fluxes). Over the
724 long term, two of the dominant processes controlling C accumulation in terrestrial
725 ecosystems are C emissions due to LULCC and C uptake due to the CO₂ fertilization effect. P
726 cycle dynamics have important impacts on both of these processes, but with opposite sign.
727 Globally, considering P cycle dynamics leads to lower carbon emissions associated with
728 deforestation by about 11% (161.21 Pg in CN vs 143.89 in CNP). Conversely, CO₂
729 fertilization at the global scale is reduced by 20% when P limitation is included during the
730 historical time period (134 Pg C vs 108 Pg C). In general, the ELMv1-CN simulation shows a
731 CO₂ fertilization effect on biomass that is too strong, which leads to a stronger than
732 observed carbon sink compared to observational constraints from both Hoffman et al.
733 (2014) and Le Quere et al. (2016). ELMv1-CN simulation also produces stronger carbon
734 emissions from LULCC due to having higher biomass compared to ELMv1-CNP. The CO₂

735 fertilization effect in the ELMv1-CN simulations is strong enough to overcome the LULCC
736 losses with the net result being too large of a sink throughout the historical time period for
737 the CN model. Both model configurations lose carbon too slowly due to LULCC in the period
738 from 1850–1940, when compared to the Hoffman et al. (2014) global estimate. Both
739 models also predict continued losses over the period 1940–1965, while the Hoffman et al.
740 (2014) estimate switches from net carbon loss to net carbon accumulation around 1940.
741 These are clearly shown in Fig. S7, which shows the time series of simulated change in land
742 carbon storage in response to changes in CO₂, LULCC, N deposition, and climate during
743 1850–2010. The ELMv1-CN and ELMv1-CNP models are similar to many other CMIP6
744 models with respect to this bias in the timing of transition from net land carbon source to
745 net land sink as shown in our ILAMB analysis of other land models in CMIP6.

746

747 We also note that, over the historical time period, P became more limiting as simulated
748 historical C accumulations became increasingly divergent between CN and CNP simulations.
749 This is mainly caused by stimulated plant productivity under higher atmospheric CO₂, which
750 leads to higher plant demand for P that is not balanced by increased supply of newly
751 mineralized P from the soil. This is consistent with other global modeling studies with
752 explicit representation of P cycle dynamics (Goll et al., 2012; Zhang et al., 2014), as well as
753 diagnostic studies that evaluated how CO₂ fertilization simulated by CMIP5 models could
754 be constrained by soil P availability using a mass balance approach (Wieder et al., 2015b;
755 Sun et al., 2017). Taken together, the limiting effect of P availability on C uptake will likely
756 have substantial consequences for projections of future C uptake.

757

758

759 **4.6. Limitations and future development**

760 While the ELMv1-CNP simulations presented here show that the model is capable of
761 representing contemporary C, N and P stocks and fluxes and capturing the observed
762 ecosystem responses to changes in atmospheric CO₂, the current configuration does have
763 limitations.

764 While the model represents disturbances such as fire and the interactions between
765 disturbances and nutrient cycle dynamics, these interactions and how they affect carbon
766 cycle processes have not been well constrained with observational data. There is a growing
767 body of literature investigating the biogeochemical signature of fire. For example, a meta-
768 analysis by Butler et al. (2018) shows that fire led to significantly higher concentration of
769 soil mineral P and lower soil and litter C:P and N:P ratios, therefore decoupling the P cycle
770 from the C and N cycles. We will take advantage of these recent findings to improve model
771 fidelity on this front.

772 Another area that needs to be improved is the treatment of N fixation and how that is
773 linked to P availability. N fixation in ELMv1-CNP is represented as a function of NPP
774 (Cleveland et al., 1999). While providing a reasonable global estimate of N fixation, the
775 approach ignores existing mechanistic understanding of nitrogen fixation processes
776 (Wieder et al., 2015a). Furthermore, several lines of evidence suggest that both symbiotic
777 and free-living N fixation rates depend on the availability of other elements, such as P and
778 molybdenum (Reed et al., 2013; Nasto et al., 2014). N fixation could have important
779 implications for the spatial distribution of N limitation vs P limitation. In the future we plan
780 to have a more mechanistic representation of N fixation in ELM.

