**Abstract.** Human exposure to mercury (Hg) is a cause of concern, due to the biomagnification of the neurotoxic species monomethylmercury (MMHg) in marine ecosystems. Previous research revealed that commercial fish species in the Mediterranean Sea ecosystems are particularly enriched in Hg, due to a combination of physical and ecological factors. Since  
10 the fate of Hg depends on the interactions among several biogeochemical and physical drivers, biogeochemical modelling is crucial to support the integration and interpretation of field data. Here, we develop and apply a coupled transport-biogeochemical-metal bioaccumulation numerical model (OGSTM-BFM-Hg), to simulate the biogeochemical cycling of the main Hg species ( $\text{Hg}^{\text{II}}$ ,  $\text{Hg}^0$ , MMHg, and DMHg) in seawater, organic detritus, and through the planktonic food web. The model is applied to a 3D domain of the Mediterranean Sea to investigate the spatial and temporal variability of MeHg  
15 distribution and bioaccumulation and major uncertainties in Hg cycling. Model results reproduce the strong vertical and zonal gradients of MeHg concentrations related to primary production consistently with the observations and highlight the role of winter deep convection and summer water stratification in shaping the MeHg vertical distribution, including sub-surface MeHg maximum. The modelled bioaccumulation dynamics in plankton food webs are characterized by a high spatial and temporal variability that is driven by plankton phenology and is consistent with available field data of Hg concentrations in plankton, as  
20 well as with other indicators, such as bioconcentration factors (BCFs) and trophic magnification factors (TMFs). Model results pointed out that the increment in water temperature linked to a decline of deep convection can cause an increase in water MeHg concentrations with cascading effects on plankton exposure and bioaccumulation.

## 1 Introduction

The anthropogenic alteration of mercury (Hg) biogeochemical cycle has led to global enrichment of Hg concentrations in all  
25 the environmental compartments (Amos et al., 2015; UNEP, 2019; Zhang et al., 2014a, 2014b) and concerns over human exposure to neurotoxic monomethylmercury (MMHg), which is produced in the ocean and biomagnifies in marine food webs (UNEP, 2019). The ocean has absorbed 50% of anthropogenic Hg historical emissions, 35% of which are currently stored in the water and the rest in the sediments (Zhang et al., 2014b): relative to pre-anthropogenic levels, the Hg enrichment is 230% in surface ocean waters, 25% in intermediate waters, and 12% in deep waters (UN Environment 2019).

30 Models and observations (Lamborg et al., 2014; Zhang et al., 2014b) suggest that the oceanic water column contains 280-370  
Mmol of anthropogenic Hg (equivalent to about 70000 tons), a large part of which is recycled within surface and intermediate  
water due to the biological carbon pump and the microbial loop (e.g. Zhang et al., 2018). Hg is scavenged from surface water  
by organic particles through adsorption and uptake, transported downward via particles sinking, and released in the dissolved  
35 phase following particles degradation. The locally increased microbial activity and availability of inorganic Hg at the depth of  
particles remineralization are also thought to promote Hg methylation (Cossa et al., 2009; Heimbürger et al., 2010; Sunderland  
et al., 2009). Concurrent biological and photochemical transformations occur in the water column driving the interconversions  
among the main mercury species in seawater (inorganic oxidized Hg [ $\text{Hg}^{\text{II}}$ ], methylmercury [MMHg], elemental Hg [ $\text{Hg}^0$ ],  
and dimethylmercury [DMHg]). Other important processes driving a fast cycling of Hg species in surface water are the  
atmospheric deposition of oxidized Hg and the gaseous exchange of  $\text{Hg}^0$  (Jiskra et al., 2021). The resulting vertical distribution  
40 of Hg species mirrors the local equilibrium among a number of biogeochemical and physical drivers. However, recent  
comprehensive reviews of the current understanding of Hg fate in the ocean (Bowman et al., 2020; Mason et al., 2012; Sonke  
et al., 2013) and in the Mediterranean Sea (Cossa et al., 2022) highlighted still high uncertainty in describing and quantifying  
most of these processes.

MeHg (defined as the sum of MMHg and DMHg) is more frequently measured than the individual methylated species. In  
45 oceanic and Mediterranean areas with high primary production, the MeHg vertical distribution is characterized by low  
concentrations at the surface due to photo-degradation and concentrations maxima coincident with the maximum in apparent  
oxygen utilization, a proxy for heterotrophic activity (Cossa et al., 2009; Sunderland et al., 2009). These observations suggest  
that most oceanic MeHg is produced in situ. This conclusion is also supported by estimates of MeHg fluxes in the ocean  
(Mason et al., 2012; Zhang et al., 2020) and by studies based on stable Hg isotopes (Blum et al., 2013; Motta et al., 2019). The  
50 role of DMHg in controlling MMHg dynamics remains puzzling: recent observations (Cossa et al., 2017) from the North  
Western Mediterranean Sea support the idea that DMHg is produced from  $\text{Hg}^{\text{II}}$  in highly productive waters and then degraded  
to MMHg (Conaway et al., 2009). However, only an abiotic pathway has been directly identified for the formation of DMHg  
(Jonsson et al., 2016) and rates of DMHg formation from  $\text{Hg}^{\text{II}}$  measured in polar water were negligible compared to  
methylation rates from  $\text{Hg}^{\text{II}}$  to MMHg (Lehnherr et al., 2011).

55 Tunas and other commercial fish species from the Mediterranean Sea are particularly enriched in Hg in comparison to the  
same species from other geographical areas (Cossa et al., 2012; Cossa and Coquery, 2005; Harmelin-Vivien et al., 2009; Tseng  
et al., 2021). It has been suggested that, along with other ecological features of the whole food web, this is due to a shallower  
occurrence of the MeHg concentrations maxima compared to the Ocean which results in higher phytoplankton exposure and  
bioaccumulation (Cossa et al., 2012). Available observations on MeHg distribution in the Mediterranean Sea suggest that  
60 concentrations are lower in the oligotrophic waters of the Ionian Sea than in the mesotrophic waters of the Northwestern  
Mediterranean (Cossa et al., 2022, 2009) and Adriatic Sea (Kotnik et al., 2015).

Recent efforts to couple the dynamics of biological carbon pump and microbial loop with Hg dynamics, including bioaccumulation in the lower food web provided global-scale assessments of MeHg production and bioaccumulation (Wu et al., 2021, 2020; Zhang et al., 2020). The only study modelling the Hg dynamics in the Mediterranean Sea (Žagar et al., 2007) did not include any biological component. Much of the current knowledge on the dynamics of MeHg in the open sea has been acquired only afterwards (Bowman et al., 2016, 2015; Cossa et al., 2017, 2009; Heimbürger et al., 2010; Lehnher et al., 2011; Monperrus et al., 2007; Munson et al., 2018, 2015; Ortiz et al., 2015; Sunderland et al., 2009).

Here, we couple a model for Hg biogeochemistry (Canu et al., 2019; Rosati et al., 2020, 2018; Zhang et al., 2020) with the 3D transport biogeochemical model OGSTM-BFM (Cossarini et al., 2021; Lazzari et al., 2021, 2010; Salon et al., 2019) to investigate spatial and temporal variability of MeHg dynamics in the Mediterranean Sea. The coupled model, which has a 1/16° horizontal resolution, describes the biotic and abiotic interconversions among four Hg species ( $\text{Hg}^{\text{II}}$ , MMHg,  $\text{Hg}^0$ , and DMHg), as well as other key processes of the Hg cycle such as partitioning to organic detritus, sinking to the seabed, exchange of gaseous Hg with the atmosphere, and bioaccumulation in 4 phyto- and 4 zooplankton functional groups (Lazzari et al., 2012; Vichi et al., 2015). The agreement with observations has been improved by tuning the sinking velocity of organic detritus and by exploring the sensitivity to alternative parameterizations of Hg methylation. A first assessment of the uncertainties concerning the fate of riverine Hg loads is also achieved and discussed along with other terms of the Hg budget in the Mediterranean Sea. Model results are compared to available observations discussing the implications of spatial and temporal variability of modelled MeHg distributions in water and plankton.

## 80 **2 Methods**

### **2.1 Study area**

The Mediterranean Sea (Fig. 1) is a semi-enclosed basin characterized by decreasing west-east gradient of primary production resulting from the superposition of biological pump and inverse estuarine circulation, as well as from the limited impact of riverine loads on the open ocean dynamics (Crise et al., 1999, Crispi et al., 2001). Due to the formation of intermediate and deep water generating thermohaline circulation, the Mediterranean is considered a miniature of the ocean (Pinardi et al., 2019). The large-scale basin circulation (Pinardi et al., 2019, 2015, Pinardi and Masetti, 2000, and references therein) is composed of three thermohaline cells (Fig. 1). A zonal vertical circulation belt is associated with the inflow of shallow Atlantic Water (AW) at the Gibraltar Strait that becomes progressively saltier due to evaporation moving eastward (MAW, Modified Atlantic Water) and eventually sinks at intermediate depths forming the Levantine Intermediate Water (LIW), outflowing at Gibraltar. The other cells are driven by dense water formation due to winter cooling, salting, and sinking of surface water. Western Mediterranean Deep Water (WMDW) originates in the Northern Western Mediterranean Sea, while Eastern Mediterranean Deep Water (EDMW) is formed in the Adriatic Sea, but also in the Aegean and the Levantine Sea. The mixing between these deep water masses is inhibited by the shallowness of the Sicily Strait (about 500 m). Long-term observations of ocean colour (Bosc et al., 2004, Bricaud et al., 2002, D'Ortenzio and D'Alcalà, 2009) and coupled transport-biogeochemical models (Di

95 Biagio et al., 2021, 2019; Lazzari et al., 2021, 2014, 2012) supported the characterization of different biogeoprovinces based on the seasonal, inter-annual, and high-frequency variability of biogeochemical processes in different areas (subbasins). Biogeochemical modelling also revealed the importance of subsurface plankton blooms, not captured by ocean colour satellite observations, highlighting the existence of a deep chlorophyll maximum that becomes deeper with increasing water oligotrophy. The most productive areas are the mesotrophic western subbasins of the Alboran Sea (*Alb*), Northern, and  
100 Southern Western Mediterranean (*Nwm* and *Swm*). The eastern Mediterranean is ultra-oligotrophic, apart from the Northern Adriatic Sea (*Nad*) which is a coastal sea, and other “intermittently blooming” areas (i.e., with high inter-annual variability) such as the Southern Adriatic Sea (*Sad*), the Aegean Sea (*Aeg*), and the Rhodes Gyre in the Levantine Sea (*Lev*).

