33 **Abstract**

34 Tundra environments are experiencing elevated levels of wildfire, and the frequency is expected to keep
35 increasing due to rapid climate change in the Arctic. Tundra wildfires can release globally significant amounts of
36 greenhouse gasses that influence the Earth's radiative balance. Here we develop a novel method for estimating
37 carbon loss and the resulting radiative forcings of gaseous and aerosol emissions from 2015 tundra wildfires in the
38 Yukon-Kuskokwim Delta (YKD), Alaska. We paired burn depth measurements using two vegetative reference
39 points that survived the fire event —*Sphagnum fuscum* and *Dicranum spp.*— with measurements of local organic
40 matter and soil carbon properties to estimate total ecosystem organic matter and carbon loss. We used remotely-
41 sensed data on fire severity from Landsat 8 to scale our measured losses to the entire fire-affected area, with an
42 estimated total loss of 2.04 Tg of organic matter and 0.91 Tg of carbon, and an average loss of 3.76 kg m⁻² of
43 organic matter and 1.68 kg m⁻² of carbon in the 2015 YKD wildfires. To demonstrate the impact of these fires on
44 Earth's radiation budget, we developed a simple but comprehensive framework to estimate the radiative forcing
45 from Arctic wildfires. We synthesized existing research on the lifetime and radiative forcings of gaseous and
46 aerosol emissions of CO₂, N₂O, CH₄, O₃ and its precursors, and fire aerosols. The model shows a net positive
47 cumulative mean radiative forcing of 3.67 W m⁻² using RCP 4.5 and 3.37 W m⁻² using RCP 8.5 at 80 years post-fire,
48 which was dominated by CO₂ emissions. Our results highlight the climate impact of tundra wildfires, which
49 positively reinforce climate warming and increased fire frequency through the radiative forcings of their gaseous
50 emissions.

51

52 **1 Introduction**

53 The Arctic region is characterized by permafrost soils with low rates of decomposition and high carbon
54 content from millennia of positive net ecosystem production (NEP; Lindgren et al., 2018). As a result, there is more
55 than twice as much carbon stored in permafrost soils as there is in the atmosphere, including roughly 1,035 ± 150 Pg
56 of carbon in the top three meters of soil (Schuur et al., 2015). Surface air temperatures in the Arctic have been
57 increasing more than twice as fast as the global average since the mid-20th century (Cohen et al., 2018) and are
58 expected to continue increasing with more variable precipitation, hence more frequently pairing hot and dry
59 conditions (IPCC, 2021; Hu et al., 2015). Changing environmental conditions will place some of this large carbon
60 stock at risk for release into the atmosphere through increased biological activity and wildfire (Natali et al., 2019,
61 Natali et al., 2015, Rocha et al., 2011a, Hu et al., 2010).

62 Fires are an increasingly important component of tundra carbon cycling. Fires are becoming more frequent
63 in Arctic systems due to increasing occurrences of hot and dry conditions coupled with more lightning ignitions
64 (Chen et al., 2021, Bieniek et al., 2020, Veraverbeke et al., 2017b). For example, the 2007 Anaktuvuk River
65 megafire on the North Slope of Alaska occurred during an especially hot and dry period and released an amount of
66 carbon similar in magnitude to annual sequestration across the entire tundra biome (Mack et al., 2011). Continued
67 and potentially accelerated rates of warming are expected to further increase the frequency of tundra wildfires,
68 thereby releasing significant amounts of carbon and altering the net carbon balance of the tundra biome (Hu et al.,
69 2015).

70 A recent body of literature indicates the potential to estimate wildfire carbon emissions in boreal forests by
71 linking geospatial predictors, most prominently satellite-derived estimates of fire severity and extent, with *in situ*
72 measurements of carbon loss (e.g. Dieleman et al., 2020, Walker et al., 2018b, Veraverbeke et al., 2015b, and
73 Rogers et al., 2014). Despite increasing incidence of tundra wildfires, these studies have primarily focused on boreal
74 forests, and few estimates are available for tundra (Mack et al., 2011). Whereas satellite-derived fire extent and
75 severity is widely available, representative *in situ* measurements of tundra wildfires are not. *In situ* measurements of
76 fire effects on tundra organic soils are challenging due to a lack of reference points (e.g., adventitious roots) that
77 survive the fire, which are used to estimate pre-fire organic matter depth and content (Walker et al., 2018a, Rogers et
78 al., 2014, Boby et al., 2010). Measurements of organic matter loss must also be region-specific because of
79 differences in vegetation and soil properties (Walker et al., 2020c, Mack et al., 2011).

80 Although carbon loss estimates from Arctic wildfires are important for understanding the impacts of
81 climate change on carbon budgets, radiative forcings from wildfire gaseous and aerosol emissions are needed to
82 properly gauge the impact on the Earth's atmosphere and climate (Huang et al., 2016, Ward et al., 2012, Randerson
83 et al., 2006). Radiative forcings from wildfires depend spatially on fire severity and atmospheric conditions and
84 temporally on changing atmospheric background concentrations in the months, years, and decades following the fire
85 (Huang et al., 2016, Joos et al., 2013). To date, radiative forcings from high-latitude wildfires have been estimated
86 for particular boreal forests (Huang et al., 2016, O'Halloran et al., 2012, Randerson et al., 2006) and within global
87 models (Ward et al., 2012), but not for tundra ecosystems.

88 Here we take a two-step approach to assess the impact of tundra wildfires on carbon budgets and climate.
89 We first developed a method for measuring carbon loss *in situ* in tundra ecosystems, particularly for the 2015 fire

90 season in the Yukon-Kuskokwim Delta, AK. We tested the agreement of multiple pre-fire reference points for
91 estimating burn depth in the field and combined these estimates with laboratory-measured organic matter and carbon
92 fractions to estimate emissions. We then used 30m remotely-sensed fire severity data (differenced Normalized Burn
93 Ratio, or dNBR; Key and Benson, 2006) from Landsat 8 to scale our measurements to the entire fire area. Finally,
94 we estimated the long-term radiative forcings of the fire season's gaseous and particulate emissions, including long-
95 lived greenhouse gasses (GHGs), ozone, ozone precursors, and aerosols, using a variety of published algorithms and
96 arctic-specific parameters when available.

97 **2 Materials and Methods**

98 **2.1 Study Area**

99 Field measurements were collected in the summer of 2019 in a burn scar from the 2015 fire season in the
100 Yukon-Kuskokwim Delta, AK (YKD; Fig. 1). The burn scar we sampled was adjacent to an uninhabited but
101 regularly accessed Arctic field research outpost in the YKD established in 2016. Base camp was situated at 61.2632
102 °N, 163.2458 °W, approximately 95 kilometers northwest of Bethel, AK, accessible by float plane and helicopter.
103 Sampling was done within about an 11-kilometer radius of the base camp (Fig. 1c). Measurements from the field
104 were scaled to all fire scars in the YKD that burned in 2015 (Fig. 1b). We used fire perimeters from the Alaska
105 Large Fire Database (ALFD; Kasischke et al., 2002).

106

107
 108 **Figure 1.** (a) The location of the YKD within Alaska, (b) the areas of fires in 2015 within the YKD, and (c) the
 109 locations of our vegetative reference point height transects in burned and unburned areas within about an 11 km
 110 radius from base camp. Fire perimeters were derived from the Alaska Large Fire Database (Kasischke et al., 2002).
 111 Sources: Esri, DigitalGlobe, GeoEye, i-cubed, USDA FSA, USGS, AEX, Getmapping, Aerogrid, IGN, IGP,
 112 swisstopo, and the GIS User Community.

113
 114 The YKD contains tussock-sedge, dwarf-shrub, and lichen and moss tundra communities over ice-rich
 115 permafrost peat plateaus (Raynolds et al., 2005). These peat plateaus were the primary land component burned in
 116 the wildfires and were separated by fens, bogs, and open water. Within our sample area, lichen was the dominant
 117 vegetation type (Frost et al., 2020), shrubs were interspersed across the landscape, and tussocks were rare. Soil is
 118 predominantly organic (Jorgenson et al., 2000), which has accumulated over sand deposits from the Pleistocene
 119 period (Shaw, 1998).