781 In ELMv1-CNP, P limitation is represented by downregulating plant growth when P
782 demand is greater than soil P availability. The mechanisms by which P fundamentally limits
783 ecosystem productivity remain uncertain (Jiang et al., 2019). Some studies proposed that
784 there are linear or log-linear relationships between leaf P concentration and
785 photosynthetic parameters, although the relationship has been shown to be weak (Walker
786 et al., 2014). P fertilization experiments in P limited ecosystems do not support this
787 proposed relationship. A P fertilization experiment on highly weathered soils in Australia
788 showed that although leaf P concentration increased significantly (+50%) compared to
789 unfertilized trees, photosynthetic capacity was unaffected (Crous et al., 2015).
790 Another fertilization experiment in Hawaii showed that the increase of aboveground NPP
791 with P fertilization was caused mainly by increases in LAI instead of photosynthesis per unit
792 leaf area (Herbert and Fownes, 1995). Further laboratory and field experiments are needed

793 to help us better understand and represent the role of P in photosynthesis. Investigating
794 the detailed mechanisms through which leaf P concentration affects photosynthesis is an
795 active field of research (Jiang et al., 2019; Norby et al., 2017; Crous et al., 2015), and
796 representing these relationships in land models remains an outstanding challenge.

797 Uncertainty also remains regarding the ELMv1-CNP representation of sorption dynamics
798 and biochemical mineralization and their responses to changes in atmospheric CO₂ and
799 climate (Fleischer et al., 2019). Motivated by our previous modeling studies, several recent
800 field studies have started focusing on improving our mechanistic understanding and
801 providing quantitative relationships for modelling these processes (Cabugao et al., 2017;
802 Brenner et al., 2019). A recent study that upscaled site-measurements of potential
803 phosphatase activity to continental Europe using machine learning technique provides a
804 potential pathway toward generating benchmark data for biochemical mineralization on
805 regional to global scale (Sun et al., 2020). There are other mechanisms that could sustain
806 productivity with increasing P limitation but were not considered in ELMv1-CNP, such as
807 flexible stoichiometry and dynamic allocation. These will be investigated further in future
808 versions of E3SM. However, as Fleischer et al. (2019) pointed out, since plant N:P ratios in
809 highly P limited tropical forests are already at the high end of the observed spectrum, the
810 role of stoichiometry plasticity in sustaining tropical productivity could be limited.

811 While the representation of NSC has helped ELMv1-CNP to capture the interannual
812 variability of atmospheric CO₂ and to generate ecosystem responses to elevated CO₂
813 consistent with FACE measurements, the sizes and turnover times of NSC pools are not well
814 constrained. We will synthesize limited measurements on NSC from literature that include
815 observational and experimental data as well as measurements from isotopic studies to
816 better understand the dynamics of the NSC pool and to evaluate and refine its
817 representation in ELM. We also advocate for more measurements on NSC and how they
818 respond to environmental changes in diverse ecosystems to have a more complete
819 understanding and quantification of NSC.

820 Finally, although models such as ELMv1-CNP and CLM5 perform similarly when
821 evaluated against present-day metrics as gathered in ILAMB, we expect that the

822 differences among models in their representation of observed processes and in their
823 assumptions about how changes in atmospheric composition and climate will impact
824 ecosystem processes will lead to diverging predictions under future climate scenarios. We
825 will explore those differences and their consequences in future work.

826

827 **5. Conclusions**

828 In this study, we provide an evaluation of ELMv1-CNP using the ILAMB benchmarking
829 system, comparison with CO₂ manipulation experiments, and comparison with other
830 observational and modeling studies. Benchmarking with ILAMB indicates ELMv1-CNP
831 produces realistic estimates of present-day carbon pools and fluxes. Compared to a
832 simulation with optimal P availability, ELMv1-CNP produces better performance,
833 particularly for the metrics that are most relevant to land-atmosphere exchange. Our
834 results from CO₂ manipulation experiments suggest that ELMv1-CNP is able to capture
835 observed responses to elevated CO₂, including those for GPP, NPP, vegetation C, and LAI.
836 Further analysis suggests that the introduction of a non-structural carbon pool in ELMv1-
837 CNP is largely responsible for these improvements. Evaluating global C, N, and P pools and
838 fluxes in the context of literature values suggests that ELMv1-CNP provides a reasonable
839 representation of contemporary global scale C, N and P cycles.