## 2.2 The coupled model

The Biogeochemical Flux Model BFM (Vichi et al., 2015) is a model that simulates the cycling of Carbon, Nitrogen  
105 Phosphorus, and Silica through dissolved, living, and non-living particulate phases of the marine environment. The description of the planktonic food web is based on the plankton functional type (PFT) approach: the pool of species having similar traits (nutrients affinities, light affinity, prey-predator relationships) are described by a single variable. In the BFM, PFTs have variable stoichiometry and simulate the lower trophic levels of marine food webs up to carnivorous zooplankton (Sect. 2.2.1). The OGSTM-BFM model has been coupled off-line to the ocean general circulation model (NEMO) to investigate different  
110 issues related to the Mediterranean biogeochemistry (Canu et al., 2015; Cossarini et al., 2021, 2015; Lazzari et al., 2021, 2016, 2014, 2012) and it is now routinely used as the backbone of the biogeochemical component of the Copernicus CMEMS Mediterranean system (<https://resources.marine.copernicus.eu/products>, Salon et al., 2019; Terzić et al., 2019). The integration of a Hg cycling module in the BFM-OGSTM model adds more flexibility to this system and opens the way to novel operational oceanography applications. Here the OGSTM-BFM-Hg model is implemented (Fig. 2), by coupling the OGSTM-BFM model  
115 with the equations describing mercury (Hg) species partitioning, transformation, transport (Sect. 2.2.2), bioconcentration in phytoplankton (Sect. 2.2.3), and trophic transfer to zooplankton (Sect. 2.2.4). The coupled model is used to investigate the Hg cycling and bioaccumulation dynamics (Sect. 2.2.5) at the base of the Mediterranean Sea food webs. The model has a 1/16° horizontal resolution (approximately 6 km) and 72 vertical levels and runs with a 300 seconds time step. A model spin-up of 13 years forced with climatological data (Sect. 2.2.6) is performed, and the results of the last year of simulation (2017) are  
120 analysed.

### 2.2.1 BFM model dynamics

The BFM model dynamically simulates 9 plankton functional types (PFTs) representative of 4 phytoplankton groups (picophytoplankton, nanophytoflagellates, diatoms, and large phytoplankton), 4 zooplankton groups (heterotrophic nanoflagellates, microzooplankton, omnivorous mesozooplankton, and carnivorous mesozooplankton), and 1 group of  
125 heterotrophic bacteria (Vichi et al. 2015). The model reproduces the fluxes of carbon, nitrogen, phosphorous, and silicates from the inorganic nutrients pool to organisms (phytoplankton, zooplankton, and bacteria) and organic compounds pools

(particulate and dissolved organic carbon, POC, and DOC) with a variable stoichiometric formulation. Non-living organic matter includes one class of organic detritus (POC) and three classes of DOC (labile, semi-labile, and semi-refractory).

## 2.2.2 Biogeochemical dynamics in the Hg model

130 The Hg biogeochemical model (Canu and Rosati, 2017; Canu et al., 2019; Melaku Canu et al., 2015; Rosati et al., 2020, 2018, in prep., Zhang et al., 2020) simulates the cycling of four mercury species in marine water (Fig. 3): inorganic divalent Hg ( $Hg^{II}$ ), monomethylmercury (MMHg), elemental mercury ( $Hg^0$ ), and dimethylmercury (DMHg). Eq. (1-4) describe the time variation of non-conservative tracers representing Hg species, omitting advective and diffusive processes that are resolved by the transport model.

$$135 \quad \frac{d Hg^{II}}{dt} = -k_{met}\{Hg^{II}\} + k_{demet}\{MMHg\} - (k_{phred} + k_{biores})\{Hg_{DOC}^{II} + HgCl_n\} + (k_{phox} + k_{biox})\{Hg^0\} + k_{phdm}(1-\alpha)\{MMHg_{DOC} + MeHgCl\} - \omega_s\{Hg_{POC}^{II}\} \quad (1)$$

$$\frac{d MMHg}{dt} = +k_{met}\{Hg^{II}\} - k_{demet} MMHg - k_{phdm}\{MMHg_{DOC} + MMHgCl\} - k_{met}\{MMHg\} + k_{phdm2} DMHg - \omega_s\{MMHg_{POC}\} + Ex_{zoo} \frac{MMHg_{zoo}}{C_{zoo}} + D_{zoo} \frac{MMHg_{zoo}}{C_{zoo}} - \frac{d MMHg_{phy}}{dt} \quad (2)$$

$$\frac{d Hg^0}{dt} = +(k_{phred} + k_{biores})\{Hg_{DOC}^{II} + HgCl_n\} - (k_{phox} + k_{biox})\{Hg^0\} + \alpha k_{phdm} + \{MMHg_{DOC} + MMHgCl\} - k_{vol}\left\{Hg_w^0 - \frac{Hg_{aim}^0}{K_H'}\right\} \quad (3)$$

$$140 \quad \frac{d DMHg}{dt} = +k_{met}\{MMHg\} - k_{phdm2}\{DMHg\} \quad (4)$$

Field observations suggest that particulate Hg dynamics are controlled by regenerative scavenging mechanisms dependent on adsorption, remineralization, and sinking, with little influence of desorption (Lamborg et al., 2016). In the coupled OGSTM-BFM-Hg model, the dynamics POC and DOC including sinking and degradation are spatially resolved by the BFM model, and their concentrations are read by the Hg model (Figs. 2 and 3) to calculate the partitioning of  $Hg^{II}$  and MMHg between particulate species (associated to organic detritus, i.e.,  $Hg_{POC}^{II}$  and  $MMHg_{POC}$ ) and dissolved species (associated to dissolved organic carbon, i.e.,  $Hg_{DOC}^{II}$  and  $MMHg_{DOC}$ , and ionic species, i.e.,  $HgCl_n$  and  $MMHgCl$ ). By combining POC and DOC concentrations with chemical partition constant  $K_D$  (Tab. S1) (Choe et al., 2003; Choe and Gill, 2003; Lamborg et al., 2016), the fraction of each Hg species with respect to its total ( $f_{Hg-POC}$ ,  $f_{Hg-DOC}$ ,  $f_{HgCl}$ ,  $f_{MeHg-POC}$ ,  $f_{MeHg-DOC}$ ,  $f_{MeHgCl}$ ) is estimated (e.g., Eq. 5-7 for  $Hg^{II}$ ) assuming repartition at thermodynamic equilibrium. The fractions are used to calculate concentrations of particulate and dissolved Hg species from the total pool of  $Hg^{II}$  and MMHg (e.g., Eq. 8). The pool of dissolved gaseous mercury species (DGM, i.e.,  $Hg^0$  and DMHg) is assumed to be entirely in the dissolved phase.

$$f_{Hg_{POC}} = \frac{Hg_{POC}^{II}}{Hg_{TOT}^{II}} = \frac{POC K_D Hg-POC}{1+DOC K_D Hg-DOC + POC K_D Hg-POC} \quad (5)$$

$$f_{Hg_{DOC}} = \frac{Hg_{DOC}^{II}}{Hg_{TOT}^{II}} = \frac{DOC K_D Hg-DOC}{1+DOC K_D Hg-DOC + POC K_D Hg-POC} \quad (6)$$

$$f_{Hg_{Cl}} = \frac{Hg_{Cl_n}}{Hg_{TOT}^{II}} = \frac{1}{1+DOC K_D Hg-DOC + POC K_D Hg-POC} \quad (7)$$

$$155 \quad Hg_{POC}^{II} = f_{Hg_{POC}} Hg_{TOT}^{II} \quad (8)$$

Once the partitioning is determined, the model computes the transformations fluxes based on first order rates ( $k_x$ ,  $d^{-1}$  Tab. S2), the bioconcentration (Sect. 2.3) and bioaccumulation fluxes (Sect. 2.4), the sinking of  $Hg_{POC}$  and  $MMHg_{POC}$ , the advective transport within the model domain and at the model boundaries (i.e. Gibraltar Strait), and the exchange of  $Hg^0$  with the atmosphere. Microbial Hg methylation ( $k_{met} Hg^{II}$ ), reduction ( $k_{bio red} \{Hg_{DOC}^{II} + Hg_{Cl_n}\}$ ), and oxidation ( $k_{bio ox} Hg^0$ ) are parameterized as functions of particulate organic matter remineralization (Zhang et al., 2020, 2014), which is read from the BFM model. The direct conversion of  $Hg^{II}$  to DMHg is assumed to be negligible, due to the low rates observed in the only dataset available for this process (Lehnherr et al., 2011). Although several observations linked Hg methylation to oxygen consumption and organic matter remineralization in the water column, a full mechanistic understanding of methylation and demethylation is still lacking (An et al., 2019; Wang et al., 2020). Here we assumed that both reactions involve the entire  $Hg^{II}$  and  $MMHg$  pools (Ortiz et al., 2015; Schaefer and Morel, 2009; Zhang et al., 2019). Photochemical transformations, i.e. photoreduction ( $k_{ph red} \{Hg_{DOC}^{II} + Hg_{Cl_n}\}$ ), photooxidation ( $k_{ph ox} Hg^0$ ), and photodegradation of  $MMHg$  ( $k_{ph dem} \{MMHg_{DOC} + MMHg_{Cl}\}$ ) and DMHg ( $k_{ph dm2} DMHg$ ) are assumed to act only on the dissolved fractions, and are a function of the attenuated shortwave flux (Zhang et al., 2014).  $MMHg$  photodegradation is assumed to yield both  $Hg^0$  and  $Hg^{II}$  ( $k_{ph dm} \{MMHg_{DOC} + MeHg_{Cl}\}$ ) due to the contrasting results in experimental studies (Luo et al., 2020).