120 2.2 Fire severity

121 Fire perimeters in the YKD in 2015 were extracted from the ALFD. We used a remotely sensed metric of
 122 fire severity from Landsat 8 Tier 1 surface reflectance imagery: dNBR (Eq. 1), which is based on the Normalized

123 Burn Ratio (NBR; Eq. 2; Key and Benson, 2006). Clouds, cloud shadows, and snow were masked from all images
124 using the provided pixel quality attributes generated from the CFMASK algorithm (Foga et al., 2017). Imagery for
125 this index was acquired as the mean Landsat 8 composite between June 1st and August 31st for one year pre- and one
126 year post-fire, and for all fire scars. All remotely sensed variables were extracted in Google Earth Engine (Gorelick
127 et al., 2017). Where in Eq. (2) NIR is near-infrared (Band 5) and SWIR is shortwave infrared (Band 7).

$$128 \quad dNBR = (NBR_{prefire} - NBR_{postfire}) \times 1000, \quad (1)$$

$$129 \quad NBR = \frac{(NIR - SWIR)}{(SWIR + NIR)}, \quad (2)$$

130 We compared dNBR from the YKD 2015 fire season to all fires in boreal and tundra Alaska to place the
131 measured dNBR in context. Using fire records from the ALFD, dNBR was acquired for all available fire perimeters
132 in Alaska. Differenced NBR was calculated in the same way as described before, but with the exception that
133 Landsat 4, 5, 7, and 8 were used in the pre and post-fire composites. Due to differences in spectral bands, Landsat 8
134 was corrected to match Landsat 7 using a regression technique (Roy et al., 2016). The first fire year we detected
135 dNBR was in 1989 and the most recent was in 2019. Boreal and tundra extents were defined using the United States
136 Environmental Protection Agency ecoregions, with tundra as level one class 2.0 and boreal as level one classes 3.0
137 and 6.0 (U.S. Environmental Protection Agency, 2010).

138 **2.3 Vegetative marker height measurements**

139 We measured the height of vegetative reference points above the surface in both unburned and burned
140 areas. Three main dominant surface vegetative reference points were available: *Sphagnum fuscum*, *Dicranum spp.*,
141 and *Eriophorum vaginatum* (tussocks; similar to the methods of Mack et al. (2011)). *S. fuscum* moss appeared in
142 large mats. *Dicranum* moss appeared in small dense patches. All vegetative reference points were particularly
143 conspicuous in burned areas as they were elevated above the burned surface (Fig. 2). In the burned area, we
144 measured the distance from the soil surface to top of the living parts of the vegetative reference points, which we
145 assumed to indicate full survival in the fire event. We did not measure dead remnants of vegetative reference points,
146 because we expect that these may not represent the actual pre-fire vegetation height.

147
148 **Figure 2.** An example burn depth measurement from the surviving top of a *Dicranum spp.* moss patch (red arrow;
149 pink string) to the top of the soil (blue arrow) in a burned transect. Transect tape was used to measure distance
150 between the moss patches.
151

152 We measured the average height along a transect between two comparable reference points. At the highest
153 living point on each moss patch, or to the top of the corms at the base of a tussock, we inserted a nail (red arrow,
154 Fig. 2). We ran a taut piece of string between the two nails (Fig. A1). In between the edges of the moss patch or
155 tussock pair (Fig. A1), we took height measurements vertically from the string to the ground, which was soil in the
156 burned areas (blue arrow, Fig. 2) or a dense vegetative surface in the unburned areas (Fig. A2). In between the
157 starting and ending point measurements on the transect we recorded height every 25 centimeters (Figs. A2 and A3).
158 The starting and ending points were never greater than 50 centimeters from the nail. Latitude and longitude were
159 recorded at all transects with an accuracy of three meters (Fig. 1) for ground-truthing remotely sensed burn severity
160 categories.

161 One potential source of error is post-fire subsidence between the vegetative reference point pairs that may
162 bias the relative height of a vegetative marker above the surface (Jones et al., 2015). We minimized this potential
163 bias by maintaining transect lengths less than four meters, and predominantly one to two meters in burned areas.
164 We also visually assessed the area between each vegetative marker for signs of subsidence, including cracked soil or

165 large elevation differences, and chose not to sample these areas. Measuring from the top of one vegetative marker to
166 the top of another marker controlled for slopes and larger landscape elevation features because the string largely
167 mimicked the angle of the landscape.

168 We selected transects for height measurements opportunistically in the burned and unburned areas.
169 However, we tried to maximize spatial separation between transects and target visually identifiable areas of varying
170 burn severity. We corrected for spatial autocorrelation biases between transect averages in our statistical analyses
171 (see below). In unburned areas we maximized the number of transects measured for each vegetative reference point,
172 *Sphagnum* (n = 38), *Dicranum* (n = 40), and *Eriophorum* (n = 19).

173 Each burn depth measurement was associated with a dNBR value based on the 90 m pixel, the mean of
174 underlying 30 m pixels, containing its centroid. Burn depth measurements that came from the lowest third, middle
175 third, and upper third of dNBR values were considered to be in low severity/unburned, moderate severity, and high
176 severity areas, respectively, and a roughly even numbers of transects were sampled in each burn severity category
177 for *Sphagnum* (n = 56: high n = 20, mod n = 17, low/unburned n = 19), *Dicranum* (n = 54: high n = 18, mod n = 17,
178 low/unburned n = 19), and *Eriophorum* (n = 24: high n = 7, mod n = 11, low/unburned n = 6). Unburned patches of
179 tundra were sometimes included in low severity pixels within the burn scar, which is why these severity classes are
180 combined.

181 **2.4 Organic matter and carbon pool measurements**

182 We calculated the total ecosystem organic matter and carbon pool sizes in unburned areas surrounding the
183 fire scar. We took vegetation and soil samples together in cores using a hand drill and hollow metal drill bit that was
184 30 centimeters in length and six centimeters in diameter. Cores were extracted at three points (start, middle, and
185 end) along transects between like vegetative reference points. We selected four sites of less than half a hectare
186 surrounding areas where we took our unburned vegetative reference point height measurements. These sites were
187 selected opportunistically to ensure the presence of an appropriate number of each of the three vegetative reference
188 points. In each site, we extracted cores from three transects per vegetative reference point pair, which totaled 27 soil
189 cores per site. In one site we found only two tussock pairs, so our total number of samples was 105. We chose
190 unburned sites separated by at least one kilometer to control for heterogeneity in local soil and vegetation
191 characteristics.

192 We measured the height of the live vegetation layer and fibric soil horizons for each core. Vegetation
193 layers and soil horizons were identified visually by soil density, texture, color, and identifiable plant parts. Each
194 core was separated into vegetation and fibric soil layers that were homogenized, weighed, and subsampled in the
195 field, and subsequently stored frozen until analyzed. In the lab, each vegetation sample and approximately 15 grams
196 of each fibric sample were dried for 48 hours at 60 °C and weighed to determine soil water content. We used the
197 proportion of dry mass to wet mass to estimate the dry weight of the field sample, which was used to determine bulk
198 density (g dry mass cm⁻³). Soil samples were combusted for five hours at 450 °C to determine organic matter
199 content and analyzed for percent carbon using an Elementar Vario Max CN analyzer at the Woodwell Climate
200 Research Center, Falmouth, MA. We assumed the dry mass of the vegetation layer was fully organic matter. Using
201 the average across all herbaceous plant organs, we assumed the carbon content of the vegetation layer was 43.04%
202 from Ma et al. (2018). To calculate organic matter and carbon pools (kg m⁻²) for each organic soil sample, we
203 multiplied bulk density by the height of the layer and percent organic matter or percent carbon, respectively. These
204 values were normalized for each sample to the average depth of the vegetation layer, which was seven centimeters,
205 and 10 centimeters in the fibric horizon.

