17 **Abstract.** Assessing nutrient critical load exceedances requires complete and accurate atmospheric deposition budgets  
18 for reactive nitrogen ( $N_r$ ). The exceedance is the total amount of  $N_r$  deposited to the ecosystem in excess of the critical  
19 load, which is the amount of  $N_r$  input below which harmful effects do not occur. Total deposition includes all forms  
20 of  $N_r$  (i.e., organic and inorganic) deposited to the ecosystem by wet and dry pathways. Here we present results from  
21 the Southern Appalachian Nitrogen Deposition Study (SANDS), in which a combination of measurements and field-  
22 scale modeling were used to develop a complete annual  $N_r$  deposition budget for a deciduous forest at the Coweeta  
23 Hydrologic Laboratory. Wet deposition of ammonium, nitrate, nitrite, and bulk organic N were measured directly.  
24 The dry deposited  $N_r$  fraction was estimated using a bidirectional resistance-based model driven with speciated  
25 measurements of  $N_r$  air concentrations (e.g., ammonia, ammonium aerosol, nitric acid, nitrate aerosol, bulk organic N  
26 in aerosol, total alkyl nitrates, and total peroxy nitrates), micrometeorology, canopy structure, and biogeochemistry.  
27 Total annual deposition was  $\sim 6.7 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ , which is on the upper end of  $N_r$  critical load estimates recently  
28 developed for similar ecosystems in nearby Great Smoky Mountains National Park. Of the total (wet + dry) budget,  
29 51.2% was contributed by reduced forms of  $N_r$  ( $\text{NH}_x = \text{ammonia} + \text{ammonium}$ ), with oxidized and organic forms  
30 contributing  $\sim 41.2\%$  and  $7.6\%$ , respectively. Our results indicate that reductions in  $\text{NH}_x$  deposition would be needed  
31 to achieve the lowest estimates ( $\sim 3.0 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ ) of  $N_r$  critical loads in southern Appalachian forests.

32  
33  
34

## 1 Introduction

35 Prior to the Industrial Revolution, Earth's ecosystems received reactive nitrogen ( $N_r$ ) deposition rates of  $\sim 0.5 \text{ kg ha}^{-1}$   
36  $\text{yr}^{-1}$  (Holland et al., 1999). Since the 19<sup>th</sup> century, anthropogenic activities, both industrial and agricultural, have  
37 resulted in unprecedented quantities of  $N_r$  being released into the atmosphere, subsequently altering biogeochemical  
38 cycles (Neff et al., 2002a,b; Ollinger et al., 2002; Bragazza et al., 2006; Doney et al., 2007; Galloway et al., 2008;  
39 Boonstra et al., 2017). Excessive atmospheric deposition of  $N_r$  to terrestrial ecosystems may lead to soil and aquatic  
40 acidification, nutrient imbalance and enrichment, plant damage and microbial community changes as well as loss of  
41 biodiversity (Bobbink et al., 1998; Lohse et al., 2008; Simkin et al., 2016). Nitrogen deposition rates in many areas,  
42 including North America, Europe and Asia, exceed  $10 \text{ kg ha}^{-1} \text{ yr}^{-1}$  and may double current rates by the year 2050 in  
43 some regions (Galloway et al., 2008).

44 The amount of  $N_r$  deposition below which significant harmful effects do not occur is known as the critical load  
45 (Nilsson and Grennfelt, 1988). Critical loads can be quantified using empirical relationships between ecosystem N  
46 input and ecosystem response (Pardo et al., 2011; Root et al., 2015), or mass balance type biogeochemical models  
47 (Lynch et al., 2017; McNulty et al., 2007). For the southern Appalachian Mountains, simple mass balance approaches  
48 yield critical loads similar to those derived from empirical approaches for forest health and biogeochemical responses.  
49 In a recent study employing a mass balance model for the Great Smoky Mountains National Park, Pardo et al. (2018)  
50 quantified critical loads for spruce-fir, beech, and mixed deciduous forests in the range of 2.8 to  $7 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ , with  
51 the highest value corresponding to a high-elevation spruce-fir site experiencing disturbance-induced regrowth.  
52 Accurate and complete deposition budgets (i.e., including all forms of N) are required to quantify the amount of N  
53 input to ecosystems in excess of the critical load (i.e., the critical load exceedance).

54 Estimates of N deposition for critical load assessments can be derived from gridded chemical transport models (CTMs)  
55 (Ellis et al., 2013; Lee et al., 2016; Simkin et al., 2016; Clark et al., 2018; Makar et al., 2018), measurement-model  
56 fusion (MMF) techniques that combine measurements with CTM output (Schwede and Lear, 2014; Nanus et al., 2017;  
57 McDonnell et al., 2018; U.S. EPA, 2019a), or inferential modeling with site specific measurements (Flechard et al.,  
58 2011; Li et al., 2016). While these approaches reflect the state-of-the-science and are widely used, they collectively  
59 suffer from incompleteness of the N deposition budget (and are therefore biased low) (Walker et al., 2019a).  
60 Monitoring networks for wet deposition (NADP/NTN) and air concentrations of  $N_r$  (CASTNET) focus only on  
61 inorganic species, excluding organic forms of N which account for  $\sim 25\%$  of total N in wet deposition on average  
62 (Jickels et al., 2013). Due to difficulties in sampling (Walker et al., 2012) and the inability to fully speciate the wide  
63 range of constituents (Neff et al., 2002a; Altieri et al., 2009, 2012; Cape et al., 2011; Samy et al., 2013, Chen et al.,  
64 2018), organic N is not routinely monitored. Hence, deposition of organic N remains uncertain, and thus N deposition  
65 budgets developed from network monitoring data and CTMs remain incomplete.

66 Current N deposition estimates also have a relatively high degree of uncertainty in the estimation of dry deposition.  
67 While wet deposition is routinely measured, direct measurements of dry  $N_r$  deposition (i.e., flux measurements) in  
68 North America are relatively few (Walker et al., 2020). Estimates of dry deposition for ecosystem assessments are  
69 therefore derived from models (Schwede and Lear, 2014; Li et al., 2016; Lee et al., 2016). Of the inorganic N species,

70 NH<sub>3</sub> is the most important contributor to dry deposition in many areas (Walker et al., 2019b) but also the most  
71 uncertain (Flechard et al., 2011) due to the bi-directionality of surface-atmosphere exchange. A paucity of flux  
72 measurements (Walker et al., 2020) precludes bias correction of dry deposition in CTMs and MMF techniques, making  
73 dry deposition much more uncertain relative to wet deposition.

74 The Coweeta study site represents southern Appalachian Mountain forests, highly diverse and productive ecosystems  
75 that provide a variety of ecosystem services, including a source of surface drinking water (Caldwell et al., 2014).  
76 While deposition of oxidized N to forests in the southeastern U.S. has declined in response to the Clean Air Act,  
77 montane ecosystems continue to receive high rates of deposition due to elevation-induced precipitation gradients  
78 (Weathers et al., 2006; Knoepp et al., 2008). Southern Appalachian forests continue to show signs of sensitivity to N  
79 deposition. For example, litterfall N fluxes and foliar N concentrations at Coweeta have steadily increased over the  
80 past two decades (Knoepp et al., 2018). Highly spatially variable meteorological patterns typical of complex terrain  
81 are difficult to model (Lehner and Rotach, 2018), leading to uncertainties in precipitation amounts and wet deposition  
82 (Zhang et al., 2018) as well as the micrometeorological processes that govern dry deposition (Cowan et al., 2022).  
83 Estimates of deposition from gridded CTMs in mountainous terrain therefore contain a higher degree of uncertainty  
84 relative to low-elevation ecosystems. For these reasons, a better understanding of total N deposition in southern  
85 Appalachian forests is needed.

86 This study investigates the N deposition budget in a remote montane forest in the southeastern U.S. We combine long-  
87 term (1978 – 2020) and seasonal intensive (2015-2016) measurements of wet deposition, speciated air concentrations  
88 of N<sub>r</sub>, micrometeorology, biogeochemistry and forest canopy structure with in-situ inferential dry deposition modeling  
89 to develop an annual, speciated, total N deposition budget, including net and component NH<sub>3</sub> fluxes as well as dry  
90 and wet organic N deposition. Seasonal and annual total N deposition fluxes are presented in the context of long-term  
91 trends in air concentrations and wet deposition of inorganic N species. Spatial representativeness is characterized  
92 using measurements of air concentrations of the primary inorganic N species and previous wet deposition  
93 measurements along an elevation gradient across the topographically complex forested basin.

## 2 Methods

### 94 2.1 Site description

95 The study was conducted at the USDA Forest Service Coweeta Hydrologic Laboratory, a 2,185-ha experimental forest  
96 in southwestern North Carolina, USA (35°3' N, 83°25' W) near the southern end of the Appalachian Mountain  
97 chain. Topography is complex, with elevations ranging from 675 to 1592 m within the Coweeta Basin. Mean annual  
98 temperature and precipitation are 12.9 °C and 1795 mm, respectively. Dominant overstory species are *Liriodendron*  
99 *tulipifera*, *Quercus alba*, *Betula lenta*, and *Acer rubrum*, which comprise 24%, 17%, 11%, and 8% of the basal area,  
100 respectively, in the low-elevation forests where the study was conducted (Oishi et al., 2018). The dominant understory  
101 woody shrub species is *Rhododendron maximum* (evergreen), which comprises 13% of the basal area (Oishi et al.,  
102 2018). Species composition in the vicinity of the eddy flux tower (EFT), further described below, is detailed in Table  
103 S1. Canopy height surrounding the EFT is ~ 30 m.

104 The Coweeta Basin has been a long-term monitoring site for atmospheric chemistry and deposition since the late  
105 1970s. Weekly wet deposition of ammonium ( $\text{NH}_4^+$ ) and nitrate ( $\text{NO}_3^-$ ), along with sulfate ( $\text{SO}_4^{2-}$ ), chloride, and base  
106 cations have been measured as part of the NADP/NTN (Site NC25, [https://nadp.slh.wisc.edu/networks/national-](https://nadp.slh.wisc.edu/networks/national-trends-network/)  
107 [trends-network/](https://nadp.slh.wisc.edu/networks/national-trends-network/)) since 1978. Weekly integrated air concentrations of particulate  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ , chloride, and base  
108 cations, as well as nitric acid ( $\text{HNO}_3$ ) and sulfur dioxide ( $\text{SO}_2$ ), have been measured by CASTNET (Site COW137,  
109 <https://www.epa.gov/castnet>) since 1987. Since 2011, biweekly integrated air concentrations of ammonia ( $\text{NH}_3$ ) have  
110 been measured by the NADP Ammonia Monitoring Network (AMoN Site NC25,  
111 <https://nadp.slh.wisc.edu/networks/ammonia-monitoring-network/>). Here we use these datasets to place our study  
112 results into historical context, supplement the more intensive atmospheric chemistry measurements described below,  
113 and as inputs for inferential modeling of dry deposition. The long-term NADP and CASTNET measurements are  
114 collected in the lower part of the basin, indicated as NC25/COW137 in Figure 1.

## 115 **2.2 Southern Appalachian Nitrogen Deposition Study**

116 Building on the long-term NADP and CASTNET measurements described above, the Southern Appalachian Nitrogen  
117 Deposition Study (SANDS) was conducted in 2015 and 2016 to better understand the atmospheric chemistry and  
118 deposition of reactive nitrogen at Coweeta. Intensive measurement campaigns were conducted from May 21–June 9,  
119 2015; August 6–25, 2015; September 9–26, 2015; April 19–May 11, 2016; and July 13–August 3, 2016. A subset of  
120 measurements was conducted continuously between May 2015 to August 2016. As described below, time-resolved  
121 and time-integrated measurement techniques were used to characterize organic N in the gas phase, in particulate  
122 matter, and in wet deposition; the temporal variability of air concentrations of gas-phase oxidized and reduced forms  
123 of N; and the spatial variability of atmospheric N concentrations across the Coweeta Basin. Vertical profiles of air  
124 concentrations were measured within the forest canopy to examine source/sink processes and measurements of soil  
125 and vegetation chemistry were conducted to characterize  $\text{NH}_3$  emission potentials. Measurements were combined with  
126 NADP and CASTNET data to develop seasonal and annual total N deposition budgets employing inferential modeling  
127 for the dry deposition component. Vertical concentration profile and biogeochemical measurements were used to  
128 inform the parameterization of  $\text{NH}_3$  bi-directional exchange. Sampling locations are described in Figure 1 and Table  
129 1. Measurement details are summarized in Table 2.

### 130 **2.2.1 Wet deposition**

131 Additional wet deposition measurements were conducted adjacent to the NTN NC25 sampler to quantify the  
132 contribution of bulk water-soluble organic N (WSON) to water-soluble total nitrogen (WSTN) in precipitation.  
133 Weekly precipitation samples were collected in a modified wet-only sampler with a borosilicate glass funnel and  
134 amber glass bottle (Walker et al., 2012), shielded from sunlight, and maintained in the field under continuous  
135 refrigeration to maintain the stability of ON until retrieval (Walker et al., 2012). Samples were sent to the NADP  
136 Central Analytical Laboratory on ice for analysis of  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ , and WSTN as described by Walker et al.  
137 (2012). WSON concentration was calculated as:  
138 
$$\text{WSON} = \text{WSTN} - (\text{NH}_4^+ + \text{NO}_3^- + \text{NO}_2^-) \quad (1)$$

139 The method detection limit for WSON is  $10 \mu\text{g N L}^{-1}$  (Walker et al., 2012). These measurements were collected  
140 continuously from February 2015 to August 2016.

141 During the spring of 2015, thymol was added to the precipitation collection bottle as a biocide to inhibit organic  
142 nitrogen loss in the sample should the refrigerated collector malfunction or lose power. Thymol negatively affected  
143 the precision of the total nitrogen measurement, and its use was discontinued in fall of 2015. Ultimately, there were  
144 no issues with the refrigerated collector, and the thymol-containing samples were excluded from the analysis presented  
145 herein. However, this data loss resulted in a gap from August 2015 to mid-October 2015 of the 12-month period for  
146 which the total deposition budget is developed. The data gap comprised eight weekly periods in which precipitation  
147 occurred. For this period, the  $\text{NH}_4^+$  and  $\text{NO}_3^-$  concentrations from the collocated NADP/NTN NC25 sampler were  
148 used. Based on the SANDS measurements, the ON concentration during this period was estimated by assuming that  
149  $\text{NH}_4^+ + \text{NO}_3^-$  contribute 89% of total nitrogen in rainfall, with WSON representing the balance (11%). For the annual  
150 budget, weekly concentrations were combined with measured precipitation depth to calculate weekly deposition ( $\text{kg}$   
151  $\text{N ha}^{-1}$ ). Comparison between SANDS and NTN concentrations of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  showed very good agreement  
152 (Supplemental Section S1, Figure S1).

### 153 **2.2.2 Air concentrations**

154 Hourly concentrations of  $\text{NO}_y$ ,  $\text{HNO}_3$ , total gas-phase peroxy nitrates ( $\Sigma\text{PN}$ ), and total gas-phase alkyl nitrates ( $\Sigma\text{AN}$ )  
155 were measured continuously from August 2015 to August 2016 at the height of 8 m adjacent to the COW137  
156 CASTNET tower (Figure 1, Tables 1 and 2).  $\text{NO}_y$  and  $\text{HNO}_3$  were measured using a modified model 42S  $\text{NO-NO}_2$ -  
157  $\text{NO}_x$  analyzer; the  $\text{NO}_y$  technique is described in detail by Williams et al. (1998). Briefly, total oxidized reactive  
158 nitrogen ( $\text{NO}_y$ ) is converted to  $\text{NO}$  using a molybdenum catalyst heated to  $325^\circ\text{C}$ . On a second channel, a metal  
159 denuder coated with potassium chloride ( $\text{KCl}$ ) is used to remove  $\text{HNO}_3$  before passing through a second molybdenum  
160 converter heated to  $325^\circ\text{C}$ . The difference between the total  $\text{NO}_y$  measurement and the  $\text{HNO}_3$ -scrubbed  $\text{NO}_y$   
161 measurement is interpreted as  $\text{HNO}_3$ . Here we refer to the method as denuder difference chemiluminescence (DD-  
162 CL).

163 Total peroxy nitrates ( $\Sigma\text{PNs}$ ) and total alkyl nitrates ( $\Sigma\text{ANs}$ ) were measured using a modification of the technique  
164 described by Day et al. (2002), in which  $\text{PNs}$  and  $\text{ANs}$  are thermally decomposed to  $\text{NO}_2$  followed by measurement  
165 of the incremental  $\text{NO}_2$  above ambient background for each decomposition step. Day et al. (2002) quantified  $\text{NO}_2$  via  
166 laser induced fluorescence, while photolytic conversion to  $\text{NO}$  and quantification of the resulting  $\text{NO}$  by  $\text{NO-O}_3$   
167 chemiluminescence is used in the current study. Here we refer to the method as thermal decomposition, photolytic  
168 conversion, chemiluminescence (TD-PC-CL). A single chemiluminescence analyzer was used for  $\text{NO}_y$ ,  $\text{HNO}_3$ ,  $\Sigma\text{PN}$ ,  
169 and  $\Sigma\text{AN}$  measurements. Additional detail on the instrument and associated QA/QC procedures is included in  
170 Supplemental Section S2.