170 The gas-exchange flux of  $Hg^0$  with the atmosphere ( $k_{vol} \{Hg_w^0 - Hg_{atm}^0 / K_H\}$ ) is using the Nightingale's parameterization (Nightingale et al., 2000) for the rate constant  $k_{vol}$ , (Eq. (9)), which depends on wind speed ( $u_{10}$ ,  $m s^{-1}$ ) and on the ratio of Hg Schmidt number to  $CO_2$  Schmidt number ( $Sc_{Hg_w} / Sc_{CO_2_w}$ ).

$$k_{vol} = (0.222u_{10}^2 + 0.333u_{10}) \left( \frac{Sc_{Hg_w}}{Sc_{CO_2_w}} \right)^{-0.5} \quad (9)$$

Current knowledge on dynamics and concentrations of DMHg in the ocean and in the atmosphere does not allow a detailed modelling representation (Baya et al., 2015; Coale et al., 2018; De Simone et al., 2014; Melaku Canu et al., 2015; Nerentorp Mastro Monaco et al., 2017; Rosati et al., 2018; Zhang et al., 2020), and simulated variations of DMHg (Eq. 4) depend on photodegradation, production upon  $MMHg$  methylation and advective transport.  $MMHg$  is uptaken from the water pool by phytoplankton ( $MMHg_{phy}$ ) (Sect. 2.3), and it is released from the biotic pool back to the water column by zooplankton

excretion ( $Ex_{zoo} \frac{MMHg_{zoo}}{C_{zoo}}$ ) and death ( $D_{zoo} \frac{zooMMHg}{C_{zoo}}$ ) (Sect. 2.4). Loadings, initial and boundary conditions are presented in

180 Sect. 2.6.

### 2.2.3 MMHg uptake by phytoplankton in the Hg model

The bioaccumulation model simulates the MMHg uptake by the phytoplankton PFTs of the BFM model assuming that the uptake flux (Eq. (10),  $nmol_{(Hg)} m^{-3}_{(w)} d^{-1}$ ) decreases at high DOC concentrations and increases with phytoplankton Surface Area:Volume ratios ( $R_{SV\_PFT}$ ), following the empirical relation estimated by Schartup et al., (2018) from multi-species  
 185 phytoplankton uptake data (Lee et al., 2017; Lee and Fisher, 2016). The bioaccumulation model also considers the phytoplankton density ( $\rho = 10^{-12} g_{(w.w.)} \mu m^{-3}_{(w.w.)}$ ), wet weight biomass ( $B_{w.w., PFT}$ , in  $g_{(w.w.)} m^{-3}_{(w)}$ ), and the water MMHg concentrations ( $\{MMHg\}_w$ , pM). Parameters values are given in Tab. S3.

$$\frac{d MMHg_{phy, PFT}}{dt} = 0.118 \cdot R_{SV\_PFT} \cdot exp^{(-0.08 \cdot DOC)} \frac{1}{\rho} B_{w.w., PFT} \frac{\{MMHg\}_w}{10^3} \quad (10)$$

$B_{w.w., PFT}$  were derived from the plankton biomasses expressed on a intracellular carbon content basis ( $C_{PFT}$ , in  $mg_{(C)} m^{-3}_{(w)}$ ),  
 190 by adopting a carbon to Wet Weight conversion factors (Tab. S4) that we estimated from a dataset of experimental data for various phytoplankton and zooplankton species (Jørgensen et al., 1979; Mahlmann et al., 2008).

### 2.2.4 Zooplankton bioaccumulation in the Hg model

According to previous studies (Schartup et al., 2018; Zhang et al., 2020), MMHg bioaccumulation in zooplankton is mostly driven by grazing (>80%), therefore the trophic transfer of MMHg from phytoplankton to zooplankton PFTs (heterotrophic  
 195 nanoflagellates, microzooplankton, omnivorous mesozooplankton, and carnivorous mesozooplankton) in the model is set proportionally to the carbon (C) transfer, neglecting direct uptake from seawater. Thus, the bioaccumulation of MMHg in each zooplankton PFT (Eq. (11)) depends on carbon grazing fluxes ( $G_{zoo, PFT}$ ,  $mg_{(C)} m^{-3} d^{-1}$ ) and the MMHg:C ratio of the preys that are grazed ( $\frac{MMHg_{phy, PFT}}{C_{phy, PFT}}$ ,  $nmol_{(Hg)} mg^{-1}_{(C)}$ ). MMHg release to the water pool occurs following carbon excretion ( $Ex_{zoo, PFT}$ ) and zooplankton death ( $D_{zoo, PFT}$ ,  $mg_{(C)} m^{-3}$ ), and depends on the variable MMHg:C quota ( $\frac{MMHg_{zoo, PFT}}{C_{zoo, PFT}}$ ,  $nmol_{(Hg)}$   
 200  $mg^{-1}_{(C)}$ ) in each zooplankton group.

$$\frac{d MMHg_{zoo, PFT}}{dt} = G_{zoo, PFT} \frac{MMHg_{phy, PFT}}{C_{phy, PFT}} - Ex_{zoo, PFT} \frac{MMHg_{zoo, PFT}}{C_{zoo, PFT}} - D_{zoo, PFT} \frac{MMHg_{zoo, PFT}}{C_{zoo, PFT}} \quad (11)$$

### 2.2.5 Indicators for MMHg bioaccumulation and biomagnification

To compare the model content of MMHg in phytoplankton and zooplankton against experimental data, the output in  $\text{nmol}_{(\text{Hg})}\text{m}^{-3}_{(\text{w})}$  was converted into  $\text{ng g}_{\text{w.w}}^{-1}$  by computing the quota of MMHg ( $Q_{\text{MMHg}, \text{PFT}}$ , Eq. (12)) to plankton wet weight  
205 ( $B_{\text{w.w.}, \text{PFT}}$ ,  $\text{g}_{\text{w.w.}} \text{m}^{-3}_{(\text{w})}$ ) and correcting for the molar mass of Hg ( $200.59 \text{ g mol}^{-1}$ ).

$$Q_{\text{MMHg}, \text{PFT}} = \frac{\text{MMHg}_{\text{phy. PFT}}}{B_{\text{w.w.}, \text{PFT}}} 200.59 \quad (12)$$

The bioconcentration factor (BCF,  $1 \text{ kg}^{-1}$ ) is used to synthesize the enrichment of Hg in plankton with respect to water concentrations (Harding et al., 2018; McGeer et al., 2003), and due to the normalization for MMHg water levels, it allows better intercomparability across ecosystems than Hg concentrations. We calculated BCFs (Eq. (13)) for each plankton PFT  
210 as the ratio between the quota  $Q_{\text{MMHg}, \text{PFT}}$  and water MMHg concentrations, using model output at monthly resolution spatially averaged. The logarithmic scale is often used to handle BCF values (e.g. McGeer et al., 2003).

$$\text{BCF} = 10^6 \frac{Q_{\text{MMHg}, \text{PFT}}}{\text{MMHg}^{\text{W}} 200.59} \quad (13)$$

The trophic magnification factor (TMF) is used to explore biomagnification across ecosystems, by expressing the increase of Hg along with trophic levels (Alava et al., 2018; Harding et al., 2018). TMF is usually calculated in field studies of the  
215 whole-food web assessing both concentrations of pollutants and trophic levels through nitrogen isotopes. Here, in agreement with other modelling studies (Wu et al., 2021, 2020; Zhang et al., 2020), TMFs were estimated from the ratio of the MMHg quota in zooplankton PFTs to that of grazed phytoplankton PFTs (Eq. (14)). The analysis was carried out considering the model plankton food web as composed of a lower trophic level “herbivorous” part and an upper “omnivorous” part.

$$\text{TMF} = \frac{Q_{\text{MMHg}, \text{zoo-PFTs}}}{Q_{\text{MMHg}, \text{phy-PFTs}}} \quad (14)$$

### 220 2.2.6 Initial conditions, boundary conditions and forcings

Model initial conditions, boundary conditions, and physical forcings at monthly resolution are set according to Lazzari et al., (2021). Initial conditions for Hg species (Tab. S5) in Mediterranean subbasins (Fig. 1) are extrapolated from published data from different investigations in the Mediterranean Sea (Cossa et al., 2017; Cossa and Coquery, 2005; Ferrara et al., 2003; Horvat et al., 2003; Kotnik et al., 2015, 2007) and boundary conditions are set in agreement with the observations from the  
225 GEOTRACES GA03 meridional transect (Bowman et al., 2015). River Hg load is estimated based on dissolved Hg concentration, assuming 3 pM and 3.5% of MMHg (Cossa et al., 2017), using a higher concentration for three rivers that are known to be highly impacted by mining (Isonzo-Soča river, 25 pM) (Hines et al., 2000), industrial activities (Po river, 6 pM) (Vignati et al., 2008) or both of them (Tiber river, 6 pM) (Lanzillotta et al., 2002; Rimondi et al., 2019), assuming MMHg is

the 1% (Hines et al., 2000). Further, a sensitivity simulation accounting for the load of particulate Hg was carried out (Sect. 2.3.3) to investigate model uncertainty regarding this source. The atmospheric  $Hg^0$  concentration is set to a constant value  $Hg_{atm}^0 = 1.6 \text{ ng m}^{-3}$  (Andersson et al., 2007; Fantozzi et al., 2013; Gårdfeldt et al., 2003), and the atmospheric deposition of  $Hg_T$  is set to  $67.5 \text{ Mg y}^{-1}$ , the 2% of which is MMHg (Cossa et al., 2022, 2017). The Hg concentrations in the Black Sea outflow at the Dardanelles strait are set at 0.2 pM in agreement with the observations from the GEOTRACES GA04 cruise and modelled fluxes (Rosati et al., 2018).

## 235 **2.3 Model sensitivity to key parameters and processes**

A set of sensitivity simulations was implemented to investigate model uncertainty and improve the fit against experimental observations, initially showing substantial underestimation of MeHg concentrations maxima. The sensitivity simulations aimed at assessing the impacts of variations of the values of the sinking velocity of organic detritus and associated Hg species (Sect. 2.3.1), and of the coefficient for Hg methylation rates (Sect. 2.3.2), as well as the loading of Hg from rivers (Sect. 2.3.3), which is a process poorly characterized by field observations (Liu et al., 2021). All the analyses of model results focus on the same simulation, which adopts a sinking velocity of  $10 \text{ m d}^{-1}$ , a methylation rate constant higher than the one used in global modeling (Zhang et al., 2020), and accounts only for dissolved input of Hg from rivers.