206 **2.5 Calculating final estimates**

207 We calculated organic matter combustion and carbon loss across the fire area using burn depth derived
208 from the moss reference points. We excluded estimates derived from tussock measurements, because our sample
209 size of tussock-based measurements was substantially lower than the moss vegetative reference points due to their
210 infrequent occurrence in our study area (Frost et al., 2020). Moreover, burn depth estimates from tussocks
211 correlated negatively with remotely sensed fire severity (Fig. A4). This negative correlation with fire severity may
212 be attributable to mechanisms that are untestable with our sample size and study design, including altered burn
213 dynamics in close proximity to tussocks. Future work could clarify the mechanism behind this discrepancy.
214 Excluding tussock measurements required reassigning dNBR values evenly as before across only *Dicranum* (n = 54:
215 high n = 18, mod n = 18, low/unburned n = 18) and *Sphagnum* (n = 56: high n = 20, mod n = 18, low/unburned n =
216 18) reference points. The highest dNBR values in the low severity/unburned and moderate severity categories
217 became the threshold values for low severity/unburned to moderate severity and moderate severity to high severity
218 burn, respectively. We split the fire area, based on these thresholds, into the three categories for burn severity.
219 There were 13,001 hectares of low severity burn, potentially including unburned patches, 8,516 hectares of moderate

220 severity burn, and 32,637 hectares of high severity burn, which summed to 54,154 hectares of total fire area (Fig.
221 A5).

222 For final analysis of organic matter and carbon loss, we averaged the height of *Sphagnum* and *Dicranum*
223 reference points in the unburned areas to determine one height for each reference point, since their respective
224 heights were statistically different ($p < 0.001$). Burn depth was calculated at each transect in the burned areas by
225 subtracting the standard unburned height from the transect average height. We also averaged the dry organic matter
226 and carbon pool within the vegetative layer and fibric horizon separately across *Sphagnum* and *Dicranum* reference
227 points to determine one pool size for our sampling area. Average organic matter or carbon loss (kg m^{-2}) was
228 estimated as the product of the organic matter or carbon concentrations and depth of the vegetation and soil that
229 burned at each burn depth transect. Average loss at each transect was the sum of loss from each horizon (see Fig.
230 A6 for schematic of organic matter and carbon loss calculation per transect). For our final calculation of total dry
231 organic matter and carbon loss, we averaged the organic matter and carbon lost across transects for *Sphagnum* and
232 *Dicranum* reference points within each fire severity category. Over the landscape, total carbon or organic matter
233 released was calculated by multiplying average carbon or organic matter loss for a given burn severity category by
234 the total burned area for that category. Total carbon or organic matter released was then calculated as the sum from
235 all three burn severity categories.

236 **2.6 Radiocarbon**

237 We used radiocarbon dating to confirm our burn depth measurements by comparing the radiocarbon age of
238 *Sphagnum* macrofossils on the burned soil surface with the radiocarbon age of *Sphagnum* macrofossils at different
239 depths of the unburned soil profile, similar to the methods of Mack et al. (2011). In the field we extracted one
240 unburned core and three burned cores of the same dimensions as our primary soil cores, described above. We
241 extracted a one-centimeter thick subsample of the cores every five centimeters in depth and froze the samples in a
242 sealed plastic bag until lab analysis. To construct an age profile, we analyzed unburned cores at depths of five to 20
243 centimeters for radiocarbon age. We assumed that a depth of zero centimeters had carbon from the time of harvest
244 in 2019. In the burned cores, we analyzed the zero-centimeter depth (i.e., surface) for radiocarbon.

245 In the lab, we visually identified *Sphagnum* branches in each of the subsamples being tested and rinsed
246 them with deionized water. The branches were then dried for 48 hours at 60 °C, and roughly five milligrams of dry
247 branch matter per sample was sent to the W.M. Keck Carbon Cycle Accelerator Mass Spectrometry Laboratory at

248 the University of California Irvine for the ^{14}C content and $\delta^{13}\text{C}$. Results for ^{14}C analysis are reported as the fraction
249 modern, which is defined as the ratio of the sample's carbon isotope ratio to that of a standard (Reimer, 2004).
250 Fraction modern values are calibrated to calendar years using OxCal online 4.4.1 (Ramsey, 2009), with the
251 appropriate modern era bomb curve taken from Hua et al. (2013). Due to the shape of the bomb curve, there are at
252 least two possible calendar years in which the carbon in the sample was fixed. However, we did not use the oldest
253 age for unburned samples with multiple calendar ages because the age of these samples must increase with depth
254 (Walker et al., 2019, Mack et al., 2011), which is not supported when considering the oldest calendar ages.
255 Furthermore, we were confident the burned samples were from the younger age because they were from visually
256 shallow burn depths. We compared the calendar age of carbon at the burned soil surface to age by depth profile
257 taken from the unburned core.

258 **2.7 Radiative forcings model**

259 We created a temporally-explicit model of radiative forcings for gaseous and aerosol emissions of tundra
260 wildfires and used it to compute the radiative forcings per unit burned area. The radiative forcings model was
261 driven using the average amount of organic matter lost across fire-wide burn severity classes and vegetative
262 reference points. Computing the radiative forcing of gaseous and aerosol emissions has been done for boreal fires
263 (e.g., Huang et al. 2016, O'Halloran et al., 2012, Randerson et al., 2006), but has yet to be applied to tundra systems.
264 Our model included the long-lived GHG species CO_2 , CH_4 , and N_2O , as well as short-lived climate forcers,
265 tropospheric O_3 , O_3 precursors, and aerosols. Ozone precursors include NO_x , non-methanogenic volatile organic
266 carbons (NMVOCs), and CO .

267 We first used emissions factors from Akagi et al. (2011) to calculate the mass of gaseous and aerosol
268 emissions from our estimated organic matter losses. Emissions factors have not been previously defined for tundra
269 burning. Given that boreal forest, whose definition for emission factors includes organic soils, peat, and woody
270 vegetation, is likely the closest ecosystem type in terms of fuel properties to tundra in Akagi et al. (2011), we
271 employed these emission factors. However, we note a possible overestimate of relative contribution from woody
272 vegetation emissions in these numbers due to the relative lack of woody vegetation on the tundra landscape.
273 Furthermore, concentrations of gasses released from combustion of the same biomass type vary based on the
274 measurement technique, such as from differences in chemical mixing in laboratory, airborne, and ground-based field
275 methods (Akagi et al., 2011). Since Akagi et al. (2011) provides estimates of each emissions factor based on a

276 combination of values from previous studies, the emissions factors may capture uncertainty associated with the
277 variable methods of these source studies.

278 Once we estimated the mass of each gaseous emission, we calculated the concentration of the gas
279 remaining in the atmosphere and its radiative forcing each year after the fire season by synthesizing existing models
280 and research on the lifetimes and radiative forcings of these gaseous emissions. Our calculations of radiative forcing
281 were dependent on the future ambient concentration of GHGs in the atmosphere. As a result, we calculated the
282 radiative forcings of gaseous emissions for three scenarios: historic, representative concentration pathway (RCP)
283 4.5, and RCP 8.5. The historic scenario assumes the ambient concentration of GHGs remains constant in the
284 atmosphere after the fire year. Future atmospheric concentrations for each RCP were taken from Meinshausen et al.
285 (2011). The radiative forcing for each gaseous emission per year was calculated separately and then summed across
286 forcing agent. Since O₃ precursors and aerosols had the most uncertain lifetimes and radiative forcings (Bond et al.,
287 2011, Quinn et al., 2008), we calculated the total radiative forcing of the emissions with and without them. A
288 flowchart of our general methodology for the entire radiative forcings calculation is presented in the appendix (Fig.
289 A7).