171 Hourly concentrations of  $\text{NH}_3$  and  $\text{HNO}_3$  were measured on the eddy flux tower (EFT, Figure 1, Tables 1 and 2) at  
172 two heights above the canopy (34 m and 37.5 m above ground during spring, 2016; 34 m and 43.5 m above ground  
173 during summer, 2016) using the Monitor for Aerosols and Gases in Ambient Air (MARGA, Metrohm Applikon B.V.,  
174 the Netherlands). Details and principles of the MARGA system have been previously described (Rumsey and Walker,

175 2016; Chen et al., 2017). Briefly, the MARGA 2S consisted of two sampler boxes positioned on the tower and a  
176 detector box located in a climate-controlled enclosure at the base of the tower. Sample boxes comprised an inlet of  
177 1.27 cm outer diameter 30 cm long PFA Teflon tubing with no particle size selection, through which air flow was  
178 mass controlled at  $\sim 16.7 \text{ L min}^{-1}$ , a wet rotating denuder (WRD) for collection of soluble gases, and a steam jet aerosol  
179 collector (SJAC). Liquid sample from the WRD and SJAC is continuously drawn from the sample boxes down the  
180 tower to the analytical box for analysis by Ion Chromatography (IC) on an hourly basis at the detector unit located in  
181 a climate-controlled enclosure at the base of the tower. At the beginning and end of the measurement intensive, multi-  
182 level liquid  $\text{NO}_3^-$  and  $\text{NH}_4^+$  standards were introduced at the WRD and SJAC, with airflow turned off, to assess the  
183 analytical accuracy of the  $\text{NH}_3$  and  $\text{HNO}_3$  measurement. MARGA measurements were conducted during the spring  
184 and summer of 2016 intensives. Comparisons of continuous and time-integrated methods for  $\text{HNO}_3$  and  $\text{NH}_3$  are  
185 summarized in Supplemental Section S1 (Figures S2 and S3).

186 Concentrations of  $\text{NH}_3$ ,  $\text{HNO}_3$ ,  $\text{SO}_2$ ,  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and  $\text{SO}_4^{2-}$  in air were measured concurrently on the EFT at 10 heights  
187 from just above the forest floor (0.5 m above ground) to several meters above the canopy (upper height of 37 m above  
188 ground during spring 2016, 43.5 m above ground during summer, 2016) using a glass annular denuder/filter pack  
189 (URG Corporation, Chapel Hill, NC) system. The sampling assembly included a 1%  $\text{Na}_2\text{CO}_3$  coated denuder for  
190 collection of acid gases followed by a 1%  $\text{H}_3\text{PO}_3$  coated denuder for collection of  $\text{NH}_3$ , and a filter pack containing a  
191 primary Teflon filter for collection of aerosol and a backup Nylon filter (47 mm, Pall Corp, Port Washington, NY) to  
192 collect  $\text{HNO}_3$  liberated by dissociation of  $\text{NH}_4\text{NO}_3$  on the primary filter. Inlets were Teflon coated glass impactors  
193 with a nominal  $2.5 \mu\text{m}$  aerodynamic diameter cutpoint (URG Corporation, Chapel Hill, NC). Sample durations were  
194 typically 3 or 4 h at a flow rate of  $\sim 16.7 \text{ L min}^{-1}$ . Flow rates were controlled by critical orifice and were verified  
195 before and after each sampling period with a NIST traceable primary standard flow meter (Bios DryCal DC-Lite  
196 flowmeter, Mesa Laboratories, Inc., Lakewood, CO).

197 Denuders and filters were extracted with 10 mL of deionized water and analyzed by ion chromatography (IC, Dionex  
198 model ICS-2100, Thermo Scientific, Waltham, MA). Extracts were analyzed for cations using Dionex IonPac 2-mm  
199 CG12 guard and CS12 analytical columns; separations were conducted using 20 mM methanesulfonic acid (MSA) as  
200 eluent at a flow rate of  $0.25 \text{ mL min}^{-1}$ . Anions were analyzed (IonPac 2-mm AG23 guard column, AS23 analytical  
201 columns) using an isocratic eluent mix of carbonate/bicarbonate (4.5/0.8mM) at a flow rate of  $0.25 \text{ mL min}^{-1}$ . Multi-  
202 point ( $\geq 5$ ) calibrations were conducted using a mixture prepared from individual inorganic standards (Inorganic  
203 Ventures, Christiansburg, VA). A mid-level accuracy check standard was prepared from certified standards mix  
204 (AccuStandard, New Haven, CT) for quality assurance/quality control. Profile measurements were conducted during  
205 each of the five SANDS intensives.

206 Bulk organic nitrogen in aerosols was measured using a high-volume (Hi-Vol) Tisch TE-1000 (Tisch Environmental,  
207 Cleves, OH) dual cyclone  $\text{PM}_{2.5}$  sampler operated at a flow rate of  $230 \text{ L min}^{-1}$ . The unit was deployed at ground level  
208 adjacent to the COW137 CASTNET tower and collected 24 h (started at 7 A.M. local time) integrated samples on  
209 pre-baked ( $550 \text{ }^\circ\text{C}$  for 12 h) quartz fiber (QF) filters (90-mm, Pall Corp, Port Washington, NY). Field blanks were  
210 collected the same way except being loaded in the sampler without the pump switched on. A QF punch ( $1.5 \text{ cm}^2$ ) from  
211 each sample was extracted with DI water ( $18.2 \text{ M}\Omega\cdot\text{cm}$ , Milli-Q Reference system, Millipore, Burlington, MA) in an

212 ultrasonic bath for 45 min. The sample extract was filtered through a 0.2- $\mu$ m pore size PTFE membrane syringe filter  
213 (Iso-disc, Sigma Aldrich, St. Louis, MO) before subsequent analyses.

214 Water-soluble total N (WSTN) concentrations were measured using a high-temperature catalytic combustion and  
215 chemiluminescence method that included a total organic carbon analyzer (TOC-VCSH) combined with a total nitrogen  
216 module (TNM-1) (Shimadzu Scientific Instruments, Columbia, MD). Briefly, the TN module converts all nitrogen  
217 compounds to NO at 720 °C in a combustion chamber, and NO is quantified by NO<sub>2</sub> chemiluminescence through  
218 reaction with ozone. A 5-point calibration was conducted with KNO<sub>3</sub> standard solution for each batch of samples.  
219 Before and after each batch of samples being analyzed, a suite of quality assurance check analysis including lab DI  
220 and accuracy check standard were conducted to ensure accuracy and precision. Inorganic species (NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, NO<sub>2</sub><sup>-</sup>)  
221 were analyzed by IC as described above, and WSON was calculated according to equation (1). Comparisons of Hi-  
222 Vol and CASTNET PM measurements are summarized in Supplemental Section S1 (Figure S4).

223 To evaluate the spatial distribution of gaseous N across the Coweeta Basin, additional passive sampling of HNO<sub>3</sub> and  
224 NH<sub>3</sub> was conducted across an elevation gradient for the full year of 2015 (Figure 1, Tables 1 and 2). Samplers were  
225 deployed for two-week periods at the height of 10 m above ground on an aluminum tilt-down tower. NH<sub>3</sub>  
226 measurements followed AMoN methods. HNO<sub>3</sub> was collected on 47-mm Nylon filters (Nylasorb, Pall Corp, Port  
227 Washington, NY) as described by Bytnerowicz et al. (2005). NH<sub>3</sub> and HNO<sub>3</sub> sampler preparation and analysis was  
228 performed by the NADP Central Analytical Laboratory and CASTNET laboratories, respectively. Field calibration of  
229 the passive HNO<sub>3</sub> measurements (Supplemental Figure S5) was based on comparison with a collocated CASTNET  
230 sampler at Screwdriver Knob site (Figure 1, Tables 1 and 2), which also operated for the full year of 2015.

### 231 **2.2.3 Micrometeorology**

232 Site characteristics of micrometeorology and ecosystem fluxes of water and carbon dioxide have been previously  
233 described (Novick et al., 2013; 2014; Oishi et al., 2018). Three-dimensional wind components were measured by sonic  
234 anemometer (Model 81000, R.M. Young Company, Traverse City, MI) above the forest canopy on the EFT.  
235 Momentum and kinematic heat fluxes were determined by eddy covariance (EC) from sonic data. For EC calculations,  
236 raw 10-Hz sonic data were processed into hourly averages after block average detrending and 2D coordinate rotation  
237 (Novick et al., 2013). Air temperature and relative humidity (RH) were measured at the top of the tower (EC155,  
238 Campbell Scientific, Logan, UT) and 2/3 canopy height (HMP-45, Vaisala, Helsinki, Finland). Photosynthetically  
239 active radiation (PAR; LI-190, LI-COR Biosciences, Lincoln, NE) and upward and downward, shortwave and  
240 longwave radiation (CNR 4, Kipp & Zonen, Delft, The Netherlands) were measured at the top of the tower. Surface  
241 wetness was measured in the canopy crown, understory and at the ground using leaf wetness sensors (Model 237,  
242 Campbell Scientific). Soil volumetric water content (VWC) averaged over 0–30 cm depth was measured in four  
243 locations around the tower using time domain reflectometry probes (CS616, Campbell Scientific). Soil temperature  
244 was measured at four depths (5, 20, 35, and 55 cm) in two locations near the tower using thermistors. For missing  
245 data, linear interpolation was used to fill short gaps (1–4 h). Longer gaps were filled by substitution using the average  
246 hourly diel profile calculated for each month. Micrometeorological data were used for inferential dry deposition  
247 modeling as described below.

## 248 2.2.4 Biogeochemistry

249 Ammonia emission potentials ( $\Gamma$ ) and compensation points for live vegetation, leaf litter on the forest floor, and soil  
250 were estimated from measurements of  $\text{NH}_4^+$  and pH in the leaf and litter tissue and soil pore water (Massad et al.,  
251 2010). Green leaves were collected from 18 species (Table S1) within the flux footprint of the tower and other locations  
252 in the Coweeta Basin. Leaf litter was collected along transects extending to the northeast and southwest (i.e.,  
253 predominant wind directions) of the flux tower ~100 m. Litter included a composite of intact leaves and leaf fragments  
254 and excluded the more decomposed material at the top of the organic soil layer. Approximately 5 g of leaf tissue was  
255 ground in liquid nitrogen using a mortar and pestle and small coffee grinder, then extracted with 20 mL of deionized  
256 water. pH was determined directly on the extracts (Oakton pH 2100 meter, Mettler Toledo InLab Micro electrode).  
257 The  $[\text{NH}_4^+]$  in the extracts, which reflects the bulk tissue concentration, was determined by ion chromatography as  
258 described above for denuder measurements either directly or, for samples with high organic content, after separation  
259 of the  $\text{NH}_4^+$  from the solution as  $\text{NH}_3$  using headspace equilibration. For the headspace method, 5 mL of tissue extract  
260 was added to a 250-mL high-density polyethylene jar containing two ALPHA passive samplers (Center for Ecology  
261 and Hydrology; Tang et al., 2001), without the diffusion barrier, affixed to the interior of the lid. The jar was sealed,  
262 and 5 mL of 0.3 N NaOH was added to the extract via a septum. The  $\text{NH}_3$  liberated from the liquid extract into the  
263 headspace was collected by the passive diffusion samplers over a period of 48 h, after which the passive sampler was  
264 extracted with 10 mL of deionized water. Extracts were then analyzed by ion chromatography as described above.  
265 Emission potentials of the vegetation ( $\Gamma_s$ ) and litter ( $\Gamma_l$ ) were estimated from measured concentrations of  $[\text{H}^+]$  (M)  
266 and  $[\text{NH}_4^+]$  ( $\mu\text{g g}^{-1}$  tissue fresh weight) in the bulk tissue as:

$$267 \Gamma_{s,l} = \frac{[\text{NH}_4^+] \times (5.56 \times 10^{-5}) \times \text{LD}}{[\text{H}^+]} \quad (2)$$

268 where LD is leaf density ( $\text{kg L}^{-1}$  fresh tissue, equivalent to  $\text{g cm}^{-3}$  fresh tissue). In this case, LD for woody deciduous  
269 and woody evergreen species are 0.37 and 0.42  $\text{kg L}^{-1}$ , respectively (Poorter et al., 2009). Emission potentials for litter,  
270 which consisted of a mix of in-tact or partial leaves and needles, assume an average density of 0.4  $\text{kg L}^{-1}$ . The factor  
271 of  $5.56 \times 10^{-5}$  in equation 2 is necessary to convert  $[\text{NH}_4^+]$  from  $\mu\text{g NH}_4^+ \text{g}^{-1}$  tissue to  $\text{mol NH}_4^+ \text{kg}^{-1}$  tissue.

272 Soil chemistry was measured in 20 m x 20 m plots located in the vicinity of the tower. During 2010, soil  $\text{NH}_4^+$  was  
273 determined on soil samples collected with PVC cores (5-cm diameter and 10-cm deep) in four locations (replicates)  
274 within each of four plots. Samples were collected bi-monthly during the growing season.  $\text{NH}_4^+$  was extracted within  
275 two hours of collection using 5 g of sieved (<5 mm) soil in 20 mL of 2M potassium chloride followed by colorimetric  
276 analysis (Astoria2 autoanalyzer, Astoria-Pacific International; Coweeta Hydrologic Laboratory, 2016). Soil pH was  
277 measured on 0–10 cm samples collected in three plots in winter of 2013 (each sample representing a composite of 20–  
278 25 2.5-cm diameter soil cores). Soil pH was determined directly after mixing 5 g soil with 10 mL 0.01M calcium  
279 chloride (Coweeta Hydrologic Laboratory, 2016). Soil emission potential ( $\Gamma_{\text{soil}}$ ) (unitless) was estimated directly from  
280 measured molar concentrations of  $[\text{H}^+]$  and  $[\text{NH}_4^+]$  as:

$$281 \Gamma_{\text{soil}} = \frac{[\text{NH}_4^+]}{[\text{H}^+]} \quad (3)$$

## 282 2.2.5 Above-canopy flux measurements

283 Above-canopy fluxes of  $\text{NH}_3$  and  $\text{HNO}_3$  were quantified from measurements of vertical concentration gradients  
284 conducted during the final (summer 2016) intensive when the tower was at maximum height and the greatest vertical  
285 separation of concentration measurements was achieved. Fluxes were determined using the modified Bowen-ratio  
286 (MBR) method (Meyers et al., 1996) as:

$$287 \quad F = -K_c(z) \frac{dC}{dz}, \quad (4)$$

288 where  $K_c$  and  $dC/dz$  are the eddy diffusivity and vertical concentration gradient of the chemical species of interest.  
289 The value of  $K_c$  for trace gases was assumed equivalent to the eddy diffusivity of heat ( $K_t$ ), calculated as:

$$290 \quad K_c = K_t = -\overline{w't'} \frac{\Delta z}{\Delta t}, \quad (5)$$

291 where  $\overline{w't'}$  is the kinematic surface heat flux measured by eddy covariance above the canopy (43.5 m above ground  
292 level),  $\Delta t$  is the air temperature difference between the levels at 43 m and 35 m above ground level, and  $\Delta z$  is the  
293 height interval of air temperature measurements. Air temperature was measured using aspirated thermocouples, and  
294  $\Delta t$  was corrected for a small bias between the sensors determined by collocated comparison. Concentration gradients  
295 were determined from URG annular denuder measurements at 34.6 m and 43 m above ground level, as described  
296 above in section 2.2.2. Given the complexity of the topography, no attempt was made to correct for potential roughness  
297 sub-layer effects on either the eddy diffusivity or concentration gradients, which should be acknowledged as a source  
298 of uncertainty in the calculated  $\text{HNO}_3$  and  $\text{NH}_3$  fluxes. Additional detail on the gradient measurements is included in  
299 Supplemental Section S3.