840 We highlight the data needs for global land model evaluation, particularly the need for
841 more synthesis datasets on nutrient pools and fluxes, as well as observations from
842 manipulation experiments that provide additional benchmark data for nutrient cycle
843 evaluation. This need is becoming increasingly pressing as more land models are including N
844 and P cycle dynamics and C-N-P interactions. We also identify challenges in constraining P
845 cycle dynamics and point to the need for soil P measurements.

846 Our simulations suggest, probably not surprisingly, that in general P is the more limiting
847 nutrient in the tropical regions while N is more limiting in the middle to high latitudes.
848 However, our results also suggest widespread N and P colimitation, even in the tropical
849 regions where P limitation is more dominant. Our results show that C sources and sinks are
850 significantly affected by P limitation, as the historical CO₂ fertilization effect was reduced by

851 20% and C emission due to LULCC was 11% lower when P limitation was considered. We
852 conclude that introduction of P cycle dynamics and C-N-P coupling will likely have
853 substantial consequences for projections of future C uptake.

1246 Figure 1: ILAMB carbon cycle scores for ELMv1-CNP and ELM-CN and a few land models in
 1247 CMIP6. Shown here is the relative score, indicating the performance of each model relative to
 1248 other models. References for benchmarking data for each variable are provided in Table S4.
 1249 Outputs for other land models are from the LS3MIP offline simulations archive in CMIP6. These
 1250 simulations were performed using the same resolution and forcing data as this study. CLM4.5 is
 1251 the land model in CMCC-ESM2. CLM5 is the land model for CESM2. OCHIDEE is the land model
 1252 for IPSL. JABACH is the land model for MPP-ESM1.2. VISIT is the land model for MIROC6.

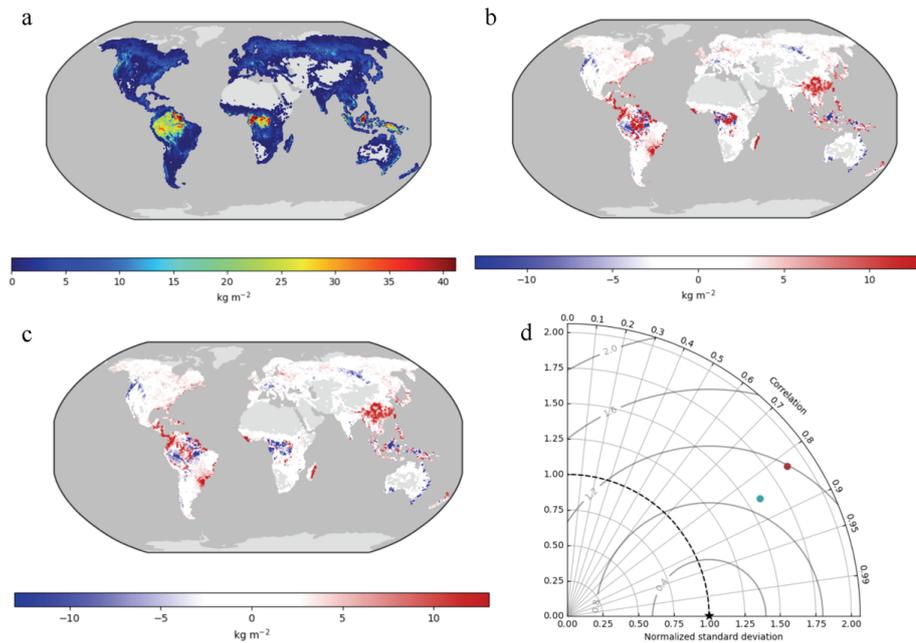

1253

1254 Figure 2: ELMv1-CNP and ELMv1-CN simulated global land carbon accumulation for the time
1255 period (a) 1960-2010 and (b) and 1850-2010. Benchmark data (black lines with uncertainty
1256 estimate in grey) are from (a) Global carbon project (Le Quere et al., 2016) and (b) Hoffman et
1257 al. (2014).