290 **2.8 Methane and Nitrous Oxide**

291 Our radiative forcing calculations for CH₄ and N₂O were based on Ward et al. (2012). For both gasses, we
292 assumed a pulse emission and calculated the concentration remaining in each year after the fires using a simple box
293 model with one outflow as shown in Eq. (3), where C_o is the initial pulse concentration of the gas, t is the number of
294 years after the fire event, and L is the lifetime of the gas. The initial pulse concentration of both gasses was
295 calculated by converting the mass emitted to a volume as a molar fraction of the atmosphere.

$$296 \quad C = C_o e^{-\frac{t}{L}}, \quad (3)$$

$$297 \quad L = L_o \left(\frac{E}{E_t} \right)^{-0.05}, \quad (4)$$

298

299 We used the atmospheric lifetimes for both gasses reported in Myhre et al. (2013). However, we calculated
300 a decreased lifetime of N₂O using Eq. (4) from Ward et al. (2012), as its ambient concentration changed in future
301 emissions scenarios, where L_o is the initial lifetime of N₂O from Myhre et al. (2013), E is the ambient concentration
302 of N₂O in the year the fires burned, and E_t is the ambient concentration of N₂O at each year after the fire event based
303 on the future emissions scenario (Meinshausen et al., 2011). We did not account for the effect of the changing
304 atmospheric concentration on the lifetime of N₂O due to the pulse emission itself. We then calculated the

305 perturbation concentrations of CH₄ and N₂O in the atmosphere each year after the fire event as the sum of the
 306 remaining pulse emissions and the ambient concentrations and used Eqs. (5) and (6) from Ward et al. (2012) to
 307 estimate the radiative forcing of both gasses. The radiative forcing of the gas at each year was RF, M was the
 308 perturbation concentration of the gas whose radiative forcing was being calculated, and M_o and N_o were the ambient
 309 concentrations of both gasses depending on which gas's radiative forcing was being calculated.

$$310 \quad RF = 0.036(\sqrt{M} - \sqrt{M_o}) - [f(M, N_o) - f(M_o, N_o)], \quad (5)$$

$$311 \quad f(M, N) = 0.47 \ln[1 + 2.01 \times 10^{-5}(MN)^{0.75} + 5.31 \times 10^{-15}M(MN)^{1.52}], \quad (6)$$

312

313 **2.9 Carbon Dioxide**

314 Carbon dioxide has a highly variable lifetime under different future emissions scenarios depending on the
 315 strength of ocean and land sinks. To account for this variation, we used impulse response functions (IRFs) from
 316 Joos et al. (2013), which represent the fraction of a pulse of CO₂ remaining in the atmosphere at each year after the
 317 pulse for each scenario. For each year post-fire, we multiplied the relevant IRF function by the concentration of
 318 CO₂ initially released to estimate the amount of CO₂ remaining in the atmosphere. Similar to N₂O and CH₄, the
 319 initial concentration of CO₂ was calculated by converting the mass emitted to a volume as a molar fraction of the
 320 atmosphere. The radiative forcing for CO₂ was calculated using Eq. (7) taken from Myhre et al. (1998), where C is
 321 the perturbation concentration and C_o is the ambient concentration of the gas in each year.

$$322 \quad RF = 5.35 \ln\left(\frac{C_o+C}{C_o}\right), \quad (7)$$

323 **2.10 Tropospheric Ozone**

324 Tropospheric O₃ is created photochemically in the smoke plumes of wildfires by the combination of
 325 sunlight and O₃ precursor gasses, and its creation can be expressed as a function of time and the amount of carbon
 326 monoxide released (Jaffe and Wigder, 2012). We used data compiled in Jaffe and Widger (2012), who provided a
 327 synthesis of O₃ and its relationship with CO for fire plumes sampled in the Arctic at various times after a fire to
 328 calculate a mean plume lifetime and derive a linear relation between plume age and the ratio of O₃ to CO. Because
 329 the average plume age sampled was five days, we assumed O₃ was created for five days after the fires. The
 330 concentration of O₃ on each of those five days was calculated by multiplying the initial concentration of CO released
 331 from the fires, calculated by converting the mass emitted to a volume as a molar fraction of the atmosphere, by the
 332 ratio of O₃ to CO we estimated for that day. After five days, we assumed no more O₃ was created, and we
 333 calculated the remaining amount of O₃ after day five using the box model approach from Eq. (3). The concentration
 334 of O₃ on day five was C_o, and L was the lifetime of O₃ taken from Myhre et al. (2013). We converted the

335 concentration of O₃ to Dobson units (DUs) and converted from DUs to radiative forcing using a conversion factor
336 from Myhre et al. (2013) each day after the fire event. The radiative forcing in each year was the mean radiative
337 forcing of all the days within that year, although the annual forcing was negligible after the first year.

338 **2.11 Ozone Precursors and Aerosols**

339 We used a method based on global warming potential (GWP), similar to Huang et al. (2016), to calculate
340 the radiative forcing of the ozone precursors and the direct aerosol effect. GWP is defined as the ratio of the time-
341 integrated radiative forcing of a pulse emission of a gaseous species to the time-integrated radiative forcing of an
342 equivalent emission mass of CO₂ (Joos et al., 2013). GWP is typically calculated for 20- and 100-year time
343 horizons. Here, we use GWPs to determine the warming effect of the precursor and aerosol emissions relative to
344 CH₄ at the 20- and 100-year time horizons, as shown in Eq. (8). We derived the radiative forcings for ozone
345 precursors based on CH₄ because the radiative forcing of ozone precursors is through their effect on methane over
346 the long-term (Collins et al., 2013). To remain consistent with our methodology for ozone precursors, we derive the
347 radiative forcings for aerosols from CH₄ as well. Furthermore, the radiative forcing of CH₄ has the simplest
348 derivation in our model, so we assume it is the strongest continuous radiative forcing from which to build our
349 continuous model using GWPs.

$$350 R_t = \frac{GWP_{t,x} \times EF_x}{GWP_{t,CH_4} \times EF_{CH_4}}, \quad (8)$$

351 The emissions factor (EF) and GWP are defined for gaseous species x, and the GWP is defined at the time
352 horizon t. For CO and NMVOCs, we interpolate this relative warming effect (R_t) between year one and year 20 by
353 assuming it remains constant. To interpolate this effect between years 20 and 100, we mirror the shape of methane's
354 cumulative radiative forcing curve over that time interval. From this curve we calculated the difference between
355 methane's cumulative radiative forcing at years 20 and 100. We then calculated the fractional decrease of this
356 difference each year between years 20 and 100. We multiplied those fractional decreases by the difference in R_t at
357 years 20 and 100 for CO and NMVOCs to derive a relative warming effect for the precursors. Finally, we
358 multiplied R_t by methane's cumulative radiative forcing curve to estimate the cumulative radiative forcing for each
359 precursor every year after the fire event. We used the global GWPs for CO and NMVOCs from Myhre et al. (2013).

360 Since NO_x has a positive GWP at the 20-year time horizon and a negative GWP at the 100-year time
361 horizon, we chose not to mimic the shape of methane's radiative forcing curve when interpolating between the two
362 time points. Instead, we calculate an R_t value for NO_x at year one by scaling R₂₀ in proportion to the change of

363 methane's cumulative radiative forcing from years one to 20. Then we interpolated between the R_t values in years
364 one, 20, and 100 using an exponential decay function of the form $ae^{-bx} + C$, whose coefficients were calculated
365 using the "nls" function in R (R Core Team 2020). We multiplied the R_t value for NO_x at each year by the
366 cumulative radiative forcing of CH_4 in that year to obtain a cumulative radiative forcing curve for NO_x . We use the
367 global GWP for NO_x from Myhre et al. (2013).