## 300 2.2.6 Seasonal and annual deposition budget

301 Speciated seasonal and annual total nitrogen deposition budgets were developed for the period August 2015 to August  
302 2016. The wet deposited components, including  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and total WSON, were directly measured. Speciated dry  
303 deposition was estimated by combining measured air concentrations, micrometeorology, biogeochemistry and canopy  
304 physical characteristics within a box version of the Surface Tiled Aerosol and Gaseous Exchange (STAGE) model,  
305 which is an option in the Community Multi-scale Air Quality Model (CMAQ) version 5.3 (Appel et al., 2021).  
306 The STAGE model treats the deposition of gases and particles separately. The air-surface exchange of gases is  
307 parameterized as a gradient process and is used for both bidirectional exchange and dry deposition following the  
308 widely used resistance model of Nemitz et al. (2001) and Massad et al. (2010):

$$309 \quad F = -f_{veg} \frac{\chi_a(z) - \chi_{z_0}}{R_a} - (1 - f_{veg}) \frac{\chi_a(z) - \chi_g}{R_a + R_g}, \quad (6)$$

310 where  $F$  is the net flux above the canopy (a negative value represents a net deposition flux and a positive value  
311 represents a net emission flux), which is the sum of the component cuticular ( $F_{cut}$ ), stomatal ( $F_s$ ), and ground ( $F_g$ )  
312 fluxes. The quantity  $\chi_a(z)$  is the ambient concentration at a reference height ( $z$ ),  $\chi_{z_0}$  is the concentration at height  $d$   
313 (displacement height) +  $z_0$  (roughness length),  $\chi_g$  is the ground layer compensation point,  $R_a$  is the aerodynamic  
314 resistance between  $z$  and  $d + z_0$ ,  $R_g$  is the total ground resistance including in-canopy aerodynamic resistance ( $R_{mc}$ ),

315 ground boundary layer resistance ( $R_{bg}$ ), and soil resistance ( $R_{soil}$ ) ( $R_g = R_{inc} + R_{bg} + R_{soil}$ ), and  $f_{veg}$  is the vegetation  
 316 coverage fraction. The ground is fully covered by vegetation at our forested site, and  $f_{veg}$  is therefore set to 1.  
 317 The quantity  $\chi_{z0}$  is related to the canopy ( $\chi_c$ ) and ground compensation points ( $\chi_g$ ) according to:

$$318 \quad \chi_{z0} = \frac{\left(\frac{\chi_a(z)}{R_a} + \frac{\chi_c}{R_{bl}} + \frac{\chi_g}{R_g}\right)}{\left(\frac{1}{R_a} + \frac{1}{R_{bl}} + \frac{1}{R_g}\right)}, \quad (7)$$

319 where  $R_{bl}$  is the leaf boundary layer resistance.  $\chi_c$  follows Nemitz et al. (2001) but is modified to account for a cuticular  
 320 compensation point ( $\chi_{cut}$ ):

$$321 \quad \chi_c = \frac{\chi_a(z)(R_a R_{bl})^{-1} + \chi_s \left[ (R_a R_s)^{-1} + (R_{bl} R_s)^{-1} + (R_g R_s)^{-1} \right] + \chi_{cut} \left[ (R_a R_{cut})^{-1} + (R_{bl} R_{cut})^{-1} + (R_g R_{cut})^{-1} \right] + \chi_g (R_{bl} R_g)^{-1}}{(R_a R_{bl})^{-1} + (R_a R_s)^{-1} + (R_a R_{cut})^{-1} + (R_{bl} R_g)^{-1} + (R_{bl} R_s)^{-1} + (R_{bl} R_{cut})^{-1} + (R_g R_s)^{-1} + (R_g R_{cut})^{-1}}, \quad (8)$$

325 where  $\chi_s$  is the leaf stomatal compensation point, and  $R_s$  and  $R_{cut}$  are the stomatal and cuticular resistances, respectively.  
 326 The stomatal, cuticular, and ground compensation points ( $\chi_s, \chi_{cut}, \chi_g$ ) are described according to Nemitz et al. (2000a)  
 327 as a function of temperature ( $T$ ) and the emission potentials ( $\Gamma$ ):

$$328 \quad \chi_{s,cut,g} = \frac{161512}{T} 10^{\frac{-4507.11}{T}} \Gamma_{s,cut,g}. \quad (9)$$

329  $\Gamma_{cut}$  is set to 0 in this study, and thus, there is only deposition to leaf cuticles. For unidirectional exchange of gases  
 330 other than  $\text{NH}_3$ ,  $\Gamma_s$  and  $\Gamma_g$  are also set to 0. In the case of  $\text{NH}_3$ , the foliage and ground layers may act as a source or  
 331 sink depending on the ratio of the ambient concentration to the respective compartment compensation point (Husted  
 332 and Schjoerring, 1995). Here values of  $\Gamma$  for  $\text{NH}_3$  are derived from measurements of live vegetation, litter, and soil  
 333 chemistry as described above. Values used in the base model simulation are described in Section 3.6, and the  
 334 sensitivity of modeled  $\text{NH}_3$  fluxes to  $\Gamma$  is discussed in Supplemental Section S5.

335 Formulas for each resistance component are summarized in Supplemental Table S2. The resistances are largely  
 336 estimated following Massad et al. (2010) with the following exceptions. The value of  $R_s$  is based on the Noah (Chen  
 337 and Dudhia, 2001) or P-X land surface schemes (Pleim and Xiu, 1995) in the Weather Research and Forecasting  
 338 (WRF) model, and in this study, the P-X scheme is used. Deposition to wetted cuticular and ground surfaces considers  
 339 the bulk accommodation coefficient, following Fahey et al. (2017), and can be a limiting factor for highly soluble  
 340 compounds. The value of  $R_{inc}$  follows Shuttleworth and Wallace (1985) as does Massad et al. (2010), but uses the  
 341 canopy momentum attenuation parameterization from Yi (2008) and in-canopy eddy diffusivity following Harman  
 342 and Finnigan (2007). This parameterization is similar to Bash et al. (2010), and detailed descriptions of model  
 343 resistances can be found in the references mentioned above.

344 Dry deposition ( $F$ ) of aerosol nitrogen ( $\text{NH}_4^+$  and  $\text{NO}_3^-$ ) is estimated as the product of the measured concentration  
 345 ( $C$ ) and the STAGE modeled dry deposition velocity ( $V_d$ ):

$$346 \quad F = -V_d(z) \times C(z). \quad (10)$$

347 Aerosol dry deposition processes include gravitational settling, Brownian diffusion, surface impaction, and rebound.  
 348 Similar to gases, STAGE calculates the averaged  $V_d$  for particles by summing the  $V_d$  over vegetative or non-vegetative

349 surfaces, weighted by vegetation cover fraction which is = 1 (full coverage) at Coweeta.  $V_d$  for a particle with  
 350 aerodynamic diameter  $D_p$  is calculated as:

$$351 \quad V_d(D_p) = \frac{V_g}{1 - \exp[-V_g(R_a + R_{bp})]} \quad , \quad (11)$$

352 where  $R_{bp}$  is the boundary layer resistance for particles, and the gravitational settling velocity ( $V_g$ ) is calculated as:

$$353 \quad V_g = \frac{\rho D_p^2 g}{18\mu} C_c \quad , \quad (12)$$

354 where  $\rho$  is the density of the aerosol,  $g$  is the acceleration of gravity,  $\mu$  is the air dynamic viscosity, and  $C_c$  is the  
 355 Cunningham slip correction factor. The turbulent transport processes are considered similar for gas and aerosol, and  
 356  $R_a$  can be formulated based on the similarity theory relationships. Unlike deposition of gases, the boundary layer  
 357 resistance usually dominates the aerosol deposition process as Brownian diffusion is much slower for particles than  
 358 molecular diffusion is for gases (Pleim and Ran, 2011). Thus,  $R_{bp}$  depends on the collection efficiency of the surface  
 359 and can be determined as:

$$360 \quad R_{bp} = \left[ F_f u_* \left( S_c^{-\frac{2}{3}} + E_{im} \right) \right]^{-1} \quad , \quad (13)$$

361 where  $u_*$  is the friction velocity, and  $S_c$  is the Schmidt number for particles. The quantity  $E_{im}$  represents the collection  
 362 efficiency by impaction and follows Slinn (1982) for vegetative canopies and Giorgi (1986) for smooth (non-  
 363 vegetative) surfaces. The quantity  $F_f$  is an empirical correction factor to account for increased deposition in convective  
 364 conditions, parameterized as:

$$365 \quad F_f = V_{fac} \left( 1 + 0.24 \frac{w_*^2}{u_*^2} \right) \quad , \quad (14)$$

366 where  $V_{fac}$  is an empirical constant representing the enhanced effects over vegetation canopies. For vegetative  
 367 canopies,  $V_{fac}$  is equal to the one-sided leaf area index (LAI) with a minimum value of one, and for non-vegetative  
 368 surface, a value of one is used. The quantity  $w_*$  is the convective velocity scale (Deardorff velocity), defined as:

$$369 \quad w_* = \left( \frac{g}{T_v} z_i \overline{w't'} \right)^{\frac{1}{3}} \quad , \quad (15)$$

370 where  $T_v$  is virtual air temperature,  $z_i$  is average depth of the mixed layer, and  $\overline{w't'}$  is the measured kinematic surface  
 371 heat flux.

372 A bulk  $V_d$  for  $PM_{2.5}$  is obtained by integrating size-resolved  $V_d$  according to the particle size distribution. The size  
 373 distribution profiles for  $NH_4^+$  and  $NO_3^-$  are from measurements at eight Canadian rural forest sites (Zhang et al., 2008)  
 374 and the size distribution for particulate organic nitrogen is estimated as an average of that for  $NH_4^+$  and  $NO_3^-$ . Model  
 375 sensitivities of particle nitrogen fluxes to assumed size distributions are discussed in Supplemental Section S5.

376 The STAGE model is extracted from the CMAQ v5.3 and executed in a one-dimensional mode. The prescribed surface  
 377 parameters (e.g.,  $z_0$ ,  $d$ ) were modified according to the site conditions. The continuous LAI data were extracted from  
 378 the MODerate resolution Imaging Spectroradiometer (MODIS) global LAI product (MCD15A2H), which is generated  
 379 daily at a 500-m spatial resolution, and each data point covers an 8-d period. The MODIS LAI (Supplemental Figure  
 380 S6) was adjusted using in-situ canopy measurements as described in Supplemental Section S4. Hourly meteorological

381 measurements, including air temperature, relative humidity,  $u_*$ , atmospheric pressure, precipitation rate, global  
382 radiation, and soil temperature/moisture, were used to drive STAGE. The Obukhov length, which is defined as:

$$383 \quad L = -\frac{u_*^3 T_v}{(kgw't^3)} \quad , \quad (16)$$

384 where  $k$  is the von Karman constant, was also calculated from micrometeorological measurements.

### 385 **2.2.7 Air concentrations for dry deposition modeling**

386 Air concentration data used for dry deposition modeling are summarized in Table 3. Hourly measurements of HNO<sub>3</sub>  
387 by DD\_CL and ΣAN and ΣPN by TD-PC-CL were conducted for a full year and were therefore used directly for  
388 modeling. Over the 12-month sampling period, 18%, 22%, and 22% of hourly HNO<sub>3</sub>, ΣAN, and ΣPN concentrations  
389 were missing or invalid, respectively. Missing data were replaced with the corresponding hour from the median diel  
390 profile comprised of days with > 75% completeness. Surrogate formulas of nitrooxy-butanol (C<sub>4</sub>H<sub>9</sub>NO<sub>4</sub>) and PAN  
391 (C<sub>2</sub>H<sub>3</sub>NO<sub>5</sub>) were assumed for ΣAN and ΣPN, respectively.

392 Continuous NH<sub>3</sub> concentrations were only measured during the last two intensives. Biweekly AMoN NH<sub>3</sub>  
393 measurements, with corrections for travel blanks and atmospheric pressure, were used to establish a continuous 12-  
394 month time series of air concentration for annual deposition modeling. Ammonia concentrations are known to exhibit  
395 pronounced diel patterns, even in remote areas (Wentworth et al., 2016). Variability in air concentration interacts with  
396 diel cycles in surface wetness, turbulence, and other factors to influence diel patterns in air-surface exchange rates. To  
397 incorporate this interaction, the diel concentration pattern determined during spring and summer 2016 by MARGA  
398 NH<sub>3</sub> measurements (Supplemental Figure S7) was imposed on the biweekly AMoN NH<sub>3</sub> concentration. The hourly  
399 profile of NH<sub>3</sub> concentrations was normalized by the corresponding overall mean concentration to produce a  
400 normalized mean diel concentration profile. This profile was then applied to each biweekly AMoN air concentration,  
401 temporally scaling the NH<sub>3</sub> concentration by time of day while maintaining the measured biweekly AMoN  
402 concentration. Gap filling of AMoN data was not required. Comparisons of NH<sub>3</sub> measurements are briefly discussed  
403 in Supplemental Section S1.

404 Hi-Vol measurements of speciated particulate N were only conducted during intensive periods to assess the relative  
405 contributions of inorganic and organic fractions to total water-soluble N. The CASTNET particulate NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup>  
406 were used to provide a continuous 12-month time series of air concentration for annual deposition modeling.  
407 Concentrations of Hi-Vol and CASTNET measurements were shown to be comparable (Supplemental Section S1).  
408 For the annual time series, particulate organic nitrogen (PON) concentration was estimated based on speciated  
409 measurements during intensives, which showed that inorganic N accounts for ~88% of WSTN on average. Weekly  
410 average PON concentration was estimated from the weekly CASTNET measurements assuming NH<sub>4</sub><sup>+</sup> + NO<sub>3</sub><sup>-</sup>  
411 represents 88% of total particulate nitrogen and PON represents the balance (12%). Weekly concentrations were then  
412 expressed at the hourly time scale for modeling. Gap filling of CASTNET data was not required.

413 Components of the atmospheric reactive N budget that are not routinely measured at Coweeta and were not directly  
414 measured during SANDS include NO, NO<sub>2</sub>, HONO, and N<sub>2</sub>O<sub>5</sub>. At the continental scale, regional model simulations  
415 suggest that NO, HONO and N<sub>2</sub>O<sub>5</sub> make minor contributions to the total dry deposition of reactive N (~ 2%), though

416 the contribution of  $\text{NO}_2$  is larger (~ 6%) (Walker et al., 2020). While  $\text{NO}$ ,  $\text{HONO}$ , and  $\text{N}_2\text{O}_5$  have been excluded from  
417 our modeling analysis, we have included an estimate of  $\text{NO}_2$  concentration, from which dry deposition is estimated.  
418 The “other” fraction of  $\text{NO}_y$  (i.e.,  $\text{NO}_y - \text{HNO}_3 - \Sigma\text{PN} - \Sigma\text{AN}$ ) measured at Coweeta represents between 47% (summer)  
419 and 76% (winter) of total  $\text{NO}_y$  on a seasonal basis. This “other” fraction includes  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HONO}$ ,  $\text{N}_2\text{O}_5$ , and some  
420  $\text{NO}_3^-$  but is likely dominated by  $\text{NO}_2$ . The measured diel profile of “other”  $\text{NO}_y$  (Supplemental Figure S8)  
421 concentration shows the typical pattern indicative of morning and evening modes related to mobile  $\text{NO}_x$  emissions.  
422 Winds at Coweeta are from the east/northeast during the morning, which is the direction of local residences, the town  
423 of Otto, NC, and U.S. Highway 23. Winds are from the west/southwest during the evening, which is the direction of  
424 the Nantahala National Forest. Consistent with the diel profile of “other”  $\text{NO}_y$ , a much larger morning peak in  $\text{NO}_2$  is  
425 therefore expected. To estimate the concentration of  $\text{NO}_2$  from the measured “other”  $\text{NO}_y$ , we examined the ratio of  
426  $\text{NO}_2$  to the quantity  $\text{NO}_y - \text{HNO}_3 - \text{PANS} - \text{NTR}$  (e.g., “other”  $\text{NO}_y$ ) simulated by CMAQ (V5.2.1) for the Coweeta  
427 site over the year 2015, where PANS represents total peroxy nitrates, and NTR represents other organic nitrates.  
428 Relative to the measured  $\text{NO}_y$  species, PANS and NTR are assumed to represent  $\Sigma\text{PN}$  and  $\Sigma\text{AN}$ , respectively. The  
429 ratio of CMAQ estimated  $\text{NO}_2$  to “other”  $\text{NO}_y$  ranges from 0.51 during summer to 0.60 during winter. These seasonal  
430 factors were applied to the measured “other”  $\text{NO}_y$  to estimate the hourly  $\text{NO}_2$  concentration. Gap filling procedures  
431 for hourly “other”  $\text{NO}_y$  follow those for  $\text{HNO}_3$ ,  $\Sigma\text{PN}$ , and  $\Sigma\text{AN}$  described above. Details of CMAQ V5.2.1 can be  
432 found in Supplemental Table S3.

433 Regarding the use of measurements from different towers (Table 3) for inferential modeling, we acknowledge  
434 that differences in tower position on the landscape (i.e., within the forest (EFT) versus adjacent clearing (COW137))  
435 and height of the measurement above the surface will be sources of variability in air concentrations. Given the  
436 complexity of the topography, no attempt was made to correct air concentrations for differences in measurement  
437 heights.