1296

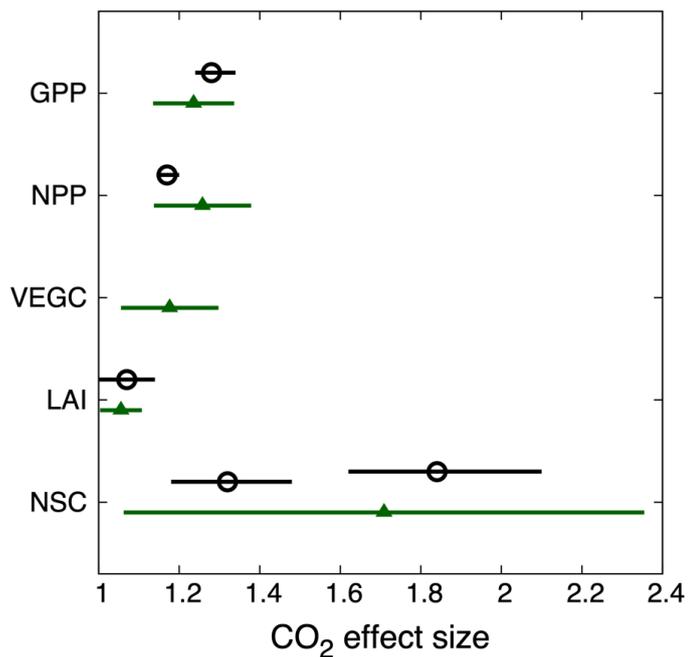

1297 Figure 6: Spatial distribution of the effect size of CO₂ enrichment on (a) GPP (b) NPP (c)

1298 Vegetation carbon (d) LAI. Effect sizes were calculated for each grid cell as the mean annual

1299 values of GPP, NPP, vegetation carbon and LAI from CO₂ enrichment simulation divided those

1300 from the control simulations between 2001-2010.

1301

1302

1303 Figure 7: Observed (open circles) and simulated (solid circles) effect size of CO₂ enrichment on

1304 GPP, NPP, LAI, vegetation carbon and non-structural carbon. Observations show the mean

1305 ($\pm 95\%$ confidence interval; Ainsworth and Long, 2005). There are two observations of NSC

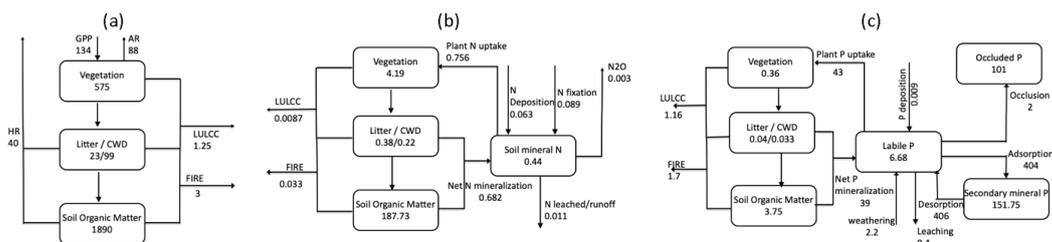

1306 shown here, one is for sugar and the other is for starch, while model conceptualization of NSC

1307 includes both sugar and starch. Simulated responses show the global mean effect sizes (\pm stand

1308 derivation; calculated to provide an estimate of spatial variation).

1309

1310

1311

1312

1313 Figure 8: (left) terrestrial C cycle, (middle) N cycle, and (right) P cycle as simulated by ELMv1-

1314 CNP, shown here are mean values between between 2001-2010. Vegetation and soil C, N and P

1315 pools are in units of Pg C, Pg N and Pg P, respectively. C and N fluxes are given in Pg C yr⁻¹ and