### **2.3.1 Sensitivity simulations for POC sinking velocity**

A sensitivity analysis of POC sinking velocity was carried out, hypothesizing that a change in this parameter would impact the vertical distribution of all Hg species due to a change in the distribution and remineralization of POC, and in the transport of particulate Hg and MeHg. We also speculate that a deeper occurrence of POC remineralization leading to deeper MeHg maximum, could result in a decreased amount of MeHg photochemically degraded and thus in higher MeHg concentrations. The current version of BFM model includes only one class of non-living organic detritus (POC) that is a sink for all the plankton state variables (Vichi et al., 2015), resulting in a homogenous POC sinking velocity representative of an ecosystem-averaged dynamic. In the field, organic particles and aggregates that originate from a continuous size-spectrum of planktonic cells of various composition, show a wide range of sinking speeds (Cael et al., 2021). The reference model simulation was run by adopting the default POC sinking velocity of  $3 \text{ m d}^{-1}$  previously used to model the biogeochemistry of the Mediterranean Sea (Lazzari et al., 2021, 2012). Here, two additional sensitivity simulations were run, by setting the POC sinking velocity at 10 and  $20 \text{ m d}^{-1}$ , assuming community-averaged cell diameters of 35 and  $50 \text{ }\mu\text{m}$ , respectively.

### 255 **2.3.2 Sensitivity simulations for Hg methylation**

Hg methylation was parameterized in the model by scaling the flux of POC remineralization for a constant  $x_{met}$  (Tab. S2), adopting the same value used in a global ocean model (Zhang et al., 2020), due to the unavailability of more specific data. We

explored the sensitivity of modelled MeHg concentrations to a threefold increase of  $x_{met}$ , as well as to an alternative parameterization that included both POC and DOC remineralization flux (Eq. S10).

### 260 2.3.3 Sensitivity simulation for river Hg load

The largest Mediterranean rivers are characterized by proximal-accumulation-dominated dispersal system, i.e., deltaic systems with fast and substantial (>50-90%) sediment accumulation in the proximity of their mouth (Walsh and Nittrouer, 2003). Consistently with this picture, a recent budget for the Mediterranean Sea estimated that the magnitude of total Hg input from rivers ( $6 \text{ Mg y}^{-1}$ ) is comparable to the Hg flux to the shelf sediments ( $6.8 \text{ Mg y}^{-1}$ ), suggesting that most of the Hg associated with riverine particles settle before reaching the open ocean (Cossa et al., 2022). We, therefore, included only the dissolved load of Hg and MMHg in the reference simulation and explored the uncertainty related to this choice with a sensitivity simulation accounting for the total load Hg species, i.e., including both the particulate and dissolved inputs of  $\text{Hg}^{\text{II}}$  and MMHg. Limited data are available to characterize the spatial and temporal variability of these sources. The most robust observations are from a time-series (2008-2010) for the Rhône River (Cossa et al., 2017) indicating  $0.85 \pm 0.45 \text{ nmol g}^{-1}$  of  $\text{Hg}_T$  and  $0.017 \pm 0.008 \text{ nmol g}^{-1}$  of MMHg. Assessments in the Ebro River, impacted by an industrially polluted water reservoir, and in the Po River, which drain the largest Italian industrial and agricultural areas, found respectively  $4.9 \text{ nmol g}^{-1}$  and  $1.15 \text{ nmol g}^{-1}$  of particulate  $\text{Hg}_T$  at the river mouth, also highlighting the role of episodic stormy event in transporting large amounts of particles and associated pollutants (Palanques et al., 2020, Vignati et al., 2003). Further, at the mouth of the Soča/Isonzo River, impacted by upstream Hg mining, concentrations of unfiltered Hg higher than  $200 \text{ pM}$  have been reported (Hines et al., 2000). Hg loads for the Mediterranean tributary were estimated based on this information as synthesized in Tab. S6, also qualitatively referring to the spatial distribution of Hg stock and erosion fluxes in European topsoils (Panagos et al., 2021) and other information on anthropogenic activities (Ahmed et al., 2018). In the reference simulation, including only the dissolved input, the loading estimate is  $0.28 \text{ Mg y}^{-1}$  for total dissolved Hg (and  $0.008 \text{ Mg y}^{-1}$  for dissolved MMHg), while in the simulation with total Hg inputs the loading is about  $4.6 \text{ Mg y}^{-1}$  including  $0.27 \text{ Mg y}^{-1}$  of MMHg. Despite the relatively high mean concentrations (Tab. S6) assumed, the estimated  $\text{Hg}_T$  load is slightly lower than the estimate ( $6 \text{ Mg y}^{-1}$ ) from Cossa et al., (2022), most likely because the water discharge used in that work ( $>350 \text{ km}^3 \text{ y}^{-1}$ ) is higher than the total discharge used in this model setup ( $>291 \text{ km}^3 \text{ y}^{-1}$ ). On the other hand, the load to the Mediterranean Sea from solely European rivers ( $2.9 \text{ Mg y}^{-1}$ ) estimated from Hg concentrations in topsoils and water erosion rates from river catchments (Panagos et al., 2021) is slightly lower than the load from European rivers in our model setup ( $3.25 \text{ Mg y}^{-1}$ ). Finally, all these estimates are lower than the  $18 \text{ Mg y}^{-1}$  computed by (Liu et al., 2021) for the Mediterranean Sea through a global river model explicitly considering water discharge, suspended solids, and Hg loadings. Based on these calculations, Liu et al., (2021) proposed a global river load ( $1000 \text{ Mg y}^{-1}$ ) much higher than the estimate from the latest global mercury assessment ( $300 \text{ Mg y}^{-1}$ ) (UNEP, 2018). They also estimated that the 70% of the load is buried in coastal and shelf sediment.

### 3 Results and discussion

#### 290 3.1 Model sensitivity and uncertainty

The sensitivity analysis showed that the sinking rate of organic detritus (POC) is an important control on the vertical distribution of MeHg (i.e., the shape of the vertical profile) along the water column but has little effect on the values of MeHg concentrations maxima and the distribution of inorganic Hg species (Supplemental Sect. S1.1 and Figs. S1 and S2). On the other hand, the increase of sinking velocity from 3 to 10 m d<sup>-1</sup> improved the agreement of modelled seasonal fluxes of POC at 295 200 m depth with available observations (Ramondenc et al., 2016) (Supplemental Sect. S1.1 and Fig. S3). The sensitivity analysis also showed that an increase in the coefficient for Hg methylation ( $x_{met}$ ) results in a higher agreement with observed MeHg concentrations (Cossa et al., 2022, 2009), while the inclusion of DOC remineralization flux results in an overestimation of surficial MeHg concentrations (Supplemental Sect. S1.2 and Fig. S3).

The inclusion of higher riverine Hg<sup>II</sup>, MMHg, and POC inputs does not improve the agreement between modelled and observed 300 concentrations of MeHg (Supplemental Sect. S1.3 and Figs. S5-S10), suggesting that the underestimation of MeHg maxima in subsurface waters is not due to an underestimation of watershed sources. These results also corroborate the idea that a substantial fraction of particulate Hg and MeHg carried by rivers settles in coastal areas along with POC (Fig. S5), as estimated in a recent budget based on field observations (Cossa et al, 2022). Nonetheless, large uncertainties in the spatial and temporal variability of riverine loadings and coastal processes remain to be addressed both at the basin and global scale (Cossarini et 305 al., 2021, Liu et al., 2021).

The underestimation of MeHg in the model does not appear to be related to inorganic Hg availability, since the concentrations of Hg<sub>T</sub> are within the experimental uncertainty of the data (Fig. S11).

Modelled fluxes of Hg<sub>T</sub> and Hg<sup>0</sup> compare well with other budget estimates (Cossa et al, 2022, Žagar et al., 2007). The net exchange of gaseous Hg<sup>0</sup> with the atmosphere indicates 44.8 Mg y<sup>-1</sup>, which is close to a previous estimate (50 Mg y<sup>-1</sup>) based 310 on aquatic biogeochemical modelling (Žagar et al., 2007) and slightly lower than the flux adopted in the budget from Cossa and coauthors (67.5 Mg y<sup>-1</sup>). Considering both Hg<sup>0</sup> exchange and atmospheric deposition of Hg<sup>II</sup> (Sect. 2.2.6 and Fig. 3), the net exchange of Hg species (~7 Mg y<sup>-1</sup>) is here significantly lower than the estimate (29.8 Mg y<sup>-1</sup>) from Cossa et al., (2020). However, while the latter estimate is based on an atmospheric model assuming a constant ocean surface Hg<sup>0</sup> concentrations (Gencarelli et al., 2014), here, the flux is estimated accounting for 3D dynamics in the marine system, including sequestration 315 of Hg species from surface waters due to the biological carbon pump. Recent evidence from isotopes studies pointed out that the ocean might be a net sink for atmospheric Hg, rather than a net source (Jiskra et al., 2021).

The modelled export of Hg<sub>T</sub> from the Alboran Sea to the Atlantic Ocean is 9.3 Mg y<sup>-1</sup>, close to the value (9.7 Mg y<sup>-1</sup>) estimated by Cossa et al., (2022). On the other hand, our estimate (2.5 Mg y<sup>-1</sup>) of MeHg outflow is significantly lower than the 5.6 Mg y<sup>-1</sup> of the budget by Cossa et al., (2022), even assuming an increased value for  $x_{met}$  and, consequently, of subsurface MeHg. 320 All in all, a calibration of the parameter  $x_{met}$  appears appropriate based on the current understanding, also considering that the initial guess for this parameter come from a global ocean application (Zhang et al., 2020). Indeed, such a global model study

underestimated the observed MeHg concentrations in the Mediterranean Sea, while reproducing with good agreement, or overestimating, observations from various cruises in the North Atlantic and Pacific Ocean, pointing out the need to better resolve spatial and temporal variability of biological processes and linked Hg dynamics (Zhang et al., 2020). A comprehensive validation of the OGSTM-BFM biogeochemical variables (Cossarini et al., 2021) highlighted good model accuracy in surface water but higher mismatches with observed oxygen and nutrients concentrations in the mesopelagic zone, attributed to uncertainties in remineralization and deep ventilation processes, which also affect methylation dynamics. In spite of uncertainties remaining to be addressed, the OGSTM-BFM-Hg model is able to reproduce the spatial gradients observed in the Mediterranean Sea, testifying the improvements in capability to simulate Hg dynamics (Žagar et al., 2014, 2007) through the coupling with key biological processes, e.g. the carbon pump and microbial loop (Bowman et al., 2020; Cossa et al., 2017, 2009; Heimbürger et al., 2010; Monperrus et al., 2007; Munson et al., 2018; Sunderland et al., 2009).