368 The radiative effect of aerosol emissions happens within a year of the fire event, as fire aerosols are
369 typically removed from the atmosphere via wet and dry deposition within a matter of weeks (Bond et al., 2011,
370 Quinn et al., 2008). We assumed that the cumulative radiative forcing of aerosols at any year after the fire event
371 would be constant and equal to the radiative forcing of aerosols in the year of the fire event. Therefore, to calculate
372 the cumulative radiative forcing from black and organic carbon direct effects in every year, we used R_{20} and
373 multiplied this value by the cumulative radiative forcing curve of CH_4 at year 20. Radiative forcings of black and
374 organic carbon were summed to report a single value for aerosols. We used the GWPs for black and organic carbon
375 estimated for open biomass burning including the cryosphere effect from Bond et al. (2011). To estimate the
376 indirect aerosol effect, we multiplied the radiative forcing of the direct effect of aerosols each year by the ratio of
377 indirect to all sky direct effect radiative forcing from wildfires defined in Ward et al. (2012).

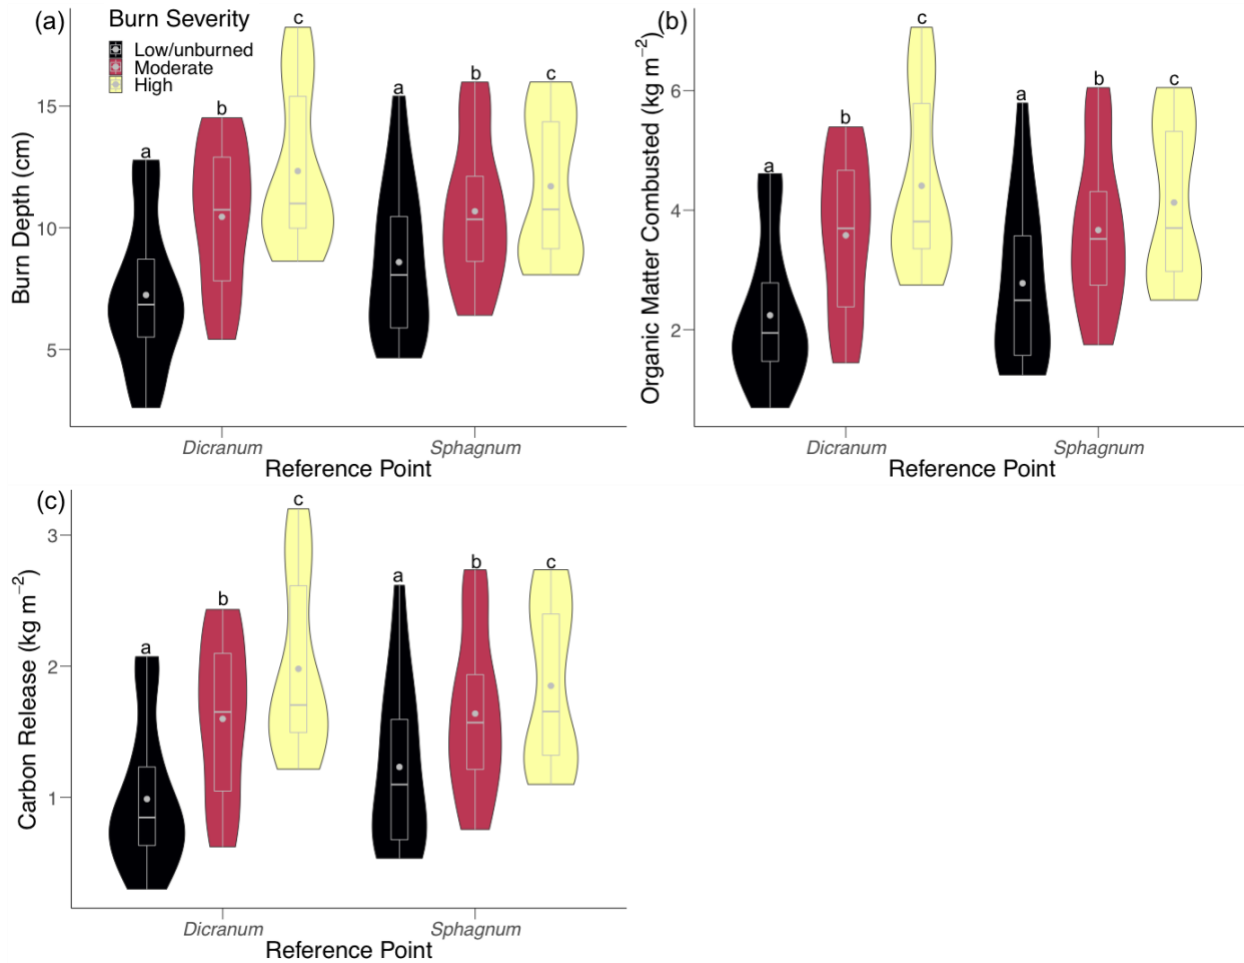

378 **2.12 Statistical analyses**

379 All statistical analyses were completed in R (R Core Team 2020) using the nlme package (Pinheiro et al.,
380 2020). For the vegetative reference point heights, we used the nlme package function "gls" to fit a linear model
381 using the generalized least squares method with average burn depth and height above the dense vegetation layer
382 along the transect as the response variable in the burned and unburned areas respectively. Within the "gls" function,
383 both models were corrected for spatial autocorrelation between transect locations by choosing the model with the
384 lowest Akaike information criterion (AIC) score across five correlation structures, exponential, Gaussian, linear,
385 rational quadratic, and spherical, to be our final model. In burned areas, the model had vegetative reference point
386 nested within burn severity type, while in unburned areas, we only modeled the effect of vegetative reference point
387 type. The model with the lowest AIC score for both burned and unburned areas had a rational quadratic correlation
388 structure. To analyze differences in organic matter and carbon pools, height, and bulk density of the vegetation and
389 fibric soil layers we used the "lme" function, defined in the nlme package, to fit linear mixed effect models with the
390 restricted maximum likelihood method. These models had the soil or vegetation layer characteristic value for each

391 core as their response variable, vegetative reference point type as a fixed effect, and transect number nested in site as
392 random effects. Finally, we created linear fit models using the “gls” function with organic matter combusted and
393 carbon lost at each transect in the burned areas as response variables with the same structure as the burn depth
394 model. These models had the lowest AIC scores with a rational quadratic correlation structure. An analysis of
395 variance (ANOVA) was used to test for significant differences between groups for all of our models.

396 **3 Results**

397 We found that burn depth measurements were consistent with burn severity classification, and burn depth
398 increased with fire severity (Fig. 3). Based on a two-factor ANOVA with vegetative reference point nested within
399 burn severity, differences in average transect burn depth were significant ($p < 0.0001$) between burn severity
400 categories. The ranges of moderate severity burn depth measurements overlapped substantially with the high
401 severity and low severity/unburned measurements. Moderate severity groups also had the most evenly distributed
402 probability densities across burn depth. *Dicranum* measurements captured the shallowest and the deepest burn
403 depths (Fig. 3). Nevertheless, across both vegetative reference points, there was a clear stepwise increase in burn
404 depth across burn severity classifications.

405
 406
 407 **Figure 3.** Distributions of average (a) burn depth, (b) organic matter combusted and (c) carbon released per unit
 408 burned area per transect within each reference point across burn severity levels. Boxes encompass the middle 50%
 409 of data, whiskers are the upper and lower quartiles, horizontal lines intersecting boxes show the median, and gray
 410 points are the mean. Letters indicate significantly different groups of data.
 411

412 We found no significant differences between vegetative reference point types in terms of mean organic
 413 matter pool size, carbon pool size, height, or bulk density for either the live vegetation layer or fibric soil horizon
 414 extracted in our unburned cores ($0.3504 < p < 0.9558$). In the unburned areas, the fibric soil horizon (17.9 ± 0.63
 415 cm) was nearly three times thicker than the vegetation layer (6.19 ± 0.60 cm) to the depth that our cores reached
 416 (~30 cm; Table 1), which is likely an underestimate of the soil organic layer depth, given that our cores only
 417 occasionally reached the mineral soil layer. However, there was larger variation in the vegetation layer ($1\sigma = 6.9$
 418 cm) than fibric horizon ($1\sigma = 2.6$ cm) height. In most cases, the fire burned through the vegetation layer, but never
 419 completely through the fibric horizon (Fig. 3, Table 1). The fibric layer (to 24.1 cm average) had almost three times

420 greater organic matter and carbon pool sizes compared to the vegetation layer because of its higher bulk density and
 421 height (Table 1).