1316 Pg N yr⁻¹, and P fluxes are given in Tg P yr⁻¹.

1327
1328 Figure 9: (a) Spatial variation of the extent of nutrient limitation on plant growth. Regions with
1329 a negative value are more limited by N, while regions with a positive value are more limited by
1330 P. Larger absolute values are associated with stronger limitation. Values plotted are the
1331 proportion by which plant growth is reduced due to N limitation or P limitation: $1-f_P$ when f_P
1332 $< f_N$ and f_N-1 when $f_N < f_P$, where f_P is the limitation factor on plant growth considering P
1333 supply and demand, while f_N is the limitation factor on plant growth considering N supply and
1334 demand (Yang *et al.*, 2014). (b) Spatial variation of the ratios between P limitation and N
1335 limitation indicating the degree of co-limitation. Values plotted are the ratios between f_N and
1336 f_P : f_N/f_P . Regions with values less than 1 indicate more N limitation and regions with values
1337 greater than 1 are more limited by P. Values close to 1 indicate NP co-limitation.
1338
1339

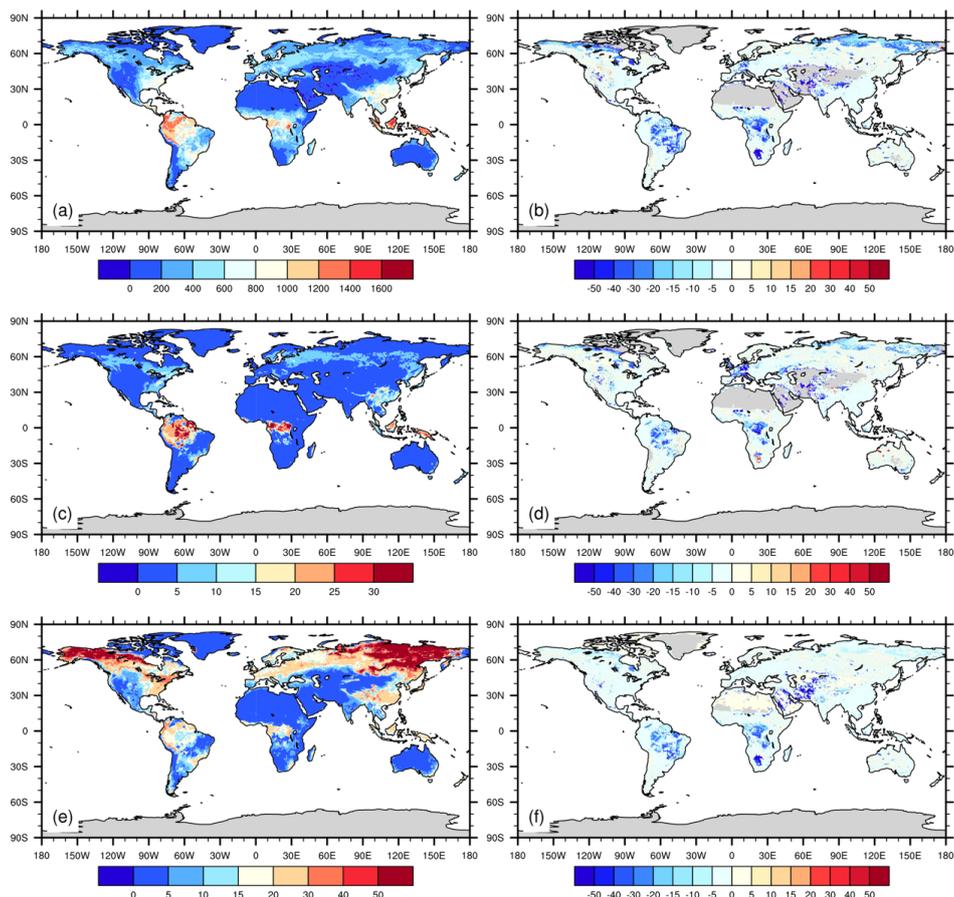

1340

1341 Fig. 10: (a) Cumulative global carbon storage from 1850 to 2010 from ELMv1-CN and ELMv1-
1342 CNP simulations with changes in land use and land cover change (LUC), atmospheric CO₂ (CO₂),
1343 climate (CLIM), N deposition (NDEP), and all factor combined (ALL). These are calculated as the
1344 accumulation of NEE between 1850 and 2010 for the historical transient model simulations
1345 listed in Table 1.