### 3.2 MeHg distribution in the water of Mediterranean Sea

The zonal and vertical gradients of MeHg concentrations reproduced by the OGSTM-BFM-Hg model show the highest concentrations in subsurface waters of the most productive subbasins of the Mediterranean Sea (Fig. 4), consistently with the available observations (Cossa et al., 2009). Modelled vertical profiles of MeHg concentrations (Fig. 5) are in good agreement with the observations in the Southern Adriatic Sea (*Sad*, Fig. 5a), and are in the lower range of the observations for the North Western Mediterranean (*Nwm*, Fig. 5b) and Ionian (*Ion*, Fig. 5c) subbasins. Seasonality affects the modelled distribution of MeHg (Figs. 4 and 5) with more marked effects in the *Sad* subbasin (Fig. 5a). The strong winter convection occurring in the *Sad* in 2017 caused remixing in the water column (Mihanović et al., 2021) leading to the disruption of the subsurface MeHg maximum from January to March and an increase in MeHg surface water concentrations, in spite of net demethylation prevailing at all depths during winter months (Fig. 6). A slighter increase in surface water MeHg concentrations during winter months is visible also for the other subbasins (Fig. 4, 5b, and 5c) but, in the absence of strong winter convection the variation is small, and the model predicts that the subsurface MeHg maximum is a permanent feature throughout the year. The *Nwm* is known to be an area of winter convection, however, other authors reported a recent decline of deep convection for this area that was weak in 2014 and never occurred in the period 2015-2017 (Margirier et al., 2020). Based on these model results, we speculate that in the long run the reduction of winter mixing can cause MeHg accumulation in the biologically active zone enhancing the exposure of marine organisms.

In the *Sad* subbasin, a progressive buildup of MeHg subsurface maxima (up to 0.18 pM) is predicted from April to September, driven by an increase in primary production triggering higher POC remineralization and in turn higher Hg methylation rate constants  $k_{\text{met}}$  (Fig. S4). However, while  $k_{\text{met}}$  are maxima in April, and net methylation fluxes (Fig. 6) are maxima in June (0.45 pmol m<sup>-3</sup> d<sup>-1</sup>), MeHg concentrations are maxima in September and remain stable until October (Fig. 5), highlighting the importance of water stratification for the formation of the subsurface maxima. Figure 6 also shows that net demethylation prevails throughout the year in deep waters (except for weak positive methylation in *Sad* and *Tyr* during summer), and for

most of the year in surface waters, suggesting that the presence of MeHg in surface and deep water depends on its formation  
355 in the intermediate waters and diapycnal mixing.

Modelled vertical profiles of MeHg in the oligotrophic *Ion* subbasin (Fig. 5c) have lower maxima (up to 0.16 pM) and a  
smoother concentration gradient compared to the more productive waters of the *Nwm* (up to 0.24 pM). The West-East gradient  
is sustained by the highest methylation rates (Fig. S12) in the Western Mediterranean, driven by higher primary productivity  
and remineralization of organic detritus, and it is further reinforced by high rates of both photochemical and biological MeHg  
360 degradation in the Eastern subbasins (Fig. S12), due to the highest water temperature, irradiance, and deeper penetration of  
shortwave radiation due to the low plankton biomass.

### 3.4 Modelled MMHg in phytoplankton and zooplankton

The spatial and temporal distributions of modelled MMHg in phytoplankton ( $MMHg_{phy}$ ) and zooplankton ( $MMHg_{zoo}$ ) of the  
Mediterranean Sea (Fig. 7) are overall comparable to the concentrations of particulate MMHg ( $0.7 \pm 1.3 \text{ pmol m}^{-3}$ ) measured  
365 in the Atlantic Ocean (Bowman et al., 2015). The model reproduced a seasonal increase in  $MMHg_{phy}$  (Fig. 7a) during late  
spring and summer that is driven by blooms of picophytoplankton (Fig. S13) combined with an increase in MMHg availability  
in surface water (Fig. S14). The amount of MMHg bioaccumulated by picophytoplankton ( $MMHg_{phy,P3}$ , Fig. S15) is high (up  
to  $0.6 \text{ pmol}_{(Hg)} \text{ m}_{(w)}^{-3}$ ) compared to the bioaccumulation by other phytoplankton PFTs (up to  $0.02 \text{ pmol}_{(Hg)} \text{ m}_{(w)}^{-3}$ , Fig. S16-S18)  
due to the model assumption of increasing bioconcentration capacity with decreasing phytoplankton cell size (Sect. 2.3).  
370 However, not all the picophytoplankton blooms result in high values of  $MMHg_{phy}$ : the strongest blooms of picophytoplankton,  
occurring in March and April at 25 m depth (Fig. S13), have a marginal impact on bioaccumulation, especially in the  
easternmost subbasins, due to the very low concentrations of MMHg in the most surficial waters (Fig. S14). On the other hand,  
much weaker blooms of picophytoplankton occurring from May to August slightly deeper in the water column (35 and 45 m  
depth) lead to a maximum in phytoplankton MMHg concentrations (Fig. 7a) because of higher water MMHg concentrations  
375 at these depths during these months (Fig. S14). The average  $MMHg_{phy,P3}$  is lower in the *Alb* subbasin than in the *Sad* subbasin  
(Tab. 1), the latter being characterized by higher availability of MMHg at 35-45 m depth and higher biomasses of  
picophytoplankton during summer (Fig. S13 and S14). The hypothesis of the cell size-effect on bioconcentration is the best  
synthesis of available knowledge (Schartup et al., 2018), however, the experimental study from which this relationship was  
derived, also showed deviations from this pattern and temperature induced effects, possibly due to phagocytosis of Hg-OM  
380 compounds by mixotroph organisms such as dinoflagellates (Lee and Fisher, 2016). One of the few field studies assessing the  
size-effect on Hg bioaccumulation in plankton (Gosnell and Mason, 2015) found an increase in MeHg% but not in MeHg  
content for smaller plankton size ( $< 5 \mu\text{m}$ ), however, the size classes analysed by that study do not overlap well with the  
functional groups of OGSTM-BFM-Hg model. More field, in vitro, and modelling studies are needed to disentangle the  
dynamics underlying key processes for Hg bioaccumulation.

385 The highest concentrations of  $MMHg_{zoo}$  (Fig. 7b) are predicted from June to September at 35 m-depth, showing a delay of  
about one month with respect to the temporal evolution of  $MMHg_{phy}$  due to the combined impacts of plankton phenology and

trophic interactions. Heterotrophic nanoflagellates bioaccumulate much more MMHg (up to  $0.5 \text{ pmol m}^{-3}$ , Fig. S19) than other zooplankton PFTs (up to  $0.1 \text{ pmol m}^{-3}$ , Fig. S20-S22) because they feed on picophytoplankton (Fig. 8) which is more enriched in MeHg than other PFTs and is an important driver for the distribution of  $MMHg_{zoo}$ . However, in spite of heterotrophic  
390 nanoflagellates being always abundant from March to October (Fig. S23), and most abundant in the eastern subbasins, the highest MMHg bioaccumulation occurs when the increase of the nanoflagellates population is coincident with an enrichment of MMHg in phytoplankton (*i.e.*, in western subbasins, as well as in the Adriatic and part of the Ionian Sea during summer). The mean MMHg quota ( $Q_{MMHg,PFT}$ ) in phytoplankton of the Mediterranean Sea is about  $3.0 \text{ ng g}_{w.w}^{-1}$  for picophytoplankton,  $0.3 \text{ ng g}_{w.w}^{-1}$  for autotrophic nanoflagellates,  $0.03 \text{ ng g}_{w.w}^{-1}$  for diatoms, and  $0.04 \text{ ng g}_{w.w}^{-1}$  for large phytoplankton. The spatial  
395 variability is highlighted by comparing the quotas estimated for the *Alb* and *Sad* subbasins (Tab. 1) that are in the lower and upper range of the values for the Mediterranean Sea. Modelled values are comparable with the few observations available for open waters of the central Pacific Ocean ( $0.1\text{-}4 \text{ ng g}_{w.w}^{-1}$ ) (Gosnell & Mason, 2015), and of the Northwest Atlantic Ocean ( $0.15 \pm 0.06 \text{ ng g}_{w.w}^{-1}$ ) (Hammerschmidt et al., 2013), as well as with data from various coastal and shelf ecosystems (Harding et al., 2018). The speciation of Hg in phytoplankton groups of the Mediterranean Sea has never been assessed (Cinnirella et al.,  
400 2019). The MMHg quota was about  $0.14 \pm 0.1 \text{ ng g}_{w.w}^{-1}$  in seston of diameter  $80\text{-}200 \mu\text{m}$  sampled in the Gulf of Lions during spring and autumn 2004-2006 (Cossa et al., 2012).

The mean  $Q_{MMHg,PFT}$  in zooplankton are  $0.8 \text{ ng g}_{w.w}^{-1}$  for heterotrophic nanoflagellates,  $0.3 \text{ ng g}_{w.w}^{-1}$  for microzooplankton,  $0.6 \text{ ng g}_{w.w}^{-1}$  for omnivorous mesozooplankton, and  $0.9 \text{ ng g}_{w.w}^{-1}$  for carnivorous mesozooplankton. The MMHg quota in carnivorous zooplankton ( $Q_{MMHg,Z3}$ ) estimated for the *Sad* subbasin is much higher ( $3.60 \pm 2.2$ ) than the average value due to  
405 the high MMHg accumulation in the whole food web (Tab. 1). However, since biomasses of carnivorous zooplankton in the *Sad* are very low (Fig. S16), the overall content of MMHg in this group ( $MMHg_{zoo,Z3}$ ) is lower ( $1.0 \cdot 10^{-3} \pm 2.7 \cdot 10^{-4}$ ) than in the *Alb* subbasin ( $1.9 \cdot 10^{-2} \pm 1.6 \cdot 10^{-3}$ ).