### 3 Results and discussion

#### 438 3.1 Long-term trends in atmospheric N at Coweeta

439 Emissions of oxidized nitrogen ( $\text{NO}_x$ ) and sulfur ( $\text{SO}_x$ ) have declined significantly in the eastern U.S. in response to  
440 the 1990 Clean Air Act Amendments (Figure 2). Trends data from U.S EPA’s National Emissions Inventory (NEI)  
441 indicate a nationwide decline of 74% and 46% for  $\text{SO}_x$  and  $\text{NO}_x$  emissions from the early 1990s to 2010s, respectively,  
442 comparing 1990–1994 to 2010–2014 annual averages (U.S. EPA, 2014). By contrast,  $\text{NH}_3$  emissions have been  
443 reported as relatively unchanged or slightly increasing for the same periods (Ellis et al., 2013; Paulot and Jacob, 2013;  
444 Xing et al., 2013), depending on the location and region of the U.S. Declining  $\text{NO}_x$  and  $\text{SO}_x$  emissions have resulted  
445 in decreasing trends in air concentrations of  $\text{HNO}_3$  and  $\text{SO}_2$  at Coweeta between the 1990s and 2010s (Figure 2).  
446 Concentrations noticeably began to decline in 2008, the timeline of which likely indicates the effect of full  
447 implementation of the 2006 Tier 2 Gasoline Sulfur Program, as well as the enactment of the Clean Air Interstate Rule  
448 (CAIR), both of which aimed to further reduce  $\text{NO}_x$  and  $\text{SO}_x$  emissions (Sickles and Shadwick, 2015; LaCount et al.,

449 2021). Compared to other species, NH<sub>3</sub> concentrations have only been measured at Coweeta for a relatively short  
450 period of time.

451 Atmospheric NH<sub>3</sub> reacts with acidic sulfate to form ammonium sulfate ((NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>) or bi-sulfate ((NH<sub>4</sub>)HSO<sub>4</sub>)  
452 aerosol. Under favorable thermodynamic conditions (low temperature and high RH), NH<sub>3</sub> in excess of acidic sulfate  
453 will react with HNO<sub>3</sub> to form ammonium nitrate aerosol (NH<sub>4</sub>NO<sub>3</sub>). Concentrations of SO<sub>4</sub><sup>2-</sup> at Coweeta have tracked  
454 SO<sub>2</sub>, and subsequently, NH<sub>4</sub><sup>+</sup> concentrations have declined substantially relative to early 1990s levels (Figure 2).  
455 However, concentrations of NO<sub>3</sub><sup>-</sup> aerosol, which are relatively low at Coweeta, have not followed trends in SO<sub>4</sub><sup>2-</sup> and  
456 NH<sub>4</sub><sup>+</sup> (Figure 2). Previous studies at other U.S. sites have also reported non-proportional changes in PM<sub>2.5</sub> mass in  
457 response to SO<sub>2</sub> and NO<sub>x</sub> control strategies (Blanchard and Hidy, 2005; Sickles and Shadwick, 2015). Non-linear  
458 reductions or increases of particulate NO<sub>3</sub><sup>-</sup> with coincident SO<sub>2</sub> and NO<sub>x</sub> emission reductions relate to the  
459 thermodynamic equilibrium of the SO<sub>4</sub><sup>2-</sup>-NO<sub>3</sub><sup>-</sup>-NH<sub>4</sub><sup>+</sup>-HNO<sub>3</sub>-NH<sub>3</sub> aerosol system. As ambient SO<sub>4</sub><sup>2-</sup> concentrations  
460 decline, the capacity for NH<sub>4</sub><sup>+</sup> formation (i.e., neutralization) also decreases, leaving additional NH<sub>3</sub> in the gas phase.  
461 Amounts of NH<sub>3</sub> in excess of acidic SO<sub>4</sub><sup>2-</sup> can subsequently react with HNO<sub>3</sub> to form NH<sub>4</sub>NO<sub>3</sub>, confounding the  
462 relationship between NO<sub>x</sub> emission reductions and atmospheric NO<sub>3</sub><sup>-</sup> concentrations.

463 The long-term trend in NO<sub>3</sub><sup>-</sup> wet deposition at Coweeta (Figure 3) has tracked the downward trend in ambient HNO<sub>3</sub>  
464 concentration. Wet deposition of NH<sub>4</sub><sup>+</sup>, however, shows no apparent trend, in contrast to the decline in NH<sub>4</sub><sup>+</sup> aerosol  
465 concentration. This pattern may relate to the combined effects of changes in regional NH<sub>3</sub> emissions, aerosol  
466 chemistry, and dry deposition rates on the long-term trend in atmospheric NH<sub>3</sub> concentrations. As noted above,  
467 declines in SO<sub>2</sub> emissions and SO<sub>4</sub><sup>2-</sup> aerosol result in less conversion of NH<sub>3</sub> to NH<sub>4</sub><sup>+</sup> aerosol, leaving more NH<sub>3</sub> in  
468 the gas phase. Furthermore, reduced air concentrations of acidic species such as SO<sub>2</sub> and HNO<sub>3</sub> result in lower dry  
469 deposition rates and subsequently less acidic deposition surfaces, which in turn reduces the deposition velocity (i.e.,  
470 increases the atmospheric lifetime) of NH<sub>3</sub> (Sutton et al., 2003). In addition to changes in emissions, these two  
471 processes are thought to be at least partly responsible for the increases in NH<sub>3</sub> air concentrations that have been  
472 observed in some locations across the U.S. (Butler et al., 2015; Yu et al., 2018; Yao and Zhang, 2019). While there is  
473 no discernable trend in NH<sub>3</sub> air concentrations over the relatively short period of record at Coweeta, a decline in wet  
474 deposition of NH<sub>4</sub><sup>+</sup> aerosol may have been offset to some extent by increased wet deposition of NH<sub>3</sub> gas (Asman et  
475 al., 1995), which is highly soluble, resulting in an overall lack of trend in NH<sub>4</sub><sup>+</sup> wet deposition at Coweeta over time.  
476 Similar to other areas in the U.S. (Li et al., 2016), the downward trend in NO<sub>3</sub><sup>-</sup> wet deposition has led to an increase  
477 in the relative contribution of reduced forms of N (i.e., NH<sub>x</sub> = NH<sub>3</sub> + NH<sub>4</sub><sup>+</sup>) to inorganic wet N deposition at Coweeta  
478 (NH<sub>4</sub><sup>+</sup>:NO<sub>3</sub><sup>-</sup>, Figure 3).

### 479 3.2 Wet deposition

480 Of the various forms of N in precipitation, ammonium was the most abundant inorganic species, contributing 47.0%  
481 of WSTN in weekly samples (*N* = 52), on average, followed by NO<sub>3</sub><sup>-</sup> (41.7%, Figure 4, Supplemental Table S4). The  
482 contribution of NO<sub>2</sub><sup>-</sup> was negligible. Organic compounds (WSON) contributed 11% of WSTN, on average, which is  
483 within the range of values (3% to 33%) reported for other locations in the U.S. (Scudlark et al., 1998; Whitall and  
484 Paerl, 2001; Keene et al., 2002; Beem et al., 2010; Walker et al., 2012; Benedict et al., 2013). While concentrations

485 of N compounds were generally higher during warm months, a seasonal pattern in the percent contribution of WSON  
486 to WSTN was not apparent. In a previous study at Coweeta (1994–1996), Knoepp et al. (2008) found that organic  
487 nitrogen contributed 21% of total nitrogen in bulk (wet + dry) deposition samples. Differences between Knoepp et al.  
488 (2008) and SANDS results may be related to interannual variability or trends in rainfall composition over the  
489 intervening two decades (e.g., Figure 3) or differences in collection method (wet only versus bulk deposition) or  
490 analytical techniques used for total N analysis (persulfate/UV digestion (Walker et al., 2012) versus total Kjeldahl N  
491 (Knoepp et al., 2008)).

### 492 **3.3 Air concentrations of oxidized N**

493 The oxidized fraction of reactive nitrogen (NO<sub>y</sub>) comprises a mixture of gaseous and particulate inorganic (NO, NO<sub>2</sub>,  
494 N<sub>2</sub>O<sub>5</sub>, HONO, HNO<sub>3</sub>, NO<sub>3</sub><sup>-</sup>) and organic compounds. Owing to its large deposition velocity and typical atmospheric  
495 concentration, HNO<sub>3</sub> is the primary contributor to dry deposition of inorganic oxidized N (Walker et al., 2020). Much  
496 less is known about the dry deposition of oxidized organic nitrogen compounds (Walker et al., 2020). Peroxy nitrates  
497 (PNs) and alkyl and multifunctional nitrates (ANs) are formed during the photochemical oxidation of volatile organic  
498 compounds (VOCs) in the presence of NO<sub>x</sub> (NO<sub>x</sub> = NO + NO<sub>2</sub>). While PNs exist in the gas phase, ANs can exist in  
499 the gas or particle phase and can be the dominant chemical sink for NO<sub>x</sub> in high biogenic VOC (BVOC)/low NO<sub>x</sub>  
500 environments (Farmer et al., 2008; Browne and Cohen, 2012; Paulot et al., 2012; Browne et al., 2013). Unlike PNs,  
501 ANs can also form at night via nitrate radical-induced oxidation of VOC. Further, PNs and ANs have been shown to  
502 contribute significantly to the total NO<sub>y</sub> budget in geographically diverse rural and forested environments (e.g., Trainer  
503 et al., 1993; Nouaime et al., 1998; Farmer et al., 2008; Browne et al., 2013; Toma et al., 2019). Flux measurements at  
504 Blodgett Forest, CA, showed that PN dry deposition contributed 4–19% of total N deposition at the site (Wolfe et al.,  
505 2009). Chemical transport modeling with current representation of the atmospheric oxidized nitrogen system suggests  
506 that PNs and ANs together contribute ~ 6% of total N deposition and ~ 12% of dry N deposition at the U.S. continental  
507 scale, compared to ~ 21% and 34% for HNO<sub>3</sub> and ~ 6% and 9% for particulate NO<sub>3</sub><sup>-</sup> (Walker et al., 2020).

508 The annual average concentration of NO<sub>y</sub> was 1.00 ppb (0.55 μg N m<sup>-3</sup>), with the highest seasonal average  
509 concentration in the winter (1.32 ppb, 0.75 μg N m<sup>-3</sup>) and lowest in the summer (0.64 ppb, 0.34 μg N m<sup>-3</sup>) (Figure 5,  
510 Table S5). The nearest rural NO<sub>y</sub> monitoring site is 85 km to the northwest at Look Rock in the Great Smoky  
511 Mountains National Park, where the annual concentration was 1.5 ppb over the same period (NPS, 2020). Similar to  
512 Coweeta, NO<sub>y</sub> concentrations at Look Rock are typically lowest during summer and highest in winter, though the  
513 seasonal cycle exhibits some interannual variability. The annual mean concentrations of HNO<sub>3</sub>, ΣPN, ΣAN determined  
514 by TD-PC-CL were 0.14 (0.08), 0.1 (0.06), and 0.09 (0.05) ppb (μg N m<sup>-3</sup>), respectively (Figure 5, Table S5). HNO<sub>3</sub>  
515 and ΣPN concentrations peaked in spring, coincident with the seasonal peak in O<sub>3</sub> concentration, while concentrations  
516 of ΣAN were similar in spring and summer. Diel patterns of HNO<sub>3</sub>, ΣPN, and ΣAN peaked during the day as expected  
517 for photochemical products. However, of the organic compounds, the ratio of peak daytime to minimum nighttime  
518 concentrations (Figure 5) was much smaller for ΣAN (2.3) compared to ΣPN (3.9), possibly indicative of the additional  
519 nighttime formation of AN.

520 Annually,  $\text{HNO}_3$  (12.8%),  $\Sigma\text{PN}$  (12.2%), and  $\Sigma\text{AN}$  (12.7%) contributed approximately the same proportions of the  
521 atmospheric  $\text{NO}_y$  load (Figure 5, Table S6). Their collective contribution ( $\text{NO}_z = \text{HNO}_3 + \Sigma\text{PN} + \Sigma\text{AN}$ ) to total  $\text{NO}_y$   
522 peaked during the summer (52.9%) and reached a minimum during winter (24.2%). The contributions of  $\Sigma\text{PN}$  (16.7%)  
523 and  $\Sigma\text{AN}$  (20.0%) exceeded  $\text{HNO}_3$  (16.2%) during summer when total  $\text{NO}_y$  concentrations were lowest. Our results  
524 fall within the range of  $\text{NO}_y$  budgets reported for other rural forested sites, in which  $\Sigma\text{PN}$  and  $\Sigma\text{AN}$  contribute ~ 8–  
525 40% (Nouaime et al., 1998; Farmer et al., 2008; Browne et al., 2013; Toma et al., 2019) and 10–22% (Day et al., 2003;  
526 Farmer et al., 2008; Browne et al., 2013) of  $\text{NO}_y$ , respectively.

527 To put the SANDS period into context with longer-term variability of oxidized N concentrations at Coweeta,  
528 CASTNET  $\text{HNO}_3$  and  $\text{NO}_3^-$  measurements for the period 2015–2020 are summarized in Figure 6 along with the  
529 SANDS period. We note here that  $\text{NH}_4\text{NO}_3$  volatility on the CASTNET Teflon filter can result in positive and negative  
530 biases in  $\text{HNO}_3$  and  $\text{NO}_3^-$ , respectively, with larger biases expected under warmer conditions (Lavery et al., 2009).  
531 Studies have shown the total  $\text{NO}_3^-$  ( $\text{TNO}_3 = \text{HNO}_3$  and  $\text{NO}_3^-$ ) to be conserved, though some portion of the  $\text{NO}_3^-$   
532 collected by the CASTNET open-faced filter may be contributed by coarse particles. The partitioning of  $\text{TNO}_3$   
533 between gas and particulate phases is important, given the much larger deposition velocity of  $\text{HNO}_3$  compared to  $\text{NO}_3^-$   
534 . The CASTNET measurements reflect relatively low concentrations of both  $\text{HNO}_3$  and  $\text{NO}_3^-$ , with  $\text{HNO}_3$  exceeding  
535  $\text{NO}_3^-$  during all seasons. Particulate  $\text{NO}_3^-$  concentrations are highest during cooler months, as expected, and negligible  
536 during the summer, a pattern that is consistent with observations from other networks across the Southeast (Kim et  
537 al., 2015). Additionally,  $\text{TNO}_3$  is primarily in the gas phase even during winter. Seasonal mean concentrations during  
538 the SANDS period fall within the interquartile range (IQR) of the 6-year period between 2015 and 2020, with SANDS  
539 annual and 6-year averages being very similar (Figure 6). Seasonal and annual mean  $\text{HNO}_3$  concentrations agreed  
540 closely with the CASTNET measurements (Figures 6 and Supplemental Section S1).

### 541 **3.4 Air concentrations of reduced N**

542 Reduced forms of nitrogen ( $\text{NH}_x$ ) represent another important component of the inorganic dry N deposition budget.  
543 At the continental scale,  $\text{NH}_3$  dry deposition contributes ~ 20% of total N deposition and ~ 32% of dry N deposition,  
544 whereas the contributions from  $\text{NH}_4^+$  aerosol are ~ 4% and ~ 6%, respectively (Walker et al., 2020). Similar to oxidized  
545 forms of N, the partitioning of mass between the gas ( $\text{NH}_3$ ) and particulate ( $\text{NH}_4^+$ ) phases affects the dry deposition  
546 rate of  $\text{NH}_x$ , given the larger deposition velocity of  $\text{NH}_3$  relative to  $\text{NH}_4^+$ .

547 During 2015–2020, with 2020 being the most recent full year of AMoN data, average concentrations of  $\text{NH}_3$  and  $\text{NH}_4^+$   
548 were similar (Figure 7). Both species displayed a seasonal pattern of lowest concentrations in the winter and higher  
549 concentrations during warm months.  $\text{NH}_3$  concentrations peaked in summer, reflecting the temperature dependence  
550 of regional agricultural and biogenic emissions.  $\text{NH}_4^+$  concentrations followed the seasonal cycle in  $\text{SO}_4^{2-}$   
551 concentrations, which were also similar in spring and summer and minimum in winter at Coweeta. The seasonal cycle  
552 of  $\text{NH}_3/\text{NH}_4^+$  partitioning was driven more by  $\text{NH}_3$  than  $\text{NH}_4^+$ , the former exhibiting more seasonal variability. Hourly  
553 measurements conducted during spring and summer 2016 showed that  $\text{NH}_3$  also displayed significant diel variability  
554 (Supplemental Figure S7), reaching a maximum around mid-day and minimum overnight. Seasonal mean  
555 concentrations during the SANDS period fall within the IQR of the 6-year period between 2015 and 2020, with

556 SANDS annual and 6-year averages being very similar. Concentrations of  $\text{NH}_x$  were higher relative to  $\text{TNO}_3$  during  
557 SANDS and over the longer term at Coweeta (Figures 6 and 7).