1346

1347

1348

1349

1350 Fig. 11: Average estimates and effects of phosphorus dynamics on (a,b) net primary
1351 productivity, (c,d) vegetation carbon and (e,f) soil organic carbon for the years 2001-2010, as
1352 estimated by ELM v1. The effects of P dynamics are expressed as percentage deviation between
1353 CNP and CN configurations

1379 Table 2: Comparison of ELMv1-CNP Simulated Mean Global Stocks and Fluxes of C, N and P
 1380 between 2001 and 2010 to Observation-based Estimates

	ELMv1-CNP	Observation-based Estimates		
			Source	Methodology
GPP (Pg C yr ⁻¹)	134.15	123±8	Beer et al., 2010	Using eddy covariance flux data and various diagnostic models
		150-175	Welp et al., 2011	Based on oxygen isotopes of atmospheric CO ₂
		119±6	Jung et al., 2011	upscaled FLUXNET observations to the global scale using the machine learning technique, model tree ensembles (MTE).
		121.60 - 129.42	Zhang et al., 2017	Light use efficiency theory, MODIS satellite data and climate data
		140	Joiner et al., 2018	Satellite Data-Driven Models and Eddy Covariance Flux Data
NPP (Pg C yr ⁻¹)	46.09	55±11	Turner et al., 2006	MODIS products
		33-49	Smith et al., 2016	MODIS NPP algorithm driven by long-term Global Inventory Modeling and Mapping Studies (GIMMS) FPAR and LAI data
Vegetation C (Pg C)	575.45	550±100	Houghton, 2003	Literature synthesis
		560±94	Defries et al., 1999	
Soil carbon (Pg C)	1890.78	1750±250	Houghton, 2003	Literature synthesis
		2344	Jobbagy and Jackson, 2000	based on >2700 soil profiles in three global databases supplemented with data for climate, vegetation, and land use.
		3000	Kochy et al., 2015	Based on the Harmonized World Soil Database(HWSD), but with more detailed estimates for permafrost and tropical wetland soil carbon
		2376–2456	Batjes, 2014	Top 2m. Based on 4353 soil profiles distributed globally and the FAO Soil Map of the World.
Top 1m soil carbon (Pg C)	1134.41	1462-1548	Batjes, 2014	Based on 4353 soil profiles distributed globally and the FAO Soil Map of the World.
		1325	Kochy et al., 2015	Based on the Harmonized World Soil Database(HWSD), but with more detailed estimates for permafrost and tropical wetland soil carbon
		1502	Jobbagy and Jackson, 2000	based on >2700 soil profiles in three global databases supplemented with

				data for climate, vegetation, and land use.
Soil organic N (Pg N)	188.79	95	Post et al. 1985	Based on 3100 soil profiles and a global map of Holdridge life zones
		133-140	Batjes et al., 2014	Top 1m. Based on 4353 soil profiles distributed globally and the FAO Soil Map of the World
N fixation (Tg N yr ⁻¹)	89	40-100	Vitousek et al., 2013	Estimates for Pre-industrial. Combining information on N fluxes with ¹⁵ N relative abundance data for terrestrial ecosystems
		52-130	Davies-Barnard and Friedlingstein (2020)	Based on a comprehensive meta-analysis of field measurements
N uptake (Tg N yr ⁻¹)	760	570	Wang et al., 2018	Data-driven estimates. Observations include observed stoichiometric ratios, N and P external input fluxes, and the fraction of gaseous losses of N to total (gaseous and leaching) losses of N from a global data set of ¹⁵ N measurements in soils
N Leaching (Tg N yr ⁻¹)	12	38	Wang et al., 2018	Data-driven estimates. See above
		28	Mayorga et al., 2010	based on a mass-balance approach for the land surface (watershed) and river system for year 2000
P uptake (Tg P yr ⁻¹)	43	26	Wang et al., 2018	Data-driven estimates. See above
P leaching (Tg P yr ⁻¹)	0.46	2.6	Wang et al., 2018	Data-driven estimates. See above
P occlusion (Tg P yr ⁻¹)	1.85	1.3	Wang et al., 2018	Data-driven estimates. See above