The modelled zooplankton quotas compare well with the observations of MMHg in mesozooplankton of the Gulf of Lions, which was  $0.52 \pm 0.39 \text{ ng g}_{w.w}^{-1}$  for the size range  $200\text{-}500 \mu\text{m}$ ,  $0.57 \pm 0.39 \text{ ng g}_{w.w}^{-1}$  for the size range  $500\text{-}1000 \mu\text{m}$ , and  $1.8 \pm 1.3 \text{ ng g}_{w.w}^{-1}$  for zooplankton  $>200 \mu\text{m}$  (Cossa, 2012). MMHg measured in the '90s in zooplankton in the Gulf of Trieste  
410 (*Nad*, Fig. 3) Hg hotspot was  $2.1 \pm 2.3 \text{ ng g}_{w.w}^{-1}$  (Horvat et al., 2014, 1999), consistently with the fact that the Gulf of Trieste is an upper bound for the Mediterranean, being subjected to high loadings of legacy Hg from the Soča-Isonzo river (Hines et al., 2000) and coastal lagoons (Melaku Canu et al., 2015, Rosati et al., 2020).

### 3.3 Bioconcentration Factors and Trophic Magnification Factors

415 Modelled log(BCFs) for phytoplankton PFTs of the Mediterranean Sea range 3.7-6.5, which is slightly lower than the range (4.3-6.8) reported for phytoplankton from the central Pacific (Gosnell and Mason, 2015) and is higher than the ranges for Long Island Sound (2.6-5.5) (Gosnell et al., 2017) and other coastal and shelf sites of the world (3.1-4.4) (Harding et al., 2018). Higher BCFs in open waters than in coastal areas are consistent with the enhanced Hg bioavailability in the open sea inferred by other authors (Gosnell and Mason, 2015; Schartup et al., 2015), which in the model is approximated through the inverse

420 relationship between MMHg uptake and DOC (Eq. (10)). Modelled zooplankton log(BCFs) in the Mediterranean Sea span from 4.0 to 6.4, comparable to the range for mesozooplankton (4.0-6.5) in the Pacific Ocean (Gosnell and Mason, 2015).

The trophic interactions among PFTs simulated by the model can be subdivided into a lower “herbivorous” part of the food web and an upper “omnivorous” part of the food web (Fig. 8). In the lower part of the food web, heterotrophic nanoflagellates (2-20  $\mu\text{m}$ ) graze on bacteria ( $<1 \mu\text{m}$ ) and picophytoplankton (0.2-2  $\mu\text{m}$ ), while microzooplankton (20 – 200  $\mu\text{m}$ ) grazes on

425 heterotrophic and autotrophic nanoflagellates (2-20  $\mu\text{m}$ ), diatoms (200- 20  $\mu\text{m}$ ), and occasionally on other PFTs. In the upper part of the food web, the omnivorous mesozooplankton (200-2000  $\mu\text{m}$ ) preys on microzooplankton and all the phytoplankton PFTs $>2 \mu\text{m}$ , while carnivorous mesozooplankton (200-2000  $\mu\text{m}$ ) preys on omnivorous mesozooplankton and large phytoplankton ( $>100 \mu\text{m}$ ). The highest BCFs (and  $Q_{MMHg,PFT}$ ) are predicted for picophytoplankton and carnivorous zooplankton (Tab. 1 and Fig. 8). Heterotrophic nanoflagellates display lower bioaccumulation than picophytoplankton because they also

430 feed on bacteria and autotrophic nanoflagellates that ‘dilute’ the MMHg intake (Fig. 8). Microzooplankton and omnivorous zooplankton, which have an intermediate position in the food web, have bioaccumulation levels comparable to those of heterotrophic nanoflagellates. The effect of biomagnification is visible only in carnivorous zooplankton, having much higher BCFs than their prey (Tab. 1). These dynamics are consistent with a global model taking into account a more complex plankton food web (366 PFTs) that found highest MMHg levels in phytoplankton than in their predators, and biomagnification in the

435 highest trophic levels with high food intake (Wu et al., 2021).

Trophic magnification factors (TMFs) were calculated for each subbasin of the Mediterranean Sea for the lower and upper parts of the food web. Low TMFs (range 0.05-0.38) were estimated for the lower food web indicating the absence of biomagnification (Fig. 9a), and higher TMFs (range 0.15-2.60) were estimated for the upper food web (Fig. 9b), in agreement with previous modelling studies suggesting that MMHg biomagnification between small zooplankton groups and

440 phytoplankton is unlikely to happen (Wu et al., 2021, 2020; Zhang et al., 2020). Biomagnification (TMF $>1$ ) in the upper food web (Fig. 9b) occurs only in subbasins with relatively abundant biomasses of carnivorous zooplankton (Fig. S24), namely in the *Alb* and *Swm* subbasins. The TMF for the *Alb* subbasin ( $2.4\pm 0.28$ ) is lower than but comparable to the biomagnification from microseston to zooplankton (TMF=4) estimated from field data for the Northwest Atlantic Ocean (Hammerschmidt et al., 2013). The other Mediterranean subbasins, due to the absence or very low abundance of carnivorous mesozooplankton

445 ( $<0.05 \text{ mg}_{(C)} \text{ m}^{-3}$ ), have a shorter food web and lower TMFs ( $<1$ ). Although oligotrophy tends to favour longer food webs enhancing biomagnification, in extremely oligotrophic ecosystems the very low primary production can limit the presence of carnivorous zooplankton populations, lowering the bioaccumulation potential (Wu et al., 2021). The TMFs $<1$  for the upper part of the food web are comparable to the estimates made with a global model for the most oligotrophic ocean regions such as the South Pacific Gyre, the North Atlantic gyre, and the South Atlantic gyre (Wu et al., 2021).

## 450 4 Conclusions

We developed and released the OGSTM-BFM-Hg model, a numerical state of the art model tracking the biogeochemistry of the main marine Hg species ( $\text{Hg}^{\text{II}}$ ,  $\text{Hg}^0$ , MMHg, and DMHg) fully coupled to the biogeochemistry of plankton and nutrients. The model, applied to a high-resolution 3D domain of the Mediterranean Sea, successfully captured the zonal and vertical variability of MeHg concentrations reproducing a decreasing MeHg gradient from West to East that is supported by the available observations. Sensitivity analysis showed that the agreement with observed MeHg concentrations and POC fluxes was improved by adopting an intermediate sinking speed for organic detritus. Modelled MeHg concentrations also improved by increasing the coefficient constant for Hg methylation rate, while the inclusion of the of dissolved organic carbon remineralization in the equation for Hg methylation increases the mismatch between model and observations, suggesting that this process might not be important in shaping MeHg distributions.

Sensitivity simulations on river Hg loadings corroborate the idea that in the Mediterranean Sea most of the inputs of particulate Hg (and POC) from rivers tend to sink in coastal and shelf areas and have a limited impact on open sea dynamics. However, as pointed out in a recent reassessment of global river inputs (Liu et al., 2021) there is a need to better assess the spatial and temporal variability of riverine loadings, especially in relation to extreme events and their increasing occurrence driven by climate changes.

Model results highlight that summer stratification of the water column is an important process for the buildup of a sub-surficial maximum of MeHg concentrations, while the occurrence of deep convection in winter results in substantial redistribution of MeHg smoothing the vertical profiles. A decrease in winter convection events linked to increasing water temperature, which has already been observed in recent years in the Mediterranean Sea, seems to limit MeHg redistribution in the water column causing higher water MeHg concentrations in the biologically active zone and, in turn, higher plankton exposure. In fact, spatial and temporal variability of plankton bioaccumulation in the model is controlled by plankton phenology and by the availability of MMHg at the depths at which plankton blooms occur. The biomagnification potential is stronger in productive areas of the Mediterranean Sea characterized by high biodiversity and longer food web length with a significant presence of carnivorous zooplankton, such as the *Alb* and *Swm* subbasins.

### Acknowledgments

475 The research has been partially funded by the PRIN project ICCO (Impacts of climate change on the biogeochemistry of contaminants in the Mediterranean Sea) and the interreg MED project SHAREMED.

### Code availability

The OGSTM-BFM-Hg model code is publicly available at Zenodo repository with DOI <https://doi.org/10.5281/zenodo.5851442> (Rosati et al., 2022).

765 Figure 1: Bathymetric map of the Mediterranean Sea (from Ocean Data View, Schlitzer, 2014). The white contours indicate the subdivision of the model domain in subbasins: Alboran Sea (*Alb*), Southwest western Mediterranean (*Swm1* and *Swm2*), Northwestern Mediterranean (*Nwm*), Tyrrhenian Sea (*Tyr1* and *Try2*), northern Adriatic Sea (*Nad*), southern Adriatic Sea (*Sad*), Ionian Sea (*Ion1*, *Ion2*, and *Ion3*), Aegean Sea (*Aeg*), and Levantine basin (*Lev1*, *Lev2*, *Lev3*, and *Lev4*). The light blue line shows the zonal cell driven by the surface inflow of Atlantic Water inflow (AW) that moves eastward forming Modified Atlantic Water (MAW) and Levantine Intermediate Water (LIW), outflowing at intermediate depths at the Gibraltar Strait. The dark blue lines show the path of meridional cells related to winter convection in the *Nwm*, *Nad*, *Sad*, *Aeg*, and *Lev* originating the Western and Eastern Mediterranean Deep Water (WMDW and EMDW).

770

## OGSTM-BFM-MERC model coupling scheme

775 Figure 2: Overview of the coupling in the OGSTM-BFM-Hg model, which integrates the biogeochemistry and bioaccumulation of Hg species in the OGSTM-BFM model, previously coupled to the transport model NEMO (Salon et al., 2019) and to a multispectral biotical model (Lazzari et al., 2021). The thick grey arrows with text highlight variables and fluxes read by the Hg biogeochemical model (Fig. 3).

780 Figure 3: Hg dynamics in the coupled model OGSTM-BFM-Hg. The Hg model simulates the cycling of inorganic ( $Hg^{II}$  and  $Hg^0$ ) and  
 785 methylated Hg species (MMHg and DMHg) resolving: the partitioning of  $Hg^{II}$  and MMHg between particulate ( $Hg_{POC}$ ,  $MMHg_{POC}$ )  
 and dissolved species ( $Hg_{Diss}$ , as  $Hg_{DOC} + Hg_{Cl_n}$ , and  $MMHg_{Diss}$ , as  $MMHg_{DOC} + MMHg_{Cl}$ ) based on partition coefficients ( $K_D$ ) and  
 concentrations of POC and DOC, the photochemical and biological transformations (dotted colored arrows) as first order kinetics  
 depending on the rate constants  $k_x$ , the evasion of  $Hg^0$  to the atmosphere controlled by wind speed through the volatilization rate  
 constant  $k_{vol}$ , and the MMHg bioaccumulation (pink arrows) driven by phytoplankton uptake in 4 different PFTs and trophic  
 transfer to 4 zooplankton PFTs.