422 **Table 1.** Bulk density, height, and carbon and organic matter percent and pool sizes of vegetation and fibric layers
 423 measured in unburned soils averaged across reference points. Carbon and organic matter pool measurements are the
 424 product of bulk density and their percent contents and are normalized to the height of the vegetation layer and 10
 425 centimeters in the fibric layer. Sample size is 72, which is equally attributable to the two reference points. Error is
 426 reported as the standard error of the mean (SEM).

Layer	Bulk Density (kg m ⁻³)	Height (cm)	Percent Carbon (%)	Carbon Pool (kg m ⁻²)	Percent Organic Matter (%)	Organic Matter Pool (kg m ⁻²)
Vegetation	26.7 ± 1.4	6.19 ± 0.60	43.04*	0.712 ± 0.037	100*	1.65 ± 0.09
Fibric	54.6 ± 5.0	17.9 ± 0.63	39.41 ± 0.56	2.07 ± 0.16	88.12 ± 1.17	4.48 ± 0.30

427 *Based on assumption

428

429 Carbon and dry organic matter loss estimates similarly increased with burn severity (Fig. 3, Table 2).

430 Based on a two-factor ANOVA with vegetative reference point nested in burn severity, average organic matter and

431 carbon loss differed between burn severity categories (carbon loss: $p < 0.0001$; organic matter loss: $p < 0.0001$) (Fig.

432 3). Similar to burn depth distributions, the moderate severity range overlapped with the high severity and low

433 severity/unburned distributions (Fig. 3).

434 **Table 2.** Carbon and organic matter loss averaged within each burn severity category across reference point, and
 435 total carbon and organic mass loss over each burn severity category area. Total loss per burn severity category is
 436 summed to calculate total loss over the total fire area by burn severity classification. Error is reported as SEM,
 437 except for total loss over the fire area which is reported as the sum of errors.

438

Severity	Sample Size	Area (hectares)	Carbon Loss		Dry Organic Matter Loss	
			Average (kg m ⁻²)	Total (Tg)	Average (kg m ⁻²)	Total (Tg)
Low/unburned	36	13,001	1.11 ± 0.10	0.144 ± 0.013	2.51 ± 0.22	0.326 ± 0.029
Moderate	36	8,516	1.62 ± 0.10	0.138 ± 0.009	3.62 ± 0.22	0.309 ± 0.019
High	38	32,637	1.93 ± 0.12	0.629 ± 0.039	4.29 ± 0.23	1.40 ± 0.08
Total	158	54,154		0.911 ± 0.039 (Tg)		2.04 ± 0.09 (Tg)

439

440 The 2015 fires burned a total of 54,154 hectares in the YKD. The distribution of dNBR values for our

441 focal fires in the YKD was intermediate compared to dNBR values from all tundra fires and on the low side but

442 within the range of dNBR values for all boreal fires in Alaska between 1989 and 2019 (Fig. A8). Roughly 60% of

443 the burned area was classified as high severity, while moderate severity and low severity/unburned accounted for

444 about 16% and 24% of the burned area, respectively (Table 2). As a result, total organic matter and carbon loss

445 within the high severity burn classification was over three times greater than the other two burn severity categories.

446 Although moderate severity occupied less fire area than the low severity/unburned, it contained roughly equal total

447 organic matter and carbon loss to the low severity/unburned areas due to about 50% higher organic matter and

448 carbon losses per unit area on average. However, it should be noted that losses from low severity/unburned areas
 449 are likely overestimates, given the inclusion of unburned areas within regions of low severity burn. Summing
 450 carbon loss and dry organic matter loss over the area of each burn severity category yielded a total loss of $2.04 \pm$
 451 0.09 Tg of dry organic matter and 0.911 ± 0.039 Tg of carbon. This magnitude of total loss corresponded to an
 452 average 3.76 kg m^{-2} of organic matter and 1.68 kg m^{-2} of carbon loss across the fire area.

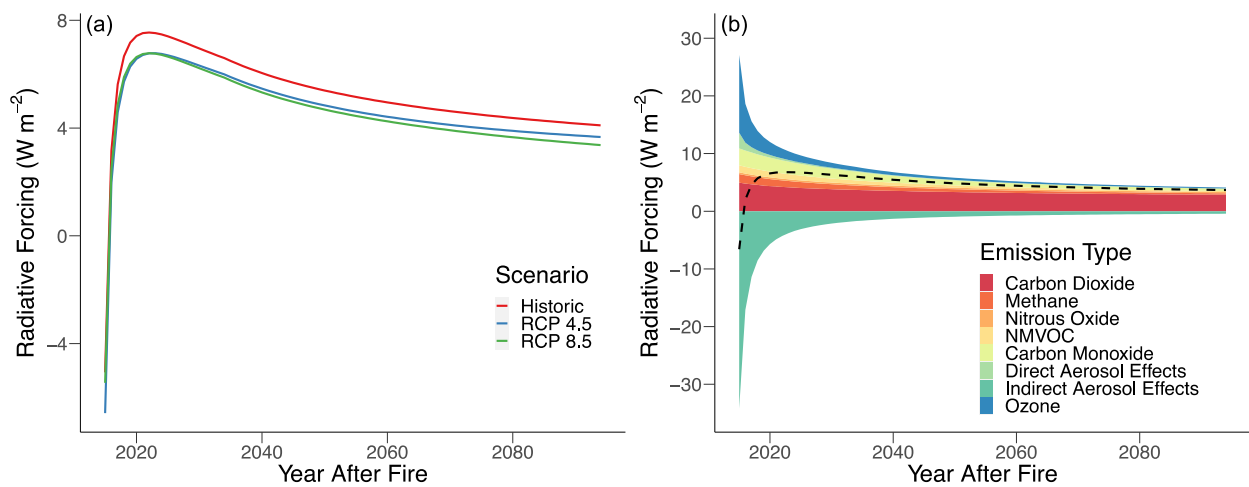

453 The age of carbon increased by ~ 50 years from 5 to 20 cm in depth in the unburned area. Surface samples
 454 from burned soils in a low severity/unburned area were dated to 2009, indicating a burn depth of about 5 cm or less,
 455 which is within the range of our low severity/unburned burn depth measurements (Table 3). The rate of change in
 456 carbon age between 0 and 5 cm was 2.4 yr cm^{-1} ; for the 15 to 20 cm interval, it was 3.6 yr cm^{-1} . Because none of
 457 our burn depth measurements exceeded 20 cm, all carbon released from the fires was likely relatively new carbon,
 458 younger than 64 years of age. Our average burn depth of 10.3 cm across burn severity and reference point indicated
 459 an average age of about 23 years for carbon released.

460 **Table 3.** The fraction of the modern standard and calibrated calendar age for each radiocarbon sample. Calendar
 461 ages are the intercepts for the fraction modern value with the calibration curve. We do not consider the oldest
 462 calendar ages.