### 558 **3.5 Aerosol N composition**

559 Ammonium was the most abundant inorganic species, contributing 86.8% of WSTN ( $N = 103$ ) on average (Figure 8,  
560 Table S7). Organic compounds (WSON) contributed 11.5% of WSTN, which is very similar to precipitation. The  
561 contributions of  $\text{NO}_3^-$  and  $\text{NO}_2^-$  were minor. Our study-wide average of %WSON is slightly lower than measurements  
562 at other North American forest sites, including Duke Forest, North Carolina (~33%, Lin et al., 2010) and Rocky  
563 Mountain National Park (14–21%) (Benedict et al., 2012), but is within the global range of 10–39% (Cape et al.,  
564 2011). Similar to precipitation chemistry, there was no seasonal pattern in the percent contribution of WSON to WSTN  
565 in  $\text{PM}_{2.5}$ . Hi-Vol measurements of inorganic PM components compared well, overall, with collocated CASTNET  
566 measurements (Supplemental Section S1).

### 567 **3.6 Biogeochemistry**

568 Estimates of  $\text{NH}_3$  emission potentials ( $\Gamma$ ) for the ground and vegetation are needed to calculate compensation points  
569 ( $\chi$ ) and fluxes in STAGE. Measurements of pH,  $\text{NH}_4^+$  and corresponding  $\Gamma$  of the leaves ( $\Gamma_s$ ) and litter ( $\Gamma_l$ ) are  
570 summarized in Figure 9 and Supplemental Tables S8 and S9. Measurements of  $\Gamma_s$  are divided into green leaves  
571 collected during the growing season (spring and summer) and senescent leaves collected in October.  $\text{NH}_3$  emission  
572 potentials ( $\Gamma$ ) for green leaves ( $\Gamma_s$ ) ranged from zero to 4070 with a median value (35.8) (Table S8) corresponding to  
573 a compensation point of  $\chi_s = 0.25 \mu\text{g NH}_3 \text{ m}^{-3}$  at 25 °C. Large intra-species variability of tissue pH and  $\text{NH}_4^+$  were  
574 observed (Table S9) and separating by crown versus understory species did not reveal distinct differences between  
575 groups. Given the variability of the observations, the median  $\Gamma_s$  was used for STAGE simulations. Senescence marks  
576 the translocation of N in leaves to storage tissues (Schneider et al., 1996). Along with a decline in photosynthetic  
577 activity, degradation of chlorophyll, and other metabolic changes, glutamine synthetase (GS) activity also declines  
578 (Pearson et al., 2002). Glutamine synthetase catalyzes assimilation of  $\text{NH}_4^+$  into glutamine and is therefore important  
579 in regulating the pool of  $\text{NH}_4^+$  available for exchange as  $\text{NH}_3$  between the leaf and atmosphere and remobilizing  
580 organic N for storage during senescence. A decline in GS activity can thus result in increased leaf  $\text{NH}_4^+$  concentrations  
581 (Pearson et al., 2002; Wang et al., 2011). Senescent leaves were similar to green leaves with respect to median tissue  
582 pH but showed distinctly higher concentrations of tissue  $\text{NH}_4^+$ . Median  $\Gamma_s$  was correspondingly higher (113),  
583 equivalent to  $\chi_s = 0.8 \mu\text{g NH}_3 \text{ m}^{-3}$  at 25 °C. For STAGE modeling, the median  $\Gamma$  for senescent leaves was used for  $\Gamma_s$   
584 during the fall.

585 Regard our method for estimating  $\Gamma_s$ , the fundamental assumption is that the chemistry of the bulk leaf tissue is  
586 representative of the apoplast. While a number of studies have shown positive correlations between bulk tissue  
587 chemistry, apoplastic chemistry, and independently quantified compensation points (David et al., 2009; Hill et al.  
588 2002; Massad et al. 2010; Mattsson and Schjoerring 2002; Mattsson et al. 2009), absolute differences between  $\Gamma_s$   
589 derived from bulk tissue versus apoplast measurements can be large. For example, Sutton et al. (2009) and Personne  
590 et al. (2015) both show that ratios derived from bulk tissue chemistry exceed those derived from apoplast chemistry.

591 We did not perform experiments to validate the use of bulk tissue chemistry as a proxy for apoplast chemistry and  
592 acknowledge this source of uncertainty. However, our estimates of  $\Gamma_s$  appear reasonable in the context of the range of  
593 existing observations (cited above and summarized by Massad et al., 2010) and the general relationship between  
594  $[\text{NH}_4^+]_{\text{bulk}}$  and  $\Gamma_s$  put forth by Massad et al. (2010, equation 6). Measurements on bulk tissue are less labor intensive  
595 and therefore more tempting than measurements on the apoplast. However, more studies comparing to two procedures  
596 are needed to extend the meta-analysis of Massad et al. (2010) to a wider range of natural ecosystems, particularly  
597 deciduous forests.

598 Leaf litter on the soil surface has been shown to be a source of  $\text{NH}_3$  to the atmosphere in both natural and agricultural  
599 ecosystems (Nemitz et al., 2000b; David et al., 2009; Hansen et al., 2013). As litter decomposes, mineralization of  
600 organic N is a source of  $\text{NH}_4^+$ , some of which is lost to the overlying air as  $\text{NH}_3$ . Litter  $\text{NH}_4^+$  concentrations were  
601 similar to green leaves but lower than senescent leaves (Figure 9). However, the pH was higher than both green and  
602 senescent leaves. The resulting median  $\Gamma_1$  (69.3) was larger than green leaves but smaller than senescent leaves,  
603 equivalent to  $\chi_1 = 0.49 \mu\text{g NH}_3 \text{ m}^{-3}$  at 25 °C. Litter  $\Gamma$  was much larger than that of the underlying soil. Average (0–10  
604 cm soil depth) soil pH (4.18) and  $\text{NH}_4^+$  (1.21 mg N  $\text{kg}^{-1}$ ) correspond to  $\Gamma_{\text{soil}} \sim 10$  at a soil mass wetness of 0.1  $\text{g g}^{-1}$ ,  
605 equivalent to  $\chi_{\text{soil}} \sim 0.1 \mu\text{g NH}_3 \text{ m}^{-3}$  at 25 °C. This very low  $\Gamma_{\text{soil}}$  results from the low pH of the shallow soil.

606 Vertical profiles of air concentrations within and above the canopy were measured to investigate patterns of air-surface  
607 exchange with specific ecosystem compartments (i.e., canopy crown, understory, and ground). A detailed analysis of  
608 bi-directional N fluxes is forthcoming; thus, we limit the discussion of these data to  $\text{NH}_3$  in the context of interpreting  
609 patterns observed in the biogeochemical emission potentials and their prescription in the STAGE model. Nitric acid,  
610  $\text{NH}_4^+$ , and  $\text{NO}_3^-$  showed expected decreasing concentrations from above the canopy to the forest floor, indicative of  
611 deposition. While  $\text{NH}_3$  profiles showed patterns of deposition to the crown and understory, concentrations near the  
612 forest floor indicated both emissions and deposition (Figure 10). Of the 76 daytime profiles measured, 40% showed  
613 decreases down to the forest floor, and 60% showed increasing concentration from approximately the lower understory  
614 ( $\sim 5$  m above ground) to the forest floor. The former pattern is interpreted as deposition to the forest floor, and the  
615 latter is interpreted as emission. Thus, the mean profile suggests a source of  $\text{NH}_3$  at the ground. The very low  $\Gamma_{\text{soil}}$   
616 suggests that emission from the soil is unlikely given such a low pH. The leaf litter layer, which indicates a much  
617 higher emission potential ( $\Gamma_1$ ) than the soil, is a more likely source of  $\text{NH}_3$ . This hypothesis is consistent with Hansen  
618 et al. (2013; 2017), in which emissions of  $\text{NH}_3$  from a beech (*Fagus sylvatica*) forest after leaf fall were attributed to  
619 the decomposition of new litter. Similar to our site, the underlying soil also had low pH (4–5). Given our observations,  
620 we used  $\Gamma_1$  (median = 69.3, Table S8) rather than  $\Gamma_{\text{soil}}$  as the ground emission potential ( $\Gamma_g$ ) in STAGE.

### 621 3.7 N deposition budget

622 Total annual N deposition for the period August 2015 – August 2016 was 6.7  $\text{kg N ha}^{-1}$  (Figure 11). Over this period,  
623 wet deposition contributed 60.7% of total N deposition, of which  $\text{NH}_4^+$  was the primary component (29.6%). Wet  
624 deposition of organic N contributed 5.4% of the total N deposition budget. Dry deposition accounted for 39.3% of  
625 total deposition, of which  $\text{NH}_3$  was the primary contributor (20.6%). Reduced forms of inorganic N were the largest

626 contributor to the budget (51.2%), with oxidized inorganic and organic N contributing 41.2% and 7.6% of total N  
627 deposition, respectively. Dry deposition of organic N made a small contribution (2.2%) to the total deposition budget.  
628 Ammonia is the most important contributor to the dry deposition budget (52.3%) and differs from the other species in  
629 that it is exchanged bidirectionally between the ground, canopy and atmosphere.

630 Seasonal net canopy-scale and component fluxes are shown in Supplemental Figure S9. The mean net flux ( $F_{net}$ ) is  
631 downward (i.e., deposition) during all seasons, generally following the seasonal pattern of the atmospheric  $NH_3$   
632 concentration. The cuticular flux ( $F_{cut}$ ), which is unidirectional in STAGE, is the dominant deposition pathway and  
633 ranged from  $-97.7 \text{ ng N m}^{-2} \text{ s}^{-1}$  (deposition) to near zero. The contribution of  $F_{cut}$  to the total net flux ranged from  
634 84.7% in spring to  $\sim 100\%$  during fall. The stomatal flux ( $F_s$ ) is bidirectional, ranging from  $-4.5 \text{ ng N m}^{-2} \text{ s}^{-1}$   
635 (deposition) to  $2.3 \text{ ng N m}^{-2} \text{ s}^{-1}$  (emission), with the largest fluxes occurring during warmer periods of the growing  
636 season when the stomatal resistance is lowest. The stomatal flux is smaller than  $F_{cut}$  for several reasons. First,  $R_s$  is  
637 generally larger than  $R_{cut}$ . Also, in the current model formulation the cuticular compensation  $X_{cut} = 0$ . Thus, the  $NH_3$   
638 concentration gradient between air above the leaf ( $X_{leaf}$ ) and  $X_s$  is smaller than for  $X_{cut}$ . Finally, low LAI and large  $R_s$   
639 in winter and fall and offsetting bidirectional fluxes in spring and summer result in a relatively small mean stomatal  
640 deposition flux ( $F_s$ ) across seasons.  $F_g$  is also bidirectional, ranging from  $-3.9 \text{ ng N m}^{-2} \text{ s}^{-1}$  (deposition) to  $2.5 \text{ ng N}$   
641  $\text{m}^{-2} \text{ s}^{-1}$  (emission). Fluxes are largest during spring as atmospheric  $NH_3$  begins to increase with warmer temperatures  
642 but before peak LAI is reached, after which the denser canopy increases the in-canopy aerodynamic ( $R_{inc}$ ) and air-side  
643 ground boundary-layer resistances ( $R_{bg}$ ) (Table S2), thereby decreasing  $F_g$ . On an annual scale,  $F_g$  and  $F_s$  make similar  
644 contributions to ( $\sim 3.0\%$ ) to  $F_{net}$ .

645 Nitric acid was the second largest component of dry deposition, contributing 36.2% of the total. While  $HNO_3$  deposits  
646 more rapidly than  $NH_3$  (Supplemental Table S10), the overall importance to the dry N budget is constrained by  
647 relatively low air concentrations at this remote forest site. Particulate species made much smaller contributions to the  
648 budget due to much lower deposition velocities ( $V_d = \text{flux}/\text{air concentration}$ ) relative to their gaseous counterparts  
649 (Supplemental Table S10). For example, while  $NH_4^+$  contributed more to the atmospheric  $NH_x$  load than  $NH_3$ , (Figure  
650 7), the  $NH_x$  flux budget was regulated by the much more rapid exchange of  $NH_3$  between the forest and atmosphere  
651 relative to  $NH_4^+$ . A similar example was observed for oxidized N. While  $NO_2$  represents an important fraction of the  
652 oxidized N concentration budget via its contribution to “Other  $NO_y$ ”,  $NO_2$  deposits much less rapidly than  $HNO_3$   
653 (Supplemental Table S10) thereby contributing a relatively small fraction (3.0%) of the dry N flux. Of the organic N  
654 species, AN contributed slightly more (2.9%) to dry N deposition than PN (2.3%) owing to a higher deposition velocity  
655 (Supplemental Table S10). Similar to particulate  $NH_4^+$  and  $NO_3^-$ , PON made a small contribution to dry N deposition  
656 (0.4%) due to its low  $V_d$  (Supplemental Table S10). Reduced forms of N accounted for the majority of dry N deposition  
657 (55.1%), with oxidized inorganic and organic forms of N contributing 39.4% and 5.5%, respectively.

658 Total N deposition peaked during the summer ( $2.5 \text{ kg N ha}^{-1}$ ) and reached a minimum in the fall ( $1.0 \text{ kg N ha}^{-1}$ ) (Figure  
659 12). Wet deposition exceeded dry deposition during all seasons. Seasonal variability in wet deposition was primarily  
660 driven by precipitation amount, whereas dry deposition was influenced by seasonality in air concentrations of the  
661 primary  $N_r$  species (Figures 6 and 7), LAI (Figure S6), turbulence, and other surface characteristics. Ammonia fluxes  
662 followed the seasonal pattern of air concentration, peaking in the summer and reaching a minimum in winter.

663 Concentrations and fluxes of HNO<sub>3</sub> peaked in the spring and reached a minimum in the fall. Deposition velocities,  
664 which can be thought of as the concentration-normalized flux, peaked during the summer and reached a minimum  
665 during winter for most N species. This pattern likely reflects the combined effect of seasonal cycles in LAI and  
666 turbulence characteristics. The seasonal pattern of  $V_d$  for HNO<sub>3</sub> differed slightly from the other species, peaking in  
667 spring and reaching a minimum in fall. In contrast to other N species, HNO<sub>3</sub> deposition is limited by turbulent transfer,  
668 the canopy (surface) resistance being zero. The pattern of HNO<sub>3</sub>  $V_d$  thus partially reflects seasonal patterns in wind  
669 speed and degree of turbulent mixing above the canopy.

### 670 3.8 Evaluation of the dry deposition model

671 While total uncertainty in the dry deposition budget cannot be rigorously quantified (Walker et al., 2019a), the  
672 sensitivity of the model to parameterizations and key inputs can elucidate important aspects of model uncertainty and  
673 inform a potential range of dry deposition estimates. Here we undertake such an exercise, evaluating several alternative  
674 modeling scenarios to assess the sensitivity of fluxes and total dry deposition to assumptions regarding LAI, NH<sub>3</sub>  
675 emission potentials ( $\Gamma_{s,i}$ ), NH<sub>3</sub> cuticular resistance ( $R_{cut,dry}$ ), and particle size distribution. We focus on NH<sub>3</sub>, as it is  
676 the most important component of the dry deposition budget and more complex with regard to air-surface exchange  
677 processes than the other species. Sensitivity tests are summarized in Supplemental Section S5 and Table S11. Of the  
678 scenarios tested, increasing  $\Gamma_1$  and  $\Gamma_s$  within the range of observations and reducing  $R_{cut,dry}$  within the variability  
679 reported by Massad et al. (2010) exerted the largest control over the dry deposition flux, establishing a range of total  
680 dry deposition from 2.0 (increasing  $\Gamma_{s,i}$ ) to 3.1 (decreasing  $R_{cut,dry}$ ) kg N ha<sup>-1</sup> around the base value of 2.6 kg N ha<sup>-1</sup>.  
681 The corresponding % contribution of NH<sub>3</sub> to total dry N deposition ranges from 36.6% to 58.5% (base = 52%) and  
682 the contribution of dry to total wet + dry deposition ranges from 33.0% to 43.0% (base = 39.4%). Our results point to  
683 the need for a better understanding of the processes of cuticular exchange and the importance of adequately  
684 characterizing the magnitude and variability of vegetation and litter emission potentials in forests.