### Methylmercury (MMHg+DMHg)

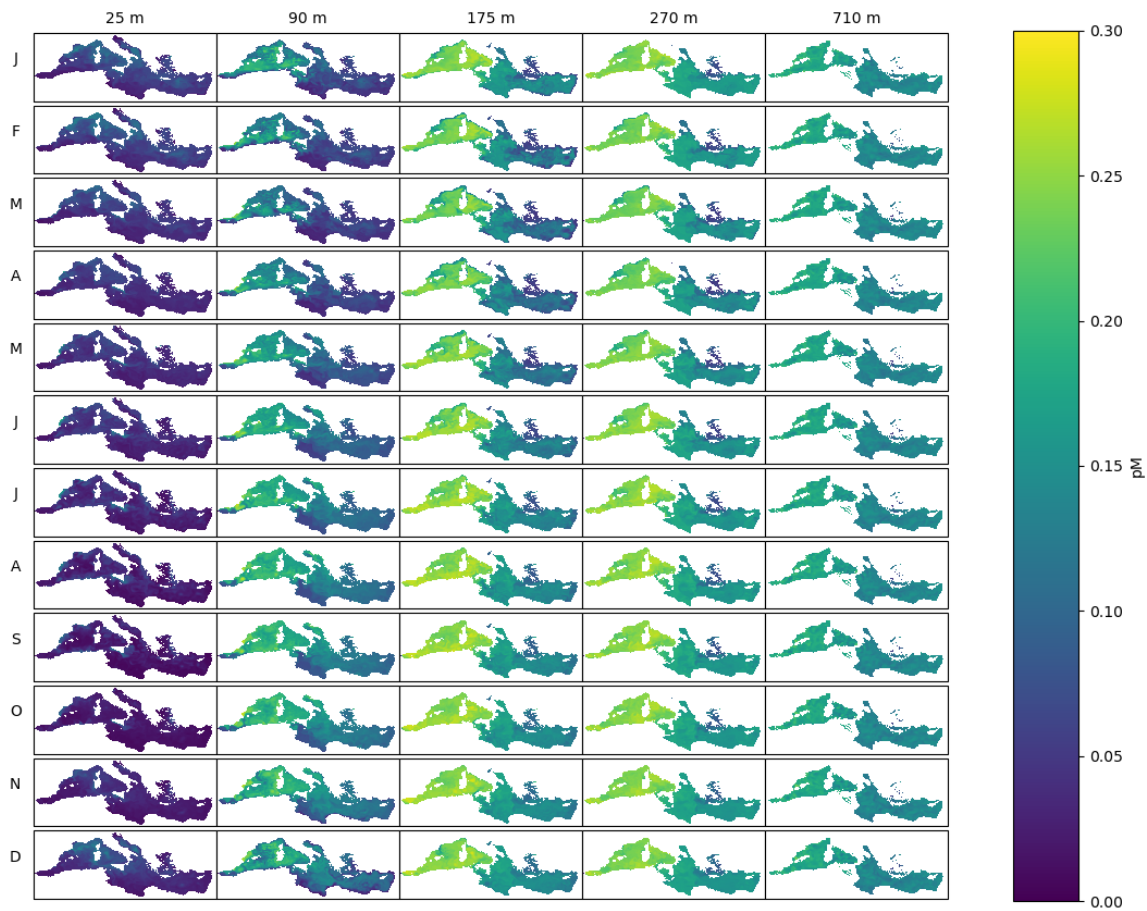

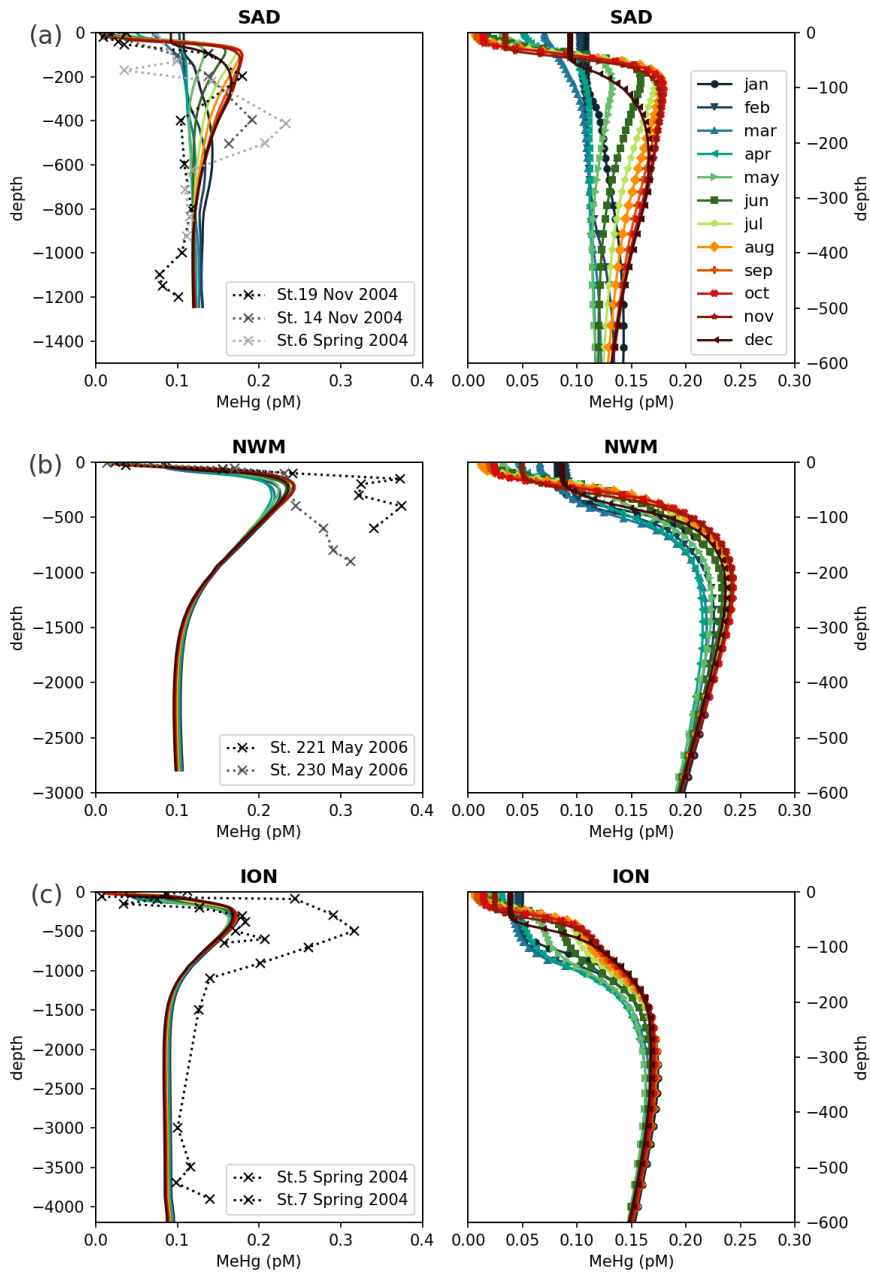

Figure 4: Spatial distribution of monthly averaged MeHg concentrations (pM) in the Mediterranean Sea at different depths in the water column (25, 90, 175, 270 and 710 m-depth) simulated with the OGSTM-BFM-Hg model.