Burn Status	Depth (cm)	Fraction Modern	Calendar Ages CE
Burned	0	1.0486 ± 0.0020	1957, 2009
Burned	0	1.0493 ± 0.0024	1957, 2009
Burned	0	1.0403 ± 0.0018	1957, 2008, 2009
Unburned	5	1.0625 ± 0.0020	1957, 2007, 2008, 2009
Unburned	10	1.1198 ± 0.0023	1958, 1996
Unburned	15	1.4603 ± 0.0024	1963, 1974
Unburned	20	1.0124 ± 0.0017	1956

463 The radiative forcing for gaseous and aerosol emissions from the 2015 fire season was positive for 80 years
 464 post-fire according to our model, regardless of the future atmospheric gas concentration scenario (Fig. 4a).
 465 However, the magnitude of the fire emissions' radiative forcings decreased with increasing ambient atmospheric gas
 466 concentrations, with RCP 8.5 having the lowest radiative forcing at 80 years post-fire (Fig. 4a). Given the lack of
 467 qualitative difference across future scenarios, below we present results for the RCP 4.5 scenario only (Table 4, Fig.
 468 4b). Nitrogen oxides were the only gas with a negative radiative forcing at the 80-year cumulative mean. However,
 469 they had a positive radiative forcing at the 20-year time horizon (Table 4). The only other negative radiative forcing
 470 came from the indirect effect of aerosols that completely counterbalanced the positive radiative forcing from other
 471 gaseous emissions in the first year, but the magnitude of this effect in terms of cumulative integrated forcing
 472 diminished rapidly after the first decade (Fig. 4b). CO_2 produced the highest radiative forcing through 80 years
 473

474 (Table 4, Fig. 4b). Nitrous oxide sustained its positive radiative forcing; however, the radiative forcing was of
 475 intermediate magnitude with respect to all gaseous emissions. In contrast, ozone and carbon monoxide exhibited
 476 high radiative forcings, but the magnitude of these diminished rapidly with respect to carbon dioxide. Likewise, the
 477 effect of the other ozone precursors, aerosols, and methane decreased relatively rapidly (Table 4). Overall, 20-years
 478 post-fire, the effect of ozone precursors increased the total radiative forcing by roughly 11%. However, this percent
 479 increase drops to 5% after 80 years, and the ozone precursors and aerosols show little effect on the percent reduction
 480 of the total radiative forcing between 20- and 80-years post fire. Therefore, the positive radiative forcing is
 481 sustained by long-lived gaseous emissions, especially carbon dioxide.

482
 483 **Figure 4.** (a) Total cumulative mean radiative forcing of gaseous emissions for three future atmospheric gas
 484 concentration scenarios, and (b) cumulative mean radiative forcing of different emissions (dashed line is net forcing)
 485 under the RCP 4.5 future scenario over 80 years post-fire from the YKD 2015 fire season.
 486

487 **Table 4.** Cumulative mean radiative forcing at 20- and 80- year time horizons post-fire for different gaseous and
 488 aerosol emissions from the 2015 fire season under the RCP 4.5 future scenario. Percent reduction refers to the loss in
 489 radiative forcing when considering an 80-year time horizon compared to 20 years.

	Radiative Forcing ($W m^{-2}$)

490
 491 **4 Discussion**

492 Here we describe a tundra wildfire season that combusted significant amounts of carbon and had a positive
 493 warming effect on the atmosphere due to its gaseous and aerosol emissions over an 80-year time horizon. Our

494 findings suggest that increasingly frequent tundra fire regimes are an under-studied source of global GHG
495 emissions. The 2015 fire season in the YKD represents a large efflux of carbon from a wetland tundra ecosystem,
496 generally not considered to be highly vulnerable to fires. In total, we estimate that about 0.911 Tg of carbon was
497 released from 54,154 hectares of burned area in the YKD. This fire area is roughly three times the 17,000 hectares
498 of tundra area burned on average annually between the years 2001 and 2018 in Alaska, but it only accounts for a
499 little more than half of the 83,000 hectares of Alaskan tundra that burned in the year 2015 (Scholten et al., 2021).
500 Over the same time frame, the 2015 fire season was the largest to burn in the YKD, with the majority of years
501 burning less than 10,000 hectares (Scholten et al., 2021). Total carbon loss was driven by a similar per unit area
502 carbon emission rate as the 2007 Anaktuvuk River fire (Mack et al., 2011), which was roughly twice the size of the
503 fire season reported here and burned predominately moderate to high severity in a tussock tundra ecosystem (Jones
504 et al., 2009). While the current status of tundra ecosystems as a sink or source of carbon remains uncertain, the 2015
505 YKD fire season alone released about a tenth of the carbon sequestered annually from tundra sink estimates
506 (Virkkala et al., 2021). If tundra ecosystems become a source of carbon to the atmosphere under warming,
507 emissions from tundra wildfires may further exacerbate this positive feedback to warming due to a changing balance
508 between respiration and productivity (Natali et al., 2019, Belshe et al., 2013). Note that we did not account for post-
509 fire effects on net ecosystem exchange of CO₂, which tend to be sources to the atmosphere with greater fire severity
510 due to continued soil respiration until sufficient vegetation recovers (Rocha and Shaver 2011a).

511 The tundra fires in the YKD and at Anaktuvuk River both lost roughly 1.7 to 2.0 kg m⁻² of carbon (Mack et
512 al., 2011). Carbon loss per area from these tundra wildfires is within the range of total above- and belowground
513 carbon loss from boreal wildfires, approximately 0.5 to 4 kg m⁻² (Walker et al., 2020a; Walker et al., 2018b; Rogers
514 et al., 2014), and close in value to the median wildfire loss of carbon, 2.54 kg m⁻², across all land cover types in
515 Alaska between 2001 and 2012 (Veraverbeke et al., 2015b). Despite the additional combustion of overstory
516 vegetation in forests, carbon loss in both tundra and boreal systems comes primarily from belowground organic
517 matter (Walker et al., 2020a; Walker et al., 2018b; Rogers et al., 2014). Compared to remote sensing-derived
518 estimates of combustion, our per unit area *in situ* measurements are on the low end but comparable to large-scale
519 means across Alaska between 2001 and 2018 (Fig. A9). However, more representative field measurements in tundra
520 fires are needed to validate remotely sensed combustion measurements, as the currently available gridded products
521 (Potter et al. 2022; Scholten et al. 2021; Veraverbeke et al. 2017a; Veraverbeke et al., 2015a) are driven entirely by

522 measurements in boreal forests. Although data from the Anaktuvuk River and YKD fires shows carbon loss per unit
523 area can be similar between boreal and tundra wildfires, information on carbon emissions from tundra wildfires is
524 substantially more limited than boreal forest studies (He et al., 2021; Veraverbeke et al., 2021).

525 Given a fire return interval in the YKD of over around 200 years (Sae-Lim, 2019), fires there likely do not
526 burn through all the carbon accumulated since the last fire. However, tundra fires may initiate post-fire successional
527 trajectories, such as increased shrub cover, that may promote shorter fire return intervals (Hu et al., 2015; Rocha et
528 al., 2012). Shorter fire return intervals, in turn, gradually deplete the available soil carbon stocks. For example, He
529 et al. (2021) showed current tundra areas with frequent fire have relatively shallow soil organic layers. Moreover,
530 our radiocarbon data show that as fires burn deeper into the tundra, they release older carbon more rapidly because
531 the density of carbon by age increases. Coupling these burn-prone successional trajectories with projected increases
532 in tundra wildfire occurrence over the next century due to more frequent hot and dry conditions (Hu et al., 2015;
533 Rocha et al., 2012; Joly et al., 2012; Hu et al., 2010), as well as increases in lightning (Chen et al., 2021; Bieniek et
534 al., 2020; Veraverbeke et al., 2017b), tundra wildfires may begin to burn carbon of an older age than the historic fire
535 return interval. In this case, some tundra regions may transition into fire-driven carbon sources, similar to what has
536 been observed in North American boreal forests (Walker et al., 2019).

537 Immediate combustion is not the only impact wildfires have on tundra carbon stocks, nor do measures of
538 carbon loss fully describe the effect of wildfire emissions on the climate. Fires drive higher soil temperatures and
539 deeper active layer depths that can persist over multiple decades after fire (He et al., 2021; Hu et al., 2015; Rocha et
540 al., 2012), which is caused by the loss of insulating vegetation and upper soil layers from combustion (Rocha and
541 Shaver, 2011b). Higher soil temperatures and deeper active layer depths may catalyze permafrost degradation and
542 thermokarst development (Jones et al., 2015) that accelerates the effects of climate warming on tundra ecosystems.
543 Tundra fires also emit multiple gaseous and aerosol species, which have a net positive radiative forcing for at least
544 80 years post-fire. Hence, even if all of the carbon lost from fire in a tundra ecosystem were to be sequestered again
545 over time through increased photosynthesis, the long-term radiative impact of gaseous and aerosol emissions would
546 still generate atmospheric warming and thus positive climate feedbacks, which are amplified by the post-fire
547 permafrost thaw and degradation not accounted for in this study.