685 Another method of evaluating model behavior is the comparison with measured  $V_d$ . During the final summer intensive,  
686 a small dataset ( $N = 19$  observations) of  $V_d$  was determined from daytime measurements of vertical concentration  
687 gradients above the canopy using the MBR method. Measured  $V_d$  was compared to  $V_d$  derived from the STAGE model  
688 for overlapping periods, and the maximum possible  $V_{dmax}$  as  $1/(R_a + R_b)$ . Of the 19 MBR measurements, four NH<sub>3</sub>  
689 profiles exhibited emissions (6.8 to 22.4 ng NH<sub>3</sub> m<sup>2</sup> s<sup>-1</sup>), which were not reproduced by STAGE. Analysis of the  
690 meteorological conditions during the MBR measurements suggests that emissions tend to occur during the warmest  
691 periods with lowest relative humidity. This would correspond to periods when  $R_{cut}$  and  $X_s$  are high and may indicate  
692 that the model is underestimating  $F_s$  emissions during these periods. Excluding the four emission periods,  $V_d$  estimated  
693 from MBR and STAGE agree reasonably well (Supplemental Figure S11). As is the case for STAGE, resistance-based  
694 models typically assume HNO<sub>3</sub> deposits at the rate of  $V_{dmax}$  (i.e.,  $R_c = 0$ ). As shown in Figure S11, fluxes measured  
695 during summer 2016 showed MBR  $V_d$  for HNO<sub>3</sub> larger than NH<sub>3</sub>, as expected, but lower than  $V_{dmax}$ . This apparent  
696 non-zero  $R_c$  could result from a real non-zero  $R_c$  caused, for example, by equilibrium of HNO<sub>3</sub> and NO<sub>3</sub><sup>-</sup> on leaf  
697 surfaces (Nemitz et al., 2004a). This pattern may also reflect the influence of flux divergence related to NH<sub>4</sub>NO<sub>3</sub>  
698 evaporation in the canopy crown, which would reduce the magnitude of the downward vertical gradients, and therefore

699 the measured  $V_d$  of  $\text{HNO}_3$  and  $\text{NH}_3$  (Nemitz et al., 2004b). In this study, concentrations of  $\text{NO}_3^-$  (mean =  $0.08 \mu\text{g m}^{-3}$ )  
700  $^3$ ) were much lower than  $\text{HNO}_3$  (mean =  $0.47 \mu\text{g m}^{-3}$ ), and  $\text{NO}_3^-$  gradients were therefore difficult to resolve, precluding  
701 a definitive explanation of  $\text{HNO}_3$   $V_d < V_{dmax}$ . Ignoring potentially significant uncertainties related to the measurement  
702 of chemical and temperature gradients within the roughness sublayer, our results suggest that periods of  $\text{NH}_3$  emission  
703 during the day, particularly at higher air temperature and lower humidity, may be underestimated. Our results also  
704 reinforce the need for temporally extensive measurements of concentrations and fluxes of  $\text{HNO}_3$ ,  $\text{NH}_3$ , and  $\text{NO}_3^-$  to  
705 examine exchange processes and uncertainties related to chemical flux divergence.

### 706 **3.9 Spatial and temporal representativeness of deposition budget**

707 The complexity of atmospheric flows in mountainous terrain influences the spatial variability of wet and dry  
708 deposition processes (Lehner and Rotach, 2018). As the deposition budget presented above is based on measurements  
709 from the lowest elevation portion of the Coweeta basin, the degree to which the budget is spatially representative must  
710 be considered. Potential effects on dry deposition were assessed by characterizing the magnitude and spatial  
711 variability of  $\text{HNO}_3$  and  $\text{NH}_3$  concentrations along an elevation gradient (Figure 1, Table 1) from the lower to upper  
712 portions of the Coweeta Basin. It should be noted that  $\text{HNO}_3$  concentrations at NC25 were measured by CASTNET  
713 while  $\text{HNO}_3$  passive samplers were used at the other locations. Concentrations are summarized in Figure 13, in which  
714 the sites are ordered left to right from lowest to highest elevation. Nitric acid and  $\text{NH}_3$  concentrations increase slightly  
715 with elevation, an explanation for which is not obvious. Nitric acid concentrations are highest at Screwdriver Knob,  
716 which is distinct from the other sites in that the measurement tower was situated on a relatively narrow exposed ridge.  
717 The measurements are therefore higher above the surrounding vegetation than at the other sites. Overall, variability  
718 of air concentrations across sites, even including SK, is sufficiently small such that spatial variability of dry deposition  
719 across the basin would likely be driven more by variability in meteorology than air concentrations.

720 A quantitative assessment of the effects of air flow on dry deposition across the basin is not possible, but the work of  
721 Hicks (2008) illustrates the relevant effects in the context of the resistance analogy for  $V_d$ . Over flat homogeneous  
722 terrain, flux to the vegetation is driven by turbulent diffusion in the vertical direction above the canopy and horizontal  
723 advection is assumed to be zero. In the extreme case of air flow approaching a steep forested slope, horizontal flow  
724 penetrates the canopy and the transfer of material (deposition) to the canopy elements becomes dominated by  
725 horizontal advection and filtration rather than vertical diffusion. In the context of  $V_d$ , this situation is analogous to the  
726 aerodynamic resistance ( $R_a$ ) approaching zero. Taking  $\text{HNO}_3$  as an example under the typical assumption that the  
727 canopy resistance ( $R_c$ ) = 0,  $V_d$  becomes limited by the quasi-laminar boundary layer resistance at the vegetation  
728 surfaces ( $R_b$ ). Following the analysis of Hicks et al. (2008),  $V_d$  for  $\text{HNO}_3$  could be enhanced by a factor of  $[1+(R_a/R_b)]^{1/2}$   
729 (Hicks, 2008). Using median values of  $R_a$  and  $R_b$  from our modeling period, this would increase  $V_d$  for  $\text{HNO}_3$  by a  
730 factor of  $\sim 1.4$ . For gases that have a significant  $R_c$ , enhancements will be smaller. Topographical relief across the  
731 Coweeta Basin may be gentle enough such that the flow separation described in the previous example is limited to  
732 certain areas and meteorological scenarios. However, as Hicks (2008) points out, flow complexity in mountainous  
733 areas has the overall effect of increasing  $V_d$ , with areal weighted fluxes being highly dependent on the topographical  
734 characteristics specific to the study area. Other effects related to katabatic flows (Novick et al., 2016) and diel patterns

735 of hillside shading that drive temperature-related processes such as  $\text{NH}_3$  compensation points introduce additional  
736 uncertainties.

737 The results of Knoepp et al. (2008) show that spatial patterns of wet deposition across the Coweeta Basin follow  
738 patterns of precipitation amount, which increase with elevation. In their study, bulk deposition of  $\text{NH}_4^+$ ,  $\text{NO}_3^-$  and total  
739 organic nitrogen was measured from 1994–1996 at sites ranging in elevation from 788 to 1389 m. Annual precipitation  
740 depth and bulk deposition increased by 25% from the lowest to the highest elevation. This increase in precipitation  
741 with elevation is consistent with the 75-year analysis of Coweeta climatological data by Laseter et al. (2012), which  
742 showed annual precipitation amount at 1398 m was 32% greater than at 686 m. In our study, wet deposition was  
743 measured at the NC25 site at 686 m and therefore represents a lower wet deposition rate than would occur in higher  
744 elevation portions of the basin. An approximate 35% enhancement in both wet and dry deposition for the highest  
745 elevations within the basin would correspond to a total N deposition rate of  $9.0 \text{ kg N ha}^{-1} \text{ yr}^{-1}$  based on our estimate  
746 of  $6.7 \text{ kg N ha}^{-1} \text{ yr}^{-1}$  for the lower basin.

747 Regarding the temporal representativeness of the deposition budget calculated here, wet deposition of inorganic N  
748 ( $\text{NO}_3^- + \text{NH}_4^+$ ) during our 12-month model period ( $3.69 \text{ kg N ha}^{-1}$ ) agrees well with the mean annual deposition rate  
749 measured at NTN site NC25 ( $3.72 \text{ kg N ha}^{-1}$ ) over the period 2015–2020, with 2020 being the most recent full year of  
750 reported observations. Air concentrations of  $\text{NO}_3^-$  and  $\text{HNO}_3$  (Figure 6) as well as  $\text{NH}_3$  and  $\text{NH}_4^+$  (Figure 7) during  
751 our model period are also similar to the 6-year (2015–2020) mean concentrations measured by CASTNET and AMoN.  
752 In this context, our results are deemed temporally representative of the most recently available complete years of  
753 monitoring data.

#### 4 Conclusions

754 Due to the success of the Clean Air Act, air concentrations and wet deposition of reactive N at Coweeta are the lowest  
755 observed since the beginning of routine monitoring in the late 1970s. However, even at historically low levels, our  
756 results show that  $\text{N}_r$  deposition remains highly ecologically relevant in the context of critical loads. Our estimate of  
757 total  $\text{N}_r$  deposition of  $6.7 \text{ kg N ha}^{-1} \text{ yr}^{-1}$  is near the upper-end estimate of mass balance derived critical loads (2.8 to 7  
758  $\text{kg N ha}^{-1} \text{ yr}^{-1}$ ) recently reported for spruce-fir, beech, and mixed deciduous forests by Pardo et al. (2018) in nearby  
759 Great Smoky Mountains National Park. Our result also falls within the range of empirical critical loads of N for  
760 combined tree health and biogeochemical responses ( $3\text{--}8 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ ) and changes in mycorrhizal fungi spore  
761 abundance, community structure and community composition ( $5\text{--}12 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ ) in eastern temperate forests (Pardo  
762 et al., 2011).

763 A key feature of the deposition budget derived for Coweeta is the predominance of reduced forms ( $\text{NH}_x$ ) of inorganic  
764 nitrogen (51.2%) over oxidized inorganic N (41.2%). Reductions in deposition of  $\text{NH}_x$  will be needed to achieve the  
765 lower-end estimates of critical N loads ( $\sim 3 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ ) for southern Appalachian forests. This presents a challenge,  
766 as emissions and air concentrations of  $\text{NH}_3$  remain unregulated. Our results also show that organic forms of N make  
767 a non-trivial contribution (7.6%) to total N deposition, primarily via wet deposition. It is noted, however, that the gas-  
768 phase dry component of deposition only considers oxidized forms as alkyl and peroxy nitrates, excluding contributions  
769 from reduced (i.e., NH) organic compounds. While our results represent an advancement in accounting for organic

770 dry  $N_r$  deposition in total  $N_r$  deposition, the application of new measurement technologies (Walker et al., 2019b) for  
771 broader chemical speciation of organic forms of dry  $N_r$  deposition is needed.  
772 Our results underscore the need for long-term measurements of reactive chemical fluxes, and the coupling of  
773 atmospheric and biogeochemical measurements, to improve air-surface exchange models. Novel measurements that  
774 more directly elucidate the role of cuticular exchange of  $NH_3$  and more temporally extensive measurements of leaf  
775  $NH_3$  emission potentials are particularly needed. For forest ecosystems, a physically representative parameterization  
776 for resistance to  $NH_3$  diffusion through the leaf litter layer and more temporally extensive measurements of the litter  
777  $NH_3$  emission potential combined with more thorough understanding of litter decay dynamics are also needed. For  
778 sensitive ecosystems located in mountainous and other topographically complex landscapes, which includes much of  
779 the Class I wilderness area in the U.S., identification of locations suitable for micrometeorological flux measurements  
780 will be challenging. Novel flux measurement methods and application of in-situ models, including translation of  
781 measurements from more ideal to complex locations, will likely be needed. Furthermore, long-term flux datasets are  
782 needed to assess the interactive effects of changing air quality and climate on both atmosphere-biosphere exchange  
783 and ecosystem response to deposition (e.g., Van Houtven et al., 2019).

1160

1161 Table 1. Sampling locations and type of sampler deployed.

Site code	Latitude(N)	Longitude(W)	Elevation(m)	Sampler type
NC25/COW137	35.0605	83.4305	686	AMoN (NC25), CASTNET (COW137), Tisch PM <sub>2.5</sub> *, DD-CL, TD-PC-CL, NTN (NC25), EPA precipitation
EFT <sup>a</sup>	35.0591	83.4274	690	MARGA*, URG*, Passive NH <sub>3</sub> and HNO <sub>3</sub> , micrometeorology
WS18	35.0512	83.4337	806	Passive NH <sub>3</sub> and HNO <sub>3</sub>
SK <sup>b</sup>	35.0482	83.4542	986	Passive NH <sub>3</sub> and HNO <sub>3</sub> , CASTNET (COW005)
CS28	35.0466	83.4650	1189	Passive NH <sub>3</sub> and HNO <sub>3</sub>
CS77	35.0303	83.4604	1425	Passive NH <sub>3</sub> and HNO <sub>3</sub>

1162 <sup>a</sup>-Eddy flux tower; <sup>b</sup>-Screwdriver Knob; \* Tisch PM<sub>2.5</sub>, MARGA, and URG denuder/filter pack  
1163 samplers were deployed only during intensive sampling periods.

1164 Table 2. Details of intensive and long-term atmospheric measurements at Coweeta.

Sampler name	Operating periods	Measured species	Resolution	Height(m)*
DD-CL, TD-PC-CL	August 2015- August 2016	HNO <sub>3</sub> , NO <sub>y</sub> , ΣAN <sup>1</sup> , ΣPN <sup>2</sup>	Hourly	8
MARGA	Spring, summer 2016 intensives	HNO <sub>3</sub> , NH <sub>3</sub> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> , NH <sub>4</sub> <sup>+</sup>	Hourly	~40
URG denuder/filter	All intensives 2015-2016	HNO <sub>3</sub> , NH <sub>3</sub> , NO <sub>2</sub> <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> , NH <sub>4</sub> <sup>+</sup>	3 or 4-hour integrated	~40
Tisch PM <sub>2.5</sub>	All intensives 2015-2016	NO <sub>2</sub> <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> , NH <sub>4</sub> <sup>+</sup> , WSTN	24hr integrated	~1
CASTNET (COW137)	Long-term	HNO <sub>3</sub> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> , NH <sub>4</sub> <sup>+</sup> , Cl <sup>-</sup> , base cations	Weekly integrated	10
AMoN (NC25)	Long-term	NH <sub>3</sub>	Bi-weekly passive	10
Passive HNO <sub>3</sub> , NH <sub>3</sub>	2015	HNO <sub>3</sub> , NH <sub>3</sub>	Bi-weekly	10
CASTNET (COW005)	2015	HNO <sub>3</sub> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> , NH <sub>4</sub> <sup>+</sup> , Cl <sup>-</sup> , base cations	Weekly integrated	10
NADP/NTN	Long-term	NO <sub>3</sub> <sup>-</sup> , NH <sub>4</sub> <sup>+</sup> , SO <sub>4</sub> <sup>2-</sup> , Cl <sup>-</sup> , H <sup>+</sup> , base cations	Weekly accumulated	Ground
EPA precipitation	February 2015- August 2016	NO <sub>2</sub> <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> , NH <sub>4</sub> <sup>+</sup> , WSTN	Weekly accumulated	Ground

1165 \*Above ground; <sup>1</sup>Total alkyl nitrates; <sup>2</sup>Total peroxy nitrates