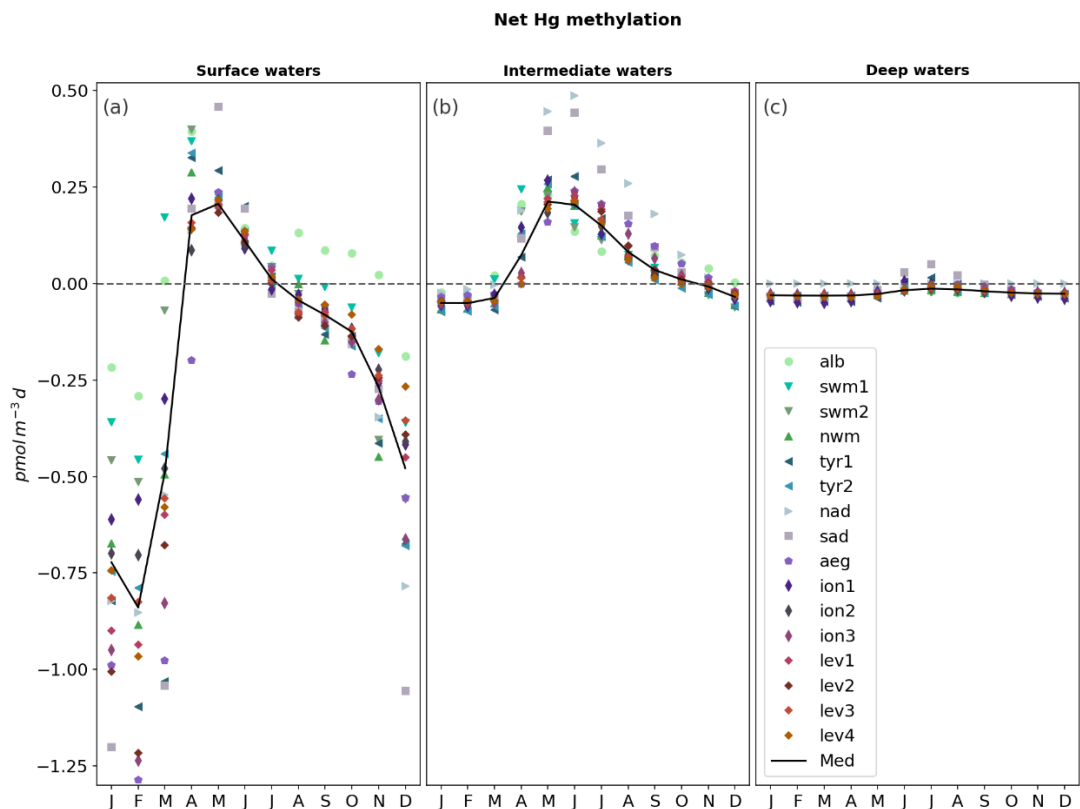

### MeHg concentrations in Mediterranean subbasins

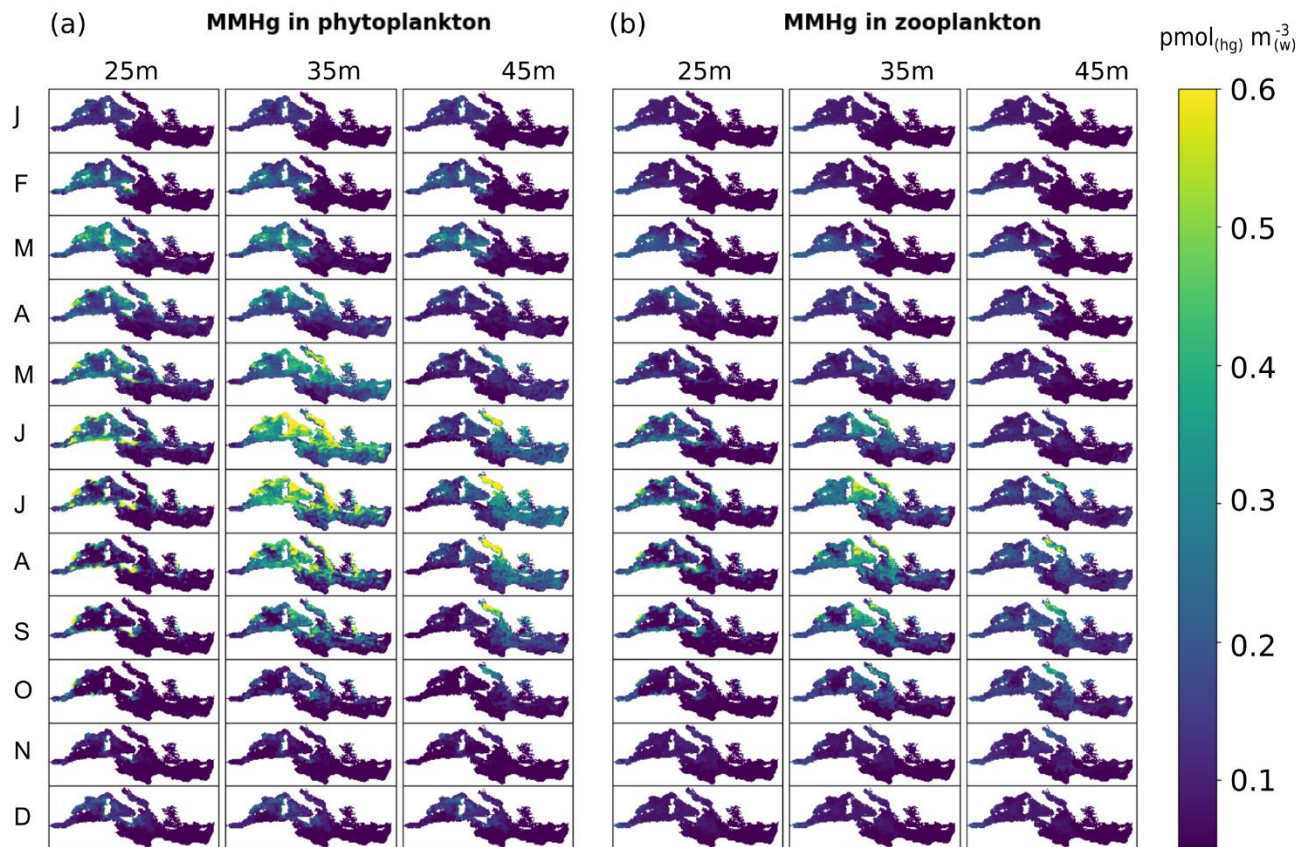

790

**Figure 5: Vertical profiles of monthly averaged MeHg (MMHg+DMHg) concentrations in the water column reproduced by OGSTM-BFM-Hg model for 2017 (coloured solid lines), compared with observations for 2004-2005 (dotted lines with crosses) available from the literature (Cossa et al., 2009) in three subbasins (Fig. 1): (a) Southern Adriatic Sea (*Sad*), (b) North Western Mediterranean (*Nwm*), and (c) Ionian Sea (*Ion2*). The right panels show the entire water column, and the left panels show a detail of modelled concentrations in the top 600 m of the same subbasins.**

795

800 **Figure 6: Monthly evolution of the net methylation fluxes ( $\text{pmol m}^{-3} \text{d}^{-1}$ ) for each subbasin (colored markers) of the Mediterranean Sea (black lines) depth-integrated for (a) surface water (0-100 m depth), (b) intermediate water (100-600 m depth), and (c) deep water (>600 m depth). Net methylation is calculated as the difference between modelled Hg methylation fluxes and demethylation fluxes (both dark and photochemical).**

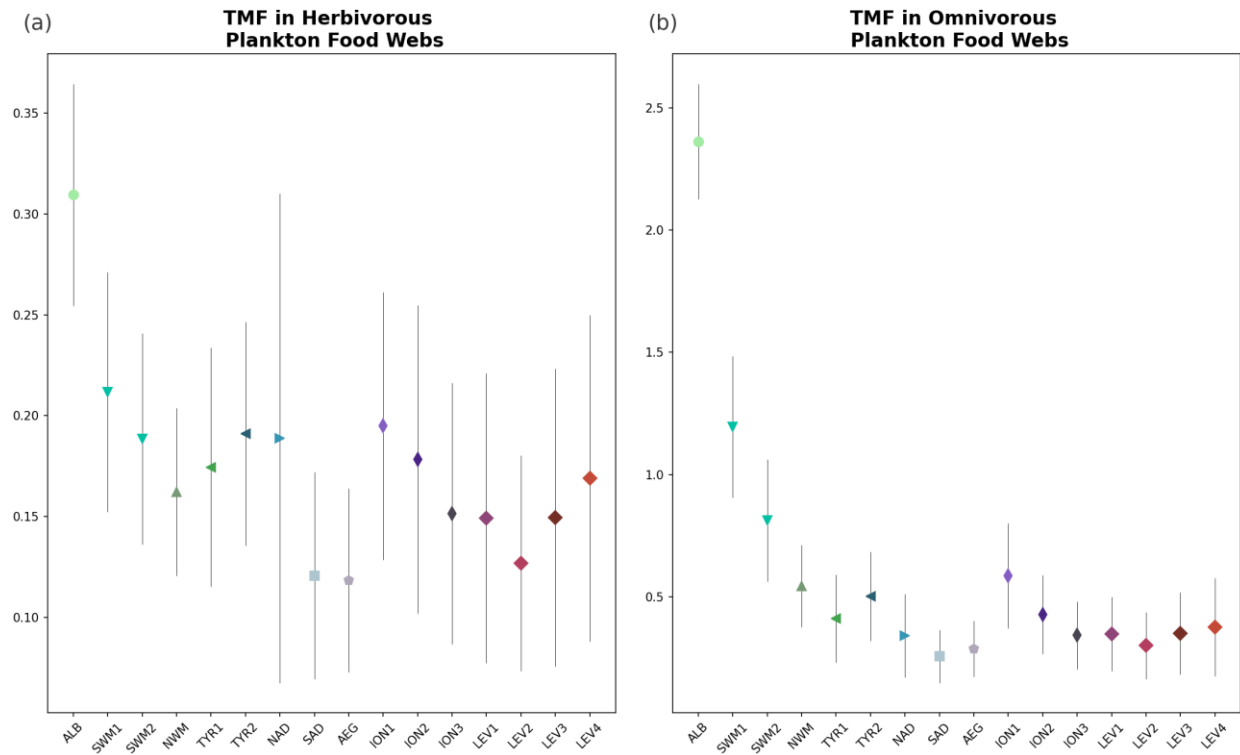

805 **Figure 7: Spatial distribution of monthly averaged (a)  $MMHg_{phy}$  and (b)  $MMHg_{zoo}$  ( $\text{pmol}_{(\text{hg})} \text{m}_{(\text{w})}^{-3}$ ) in the Mediterranean Sea at different water depths (25 m, 35 m, and 45 m) simulated with the OGSTM-BFM-Hg model for 2017. The plots show the sum of all variables of MMHg in phytoplankton (Fig. S7-S10) and zooplankton (Fig. S11-S14).**

810 Figure 8. Conceptual model of MMHg bioaccumulation in the plankton food web of the OGSTM-BFM-Hg model, subdivided into  
 a lower “herbivorous” (red arrows) and upper “omnivorous” (blue arrows) food webs. The squares with bold numbers show  
 815 estimated values of the Bioconcentration factors (log(BCF)) for each PFT, calculated for the *Sad* subbasin from spatially averaged  
 model output at monthly resolution. The green circles indicate the four phytoplankton PFTs (P1, P2, P3, P4, representative  
 respectively of diatoms, autotrophic nanoflagellates, picophytoplankton and large phytoplankton), the light blue circles indicate the  
 four zooplankton PFTs (Z3, Z4, Z5, Z6, representative respectively of carnivorous mesozooplankton, omnivorous mesozooplankton,  
 820 microzooplankton, and heterotrophic nanoflagellates), the purple circle indicate bacteria (B1, representative of all heterotrophic  
 bacteria), and the grey circles indicate particulate organic carbon (POC, representative of all organic detritus) and semi-refractory  
 dissolved organic matter (DOC<sub>sr</sub>). The solid arrows show the preferential trophic interactions, the dashed arrows are for secondary  
 trophic interactions (diet switch if the favorite preys are not available), and the circle dashed arrows are for cannibalization within  
 the same zooplankton group. The dash and dotted arrows indicate passive uptake of MMHg by phytoplankton. The dotted arrows  
 indicate the processes of transformation related to carbon recycling by bacteria (remPOC) and of Hg methylation, whose kinetics  
 are coupled through the parameter  $k_{met}$ , converting Hg<sup>II</sup> into MMHg.

825

**Figure 9. Trophic magnification factor (TMF, unitless) for the (a) omnivorous and (b) carnivorous plankton food webs (Figure 8) for each subbasin of the Mediterranean Sea (Figure 3), calculated by integrating over 0-100 m depth the monthly outputs of the OGSTM-BFM-Hg model.**