1166 Table 3. Summary of air concentration data sources for STAGE dry deposition modeling.

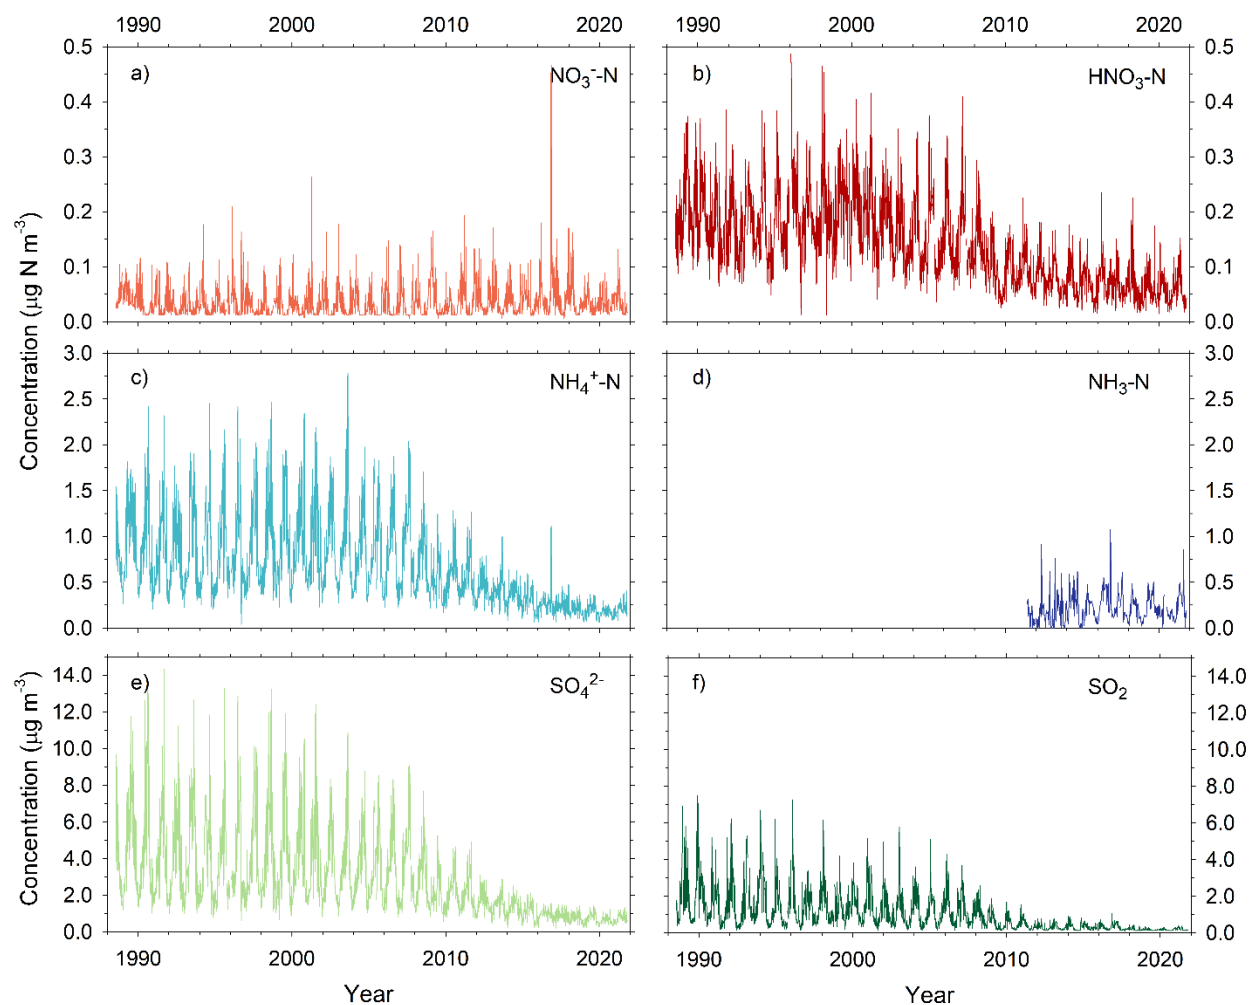

Chemical Species	Data Source	Details
NH <sub>3</sub>	Measurement	AMoN measurement with diurnal profile imposed
HNO <sub>3</sub>	Measurement	Continuous DD-CL
ΣPN	Measurement	Continuous TD-PC-CL. Assume molecular weight (MW = 121.1) of PAN (C <sub>2</sub> H <sub>3</sub> NO <sub>5</sub> )
ΣAN	Measurement	Continuous TD-PC-CL. Assume molecular weight (MW = 135.1) of nitrooxy-butanol (C <sub>4</sub> H <sub>9</sub> NO <sub>4</sub> )
NH <sub>4</sub> <sup>+</sup>	Measurement	CASTNET
NO <sub>3</sub> <sup>-</sup>	Measurement	CASTNET
PON	Estimated based on measured NH <sub>4</sub> <sup>+</sup> + NO <sub>3</sub> <sup>-</sup>	Based on intensive direct measurements, assume PON represents 12% of total PON + NH <sub>4</sub> <sup>+</sup> + NO <sub>3</sub> <sup>-</sup>
NO <sub>2</sub>	Estimated based on measured NO <sub>y</sub>	Based on ratio of NO <sub>2</sub> /NO <sub>y</sub> simulated by CMAQ V5.2.1 at Coweeta

1167

1170

Figure 1. Elevation map of Coweeta Basin with sampling sites in Table 1 indicated.

1175 Figure 2. Long-term CASTNET (weekly, Site COW137) and AMoN (biweekly, Site NC25) air concentrations (as N) of  $\text{NO}_3^-$  (a),  $\text{HNO}_3$  (b),  $\text{NH}_4^+$  (c),  $\text{NH}_3$  (d),  $\text{SO}_4^{2-}$  (e), and  $\text{SO}_2$  (f).

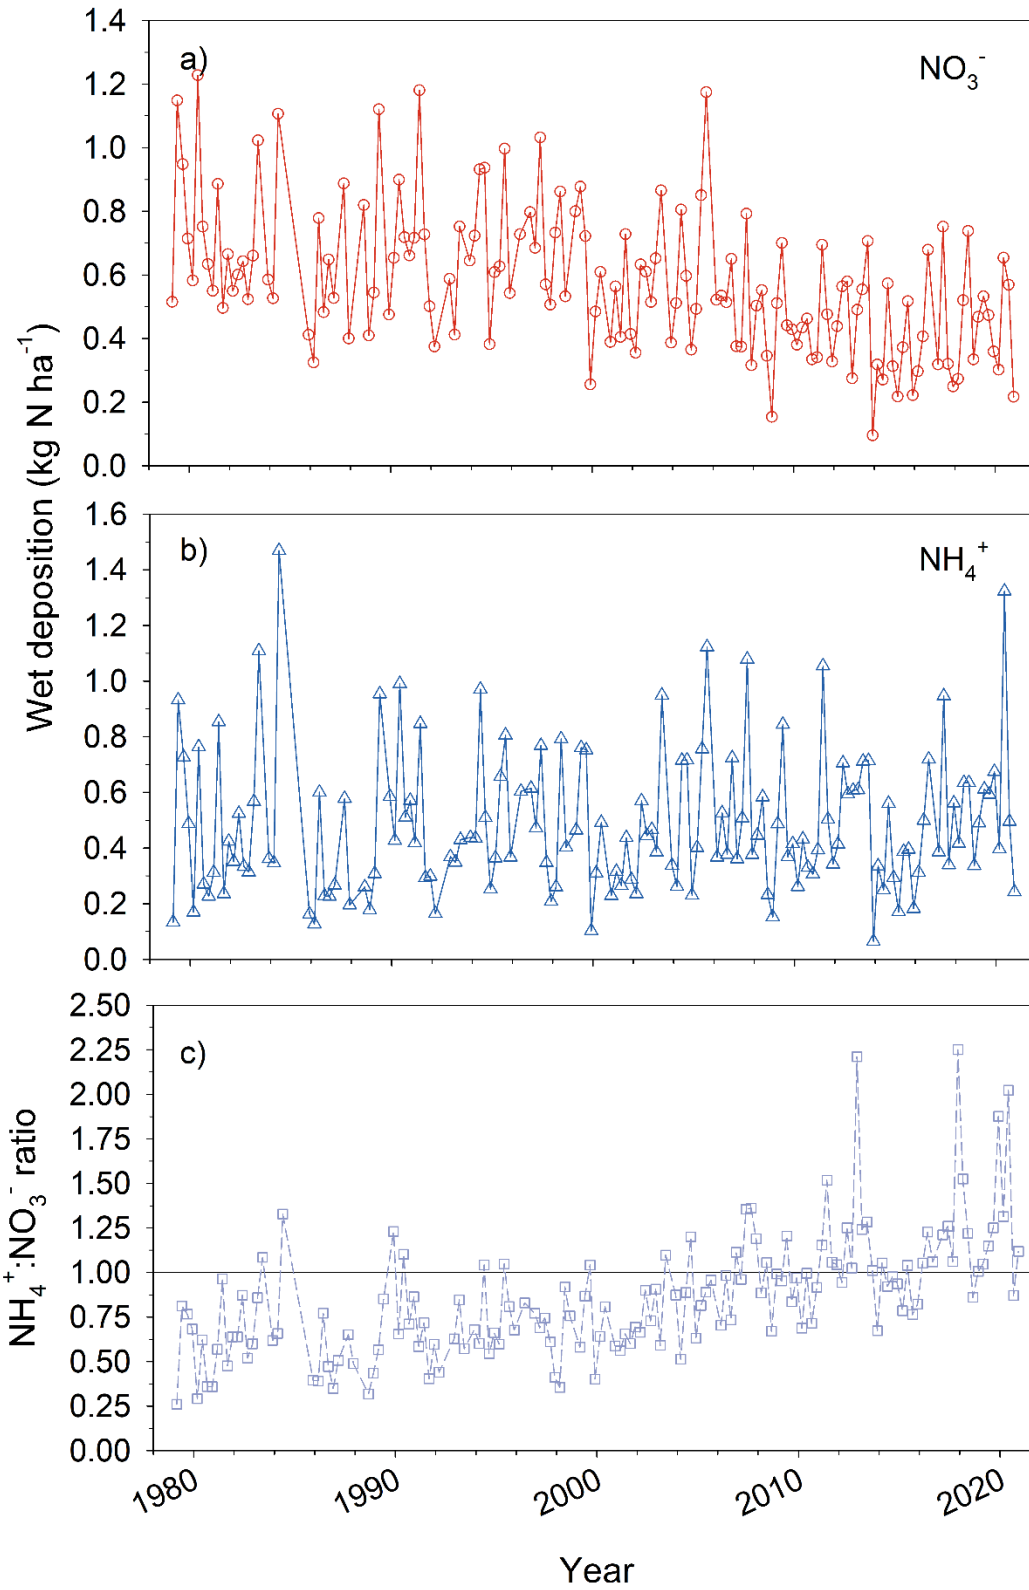

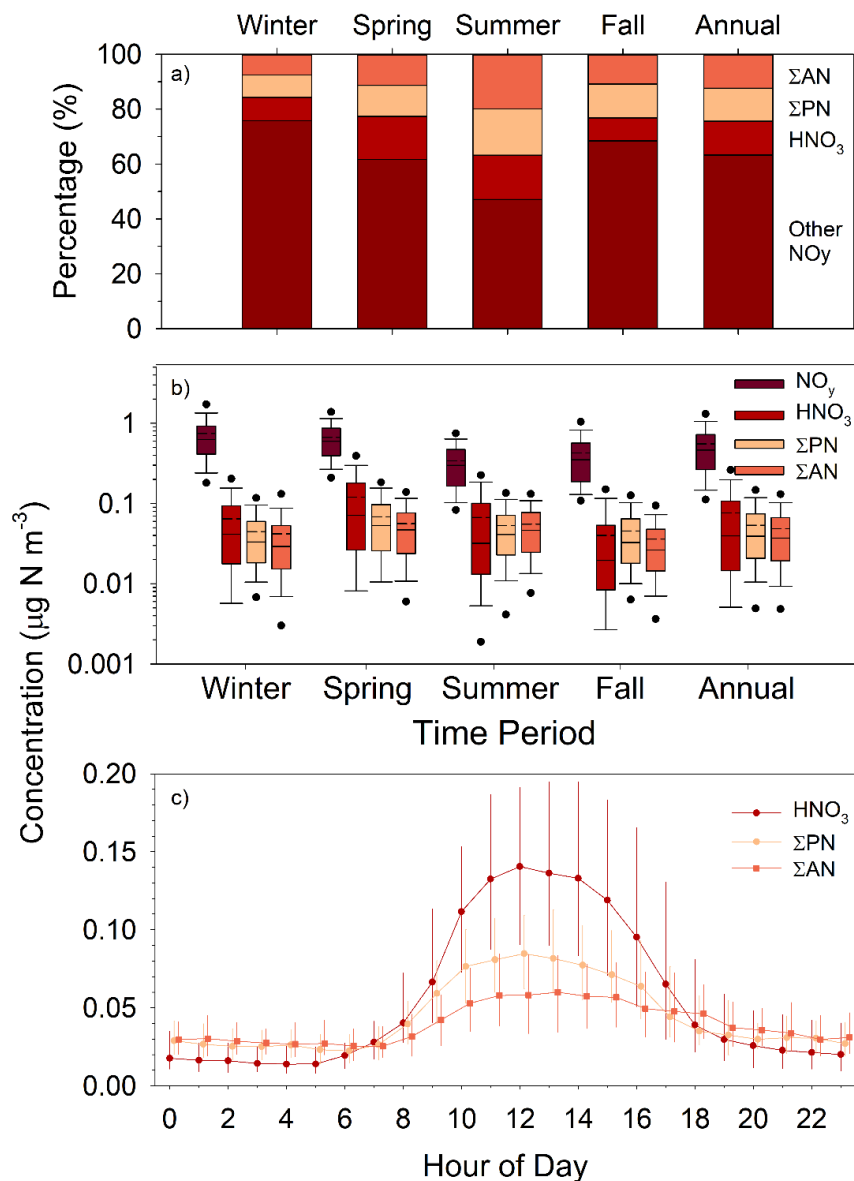

Figure 3. Long-term NTN NC25 measurements of seasonal  $\text{NH}_4^+$  (a) and  $\text{NO}_3^-$  (b) wet deposition along with the ratio of  $\text{NH}_4^+$  to  $\text{NO}_3^-$  as nitrogen and 1:1 reference line (c).

1180

Figure 4. Concentrations of nitrogen species in weekly precipitation samples (a), percentage contribution of WSON to WSTN in precipitation (b), and precipitation amount (c). Vertical line marks discontinuity due to missing data from 06/01/2015 to 10/19/2015.

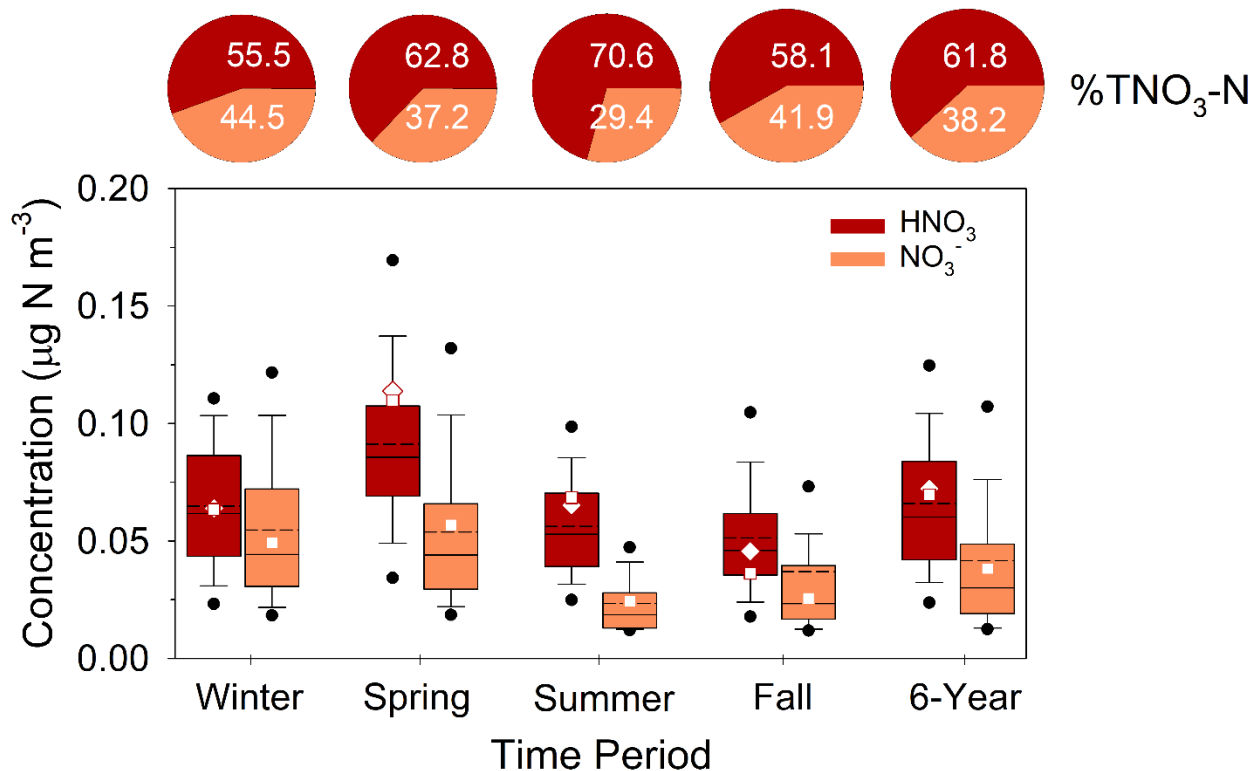

1185

Figure 5. Seasonal and annual % contribution of HNO<sub>3</sub>, ΣPN, ΣAN, and other compounds to total Noy (a); seasonal and annual boxplots of NO<sub>y</sub>, HNO<sub>3</sub>, ΣPN and ΣAN where solid and dashed lines inside box represent median and mean, respectively; top and bottom of box represent 75<sup>th</sup> and 25<sup>th</sup> percentiles; whiskers represent 10<sup>th</sup> and 90<sup>th</sup> percentiles, and dots represent 5<sup>th</sup> and 95<sup>th</sup> percentiles (b); and diurnal profiles of HNO<sub>3</sub>, ΣPN, and ΣAN where observations represent median hourly concentration and bars represent interquartile range (c). “Other NO<sub>y</sub>” is calculated as NO<sub>y</sub> – HNO<sub>3</sub> – ΣPN – ΣAN which, while primarily comprised of NO<sub>x</sub>, includes N<sub>2</sub>O<sub>5</sub>, HONO, NO<sub>3</sub><sup>-</sup>, and possibly other organics.

1190

1195 Figure 6. Summary of CASTNET HNO<sub>3</sub> and NO<sub>3</sub><sup>-</sup> concentrations (as N) from 2015-2020 during  
 winter, spring, summer and fall. Solid and dashed lines inside box represent median and mean,  
 respectively. Top and bottom of box represent 75<sup>th</sup> and 25<sup>th</sup> percentiles. Whiskers represent 10<sup>th</sup>  
 and 90<sup>th</sup> percentiles and dots represent 5<sup>th</sup> and 95<sup>th</sup> percentiles. “6-Year” represents the statistics  
 for the entire 6-Year period. Squares and diamonds represent the seasonal and annual mean  
 1200 CASTNET (HNO<sub>3</sub> and NO<sub>3</sub><sup>-</sup>) and continuous DD-CL HNO<sub>3</sub> for the August 2015 – August 2016  
 modeling period, respectively. Pie charts represent average % contribution of HNO<sub>3</sub> and NO<sub>3</sub><sup>-</sup> to  
 total NO<sub>3</sub><sup>-</sup> (HNO<sub>3</sub> + NO<sub>3</sub><sup>-</sup>) expressed as nitrogen.

1205

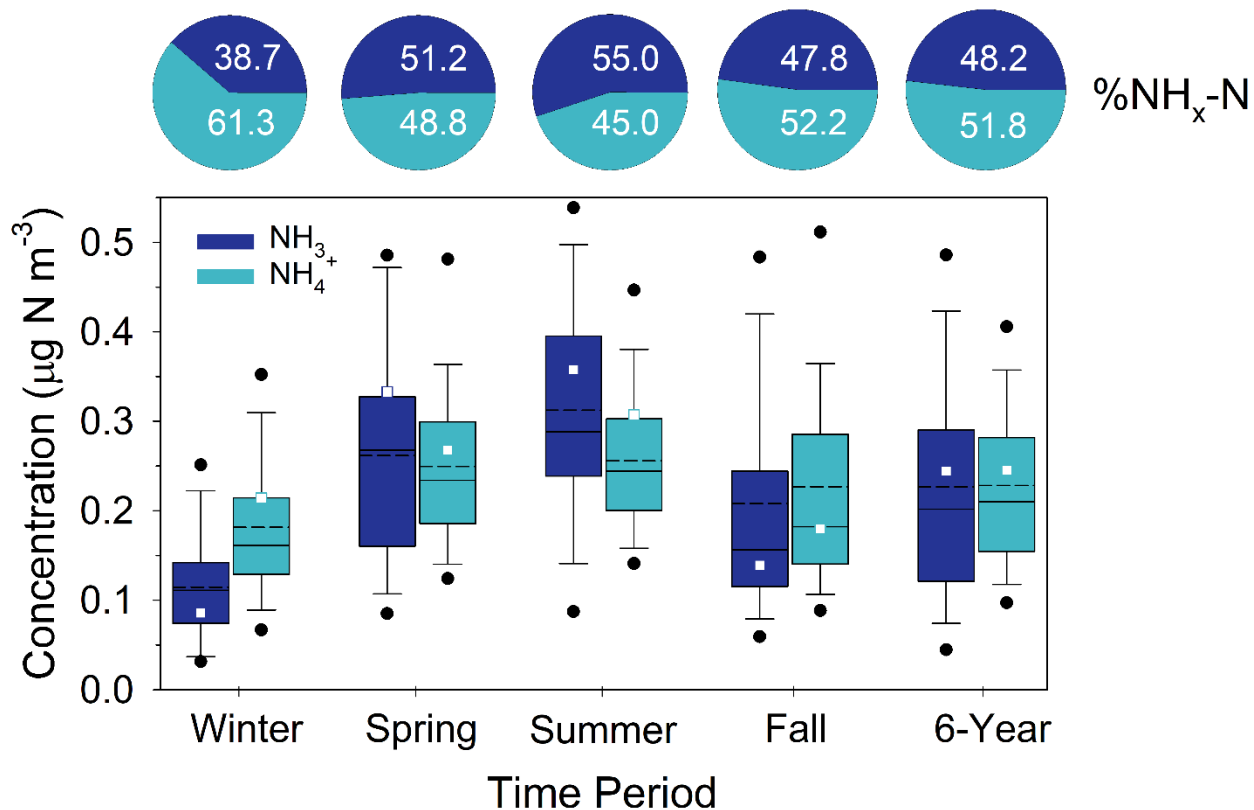

Figure 7. Summary of AMoN NH<sub>3</sub> and CASTNET NH<sub>4</sub><sup>+</sup> concentrations (as N) from 2015-2020 during winter, spring, summer and fall. Solid and dashed lines inside box represent median and mean, respectively. Top and bottom of box represent 75<sup>th</sup> and 25<sup>th</sup> percentiles. Whiskers represent 10<sup>th</sup> and 90<sup>th</sup> percentiles and dots represent 5<sup>th</sup> and 95<sup>th</sup> percentiles. “6-Year” represents the statistics for the entire 6-Year period. Squares represent the seasonal and annual mean concentration for the August 2015 – August 2016 modeling period. Pie charts represent average % contribution of NH<sub>3</sub> and NH<sub>4</sub><sup>+</sup> to total NH<sub>x</sub> (NH<sub>3</sub>+NH<sub>4</sub><sup>+</sup>) expressed as nitrogen. AMoN concentrations were adjusted by subtracting the mean travel blank for the 6-year period.

1215

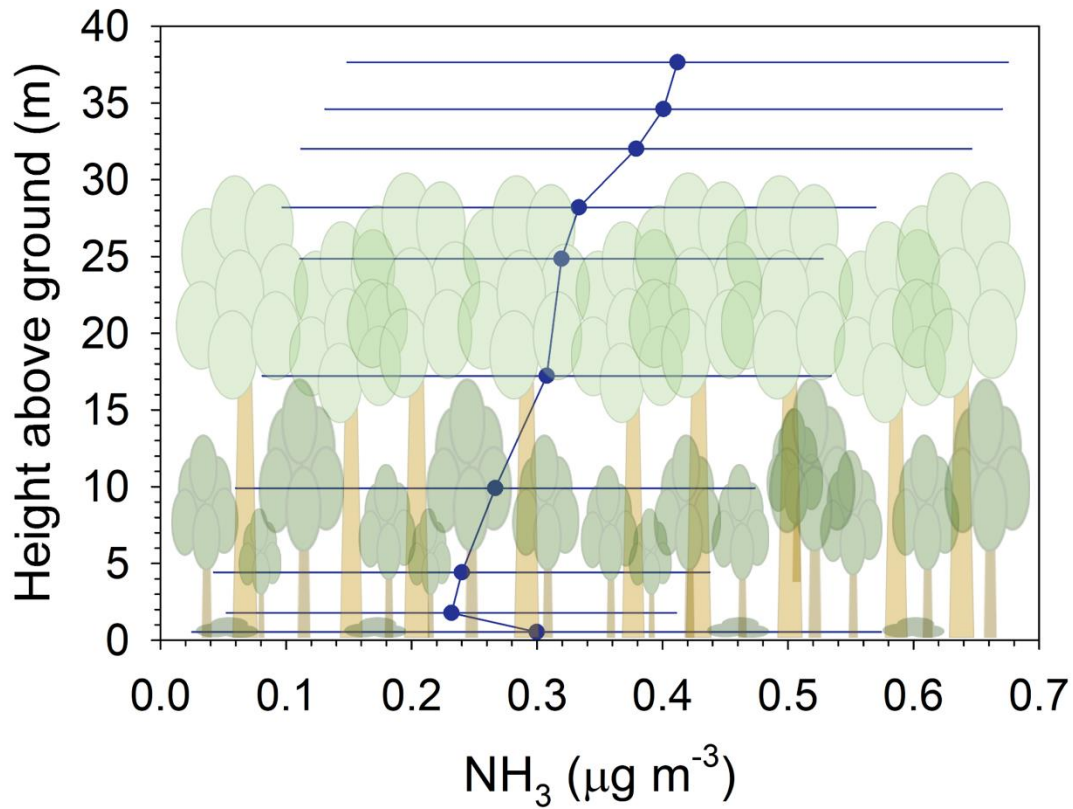

1220

Figure 8. Contributions of N aerosol species to WSTN in 24-hour Hi-Vol  $\text{PM}_{2.5}$  samples during seasonal SANDS intensives (a) along with percentage of WSON to WSTN (b).

1225

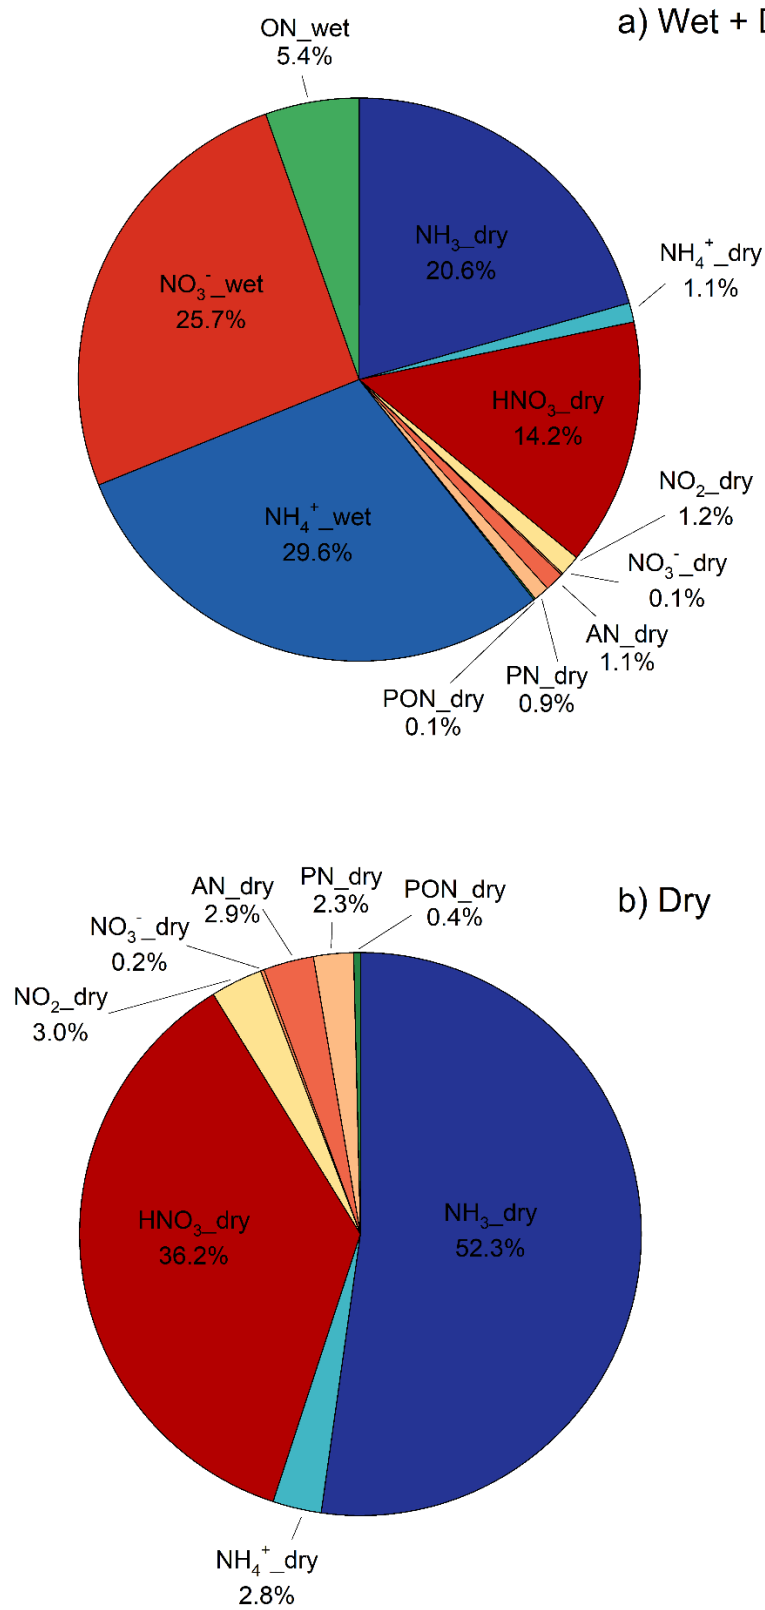

1230 Figure 9. Boxplots of pH (a),  $\text{NH}_4^+$  (b) concentration ( $\mu\text{g g}^{-1}$  fresh tissue), and equivalent emission potential ( $\Gamma$ ) (c) in tissue of green leaves, senescent leaves, and litter on the forest floor. Solid line inside box represents median. Top and bottom of box represent 75<sup>th</sup> and 25<sup>th</sup> percentiles. Whiskers represent 10<sup>th</sup> and 90<sup>th</sup> percentiles and dots represent 5<sup>th</sup> and 95<sup>th</sup> percentiles.

1235

Figure 10. Vertical concentration profiles of NH<sub>3</sub>. Mean (filled circle) and standard deviation (bars) of concentrations are shown for  $N = 76$  daytime profiles.

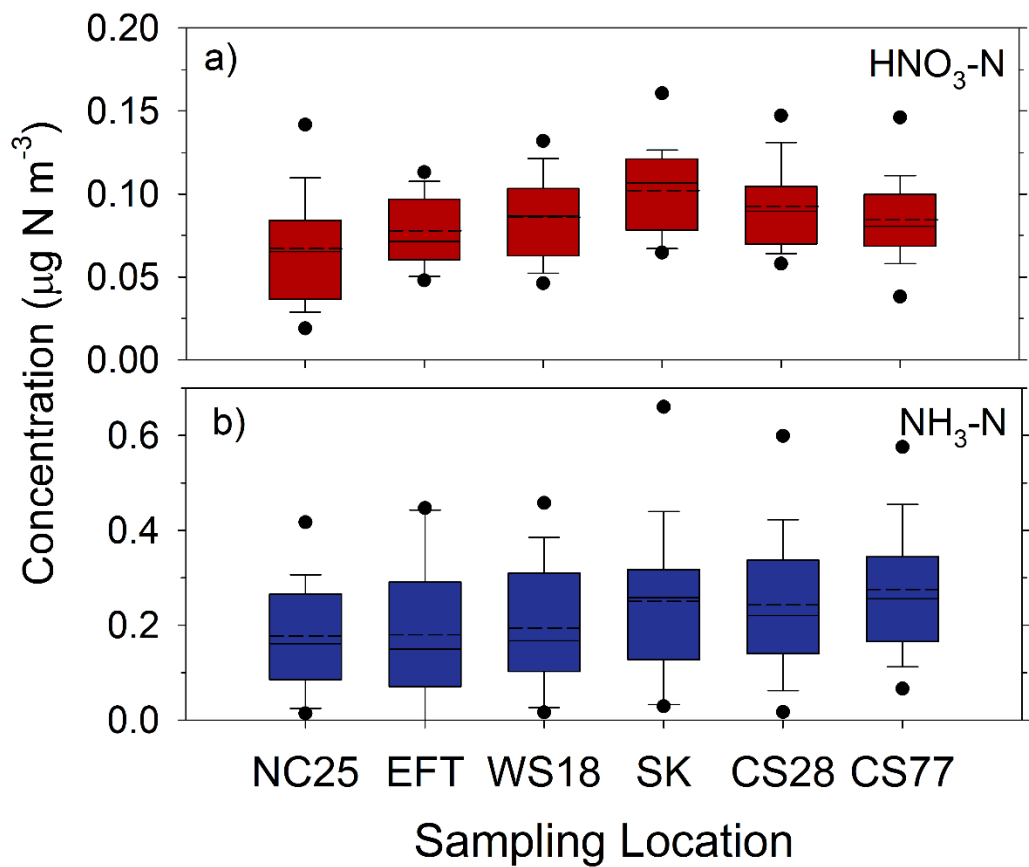

1240

Figure 11. Speciated annual total (wet and dry) (a) and dry (b) deposition showing percent contribution of individual components.

1245 Figure 12. Seasonal speciated deposition budget. Nr species are listed in the legend as defined in the text, along with indication of the deposition pathway (dry or wet).

1250 Figure 13. Concentrations (as N) of HNO<sub>3</sub> (a) and NH<sub>3</sub> (b) measured at different elevations, increasing from left to right (see Figure 1 and Table 1), across the Coweeta Basin. Solid and dash lines inside box represent median and mean, respectively. Top and bottom of box represent 75<sup>th</sup> and 25<sup>th</sup> percentiles. Whiskers represent 90<sup>th</sup> and 10<sup>th</sup> percentiles and dots represent 95<sup>th</sup> and 5<sup>th</sup> percentiles.

1255