548 This positive radiative forcing is driven by sustained radiative forcings from long-lived GHGs, as well as
549 significant contributions from short-lived climate forcers (SCLFs) such as ozone, NMVOCs, and CO. Carbon

550 dioxide has the highest radiative forcing at both short and long time horizons because it is emitted in the highest
551 quantity (Akagi et al., 2011) and its concentration decreases relatively slowly over time, especially in the RCP 4.5
552 and 8.5 scenarios (Joos et al., 2013). Aerosols and NO_x are SCLFs with both positive and negative radiative
553 forcings due to distinct mechanisms for affecting the Earth's radiative balance. Aerosols exert a direct radiative
554 forcing by reflecting or absorbing sunlight in the atmosphere and when deposited on high-albedo surfaces, mainly
555 snow and ice (Bond et al., 2011). Although black carbon aerosols have a positive direct radiative forcing effect and
556 organic carbon aerosols have a negative direct radiative forcing effect, the magnitude of black carbon's radiative
557 forcing far exceeds that from organic carbon (Myhre et al., 2013) (note these are combined in our representation).
558 Indirectly, aerosols serve as the nuclei for cloud formation, which increases the Earth's albedo and exerts a negative
559 radiative forcing (Ward et al., 2012). Nitrogen oxides have a near-term positive radiative forcing because they act in
560 concert with NMVOCs and CO to increase ozone concentrations, yet they have a long-term negative radiative
561 forcing because they decrease the lifetime of CH₄ (Collins et al., 2013).

562 We include a total radiative forcing with and without aerosols and ozone precursors, CO, NMVOCs, and
563 NO_x. The radiative forcing of these ozone precursors and aerosols is uncertain within current literature, especially
564 when originating in the Arctic, because of their short atmospheric lifetimes and dependence on regional transport
565 patterns (Bond et al., 2011, Quinn et al., 2008). However, the long-term cumulative radiative effect of these gaseous
566 emissions is relatively minimal in comparison to the long-lived GHGs and ozone, and both estimates of total
567 radiative forcing are of the same order of magnitude as previous estimates of the radiative forcing of gaseous
568 emissions from boreal forest fires (Huang et al., 2016; O'Halloran et al., 2012).

569 We found that as the predicted concentration of future emissions increases across RCP scenarios
570 (Meinshausen et al., 2011), the net radiative forcing of gaseous and aerosol emissions from the fires decreases
571 slightly. Although counterintuitive, this result is due to the dependency of the radiative forcing equations for long-
572 lived GHGs, namely CO₂, CH₄, and N₂O, on the ambient concentration of a gas. In more extreme future climate
573 scenarios, the atmosphere generally has higher concentrations of these GHGs, meaning the additional quantity of gas
574 emitted by fire has a more diluted effect. This effect is largely counter balanced by the fact that land and ocean CO₂
575 sink capacities are diminished in more extreme future climate scenarios, leading to longer atmospheric CO₂ lifetimes
576 (Fig. A10). The net result is that tundra wildfires have a relatively similar positive radiative forcing under all future
577 emissions scenarios.

578 While the positive radiative forcing due to gaseous emissions we calculate for the 2015 YKD fire season is
579 within the range of previously calculated radiative forcings for gaseous emissions from boreal wildfires (e.g., Huang
580 et al., 2016, Randerson et al., 2006), boreal forests also have significant multi decadal post-fire albedo changes due
581 predominantly to the combustion of overstory trees that expose snow in the fall, winter, and spring (Lyons et al.,
582 2008). Randerson et al. (2006) and O’Halloran et al. (2012) show that the negative radiative forcing of these albedo
583 changes can exceed the positive radiative forcing of gaseous emissions and generate a net cooling effect for boreal
584 forest fires over long time horizons in specific locations. It should be noted, however, that (i) the net cooling or
585 warming is heavily dependent on combustion levels, pre-fire canopy composition, and time horizon; (ii) fire-induced
586 albedo forcings predominantly impact the regional climate (Rogers et al., 2013), as opposed to globally-mixed
587 GHGs; and (iii) this cooling impact is expected to diminish with future climate change due to decreases in spring
588 snow cover (Potter et al., 2020).

589 In contrast, tundra ecosystems lack an overstory, and hence fires generate relatively short-lived decreases in
590 albedo (Rocha et al., 2012, French et al., 2016). These albedo changes are only caused by char and the exposed soil
591 surface in the summer because tundra vegetation rarely exists above the snow layer (Mack et al., 2011). As a result,
592 within four years after the Anaktuvuk River fire, low post-fire surface albedo recovered to its pre-fire reflectance as
593 the vegetation grew over the charred soil surface (French et al., 2016; Rocha and Shaver, 2011b). The decreased
594 surface reflectance contributes to increases in soil temperature and thaw depth after fire (Rocha and Shaver 2011b).
595 Therefore, the positive radiative forcing caused by tundra wildfire gaseous and aerosol emissions is not offset by
596 post-fire albedo changes as seen in boreal forest fires. From 2001 to 2018 about 0.5 Mha of boreal forest burned on
597 average yearly compared to a yearly average of 0.017 Mha of tundra in Alaska (Scholten et al., 2021). Given
598 potentially comparable per area emissions from boreal and tundra fires, boreal fires still release more carbon
599 globally. However, the predicted increase in frequency of tundra wildfires, their lack of cooling from post-fire
600 albedo, and their contribution to increased permafrost thaw highlights their importance to climate change processes.

601 For the purpose of calculating the radiative forcing of wildfires in future research, we make our
602 computational code available on Github (see Code and Data Availability section). Our workflow is applicable to
603 wildfires in other arctic-boreal ecosystems, and it could be applied to any ecosystem globally with the adjustment of
604 emissions factors for the specific material burning (Akagi et al., 2011) and global warming potentials for SCLFs
605 based on the geographic region of the wildfire (Myhre et al., 2013). As a result, our method of calculating the

606 radiative forcing of wildfires can be used for studies across multiple regions with the appropriate parameters, which
607 can advance a more complete understanding of the effects of wildfires on the climate.

608 Future work could clarify some of the uncertainties that were not explicitly analyzed in our final estimates
609 of carbon loss and radiative forcing. We did not account for combustion of aboveground tall woody vegetation in
610 our estimates of carbon loss from the YKD fires. Although woody biomass is relatively sparse on the YKD
611 landscape, it represents an additional source of carbon from combustion (for boreal forest fires, see Walker et al.,
612 2020c). Despite the lack of difference we found between soil and vegetation matter characteristics across vegetative
613 reference point groups, there could have been variation in these characteristics outside of the primarily peat plateau
614 areas that we sampled. Burn depth estimated between *Dicranum* reference points was more variable (although not
615 significantly different) than burn depth estimated between *Sphagnum* reference points. This variation could indicate
616 more variable burn dynamics around *Dicranum* or better efficacy of *Dicranum* for measuring extreme burn depths,
617 which highlights the potential bias introduced by choosing specific combustion markers. Likewise, we eliminated
618 tussock measurements from our final analysis because they were relatively scarce on the landscape and yielded
619 inconsistent results, perhaps due to burn dynamics around tussocks that remain obscure using our combustion
620 measurement method. Minimizing potential bias by identifying combustion markers and soil characteristics for
621 different land cover types at a higher resolution within a fire, similar to how different combustion markers are used
622 regionally (Walker et al., 2020c; Mack et al., 2011; Boby et al., 2010) would further improve estimates of carbon
623 loss following wildfire in tundra systems.

624 Our assignment of low, moderate, and high severity was based on our particular collection of field
625 measurements and therefore may not translate well to other fire complexes. While dNBR is widely used to assess
626 fire severity, its accuracy in high latitude tundra systems may be diminished by environmental and methodological
627 factors, such as the timing of image selection and rapid post-fire greening (Chen et al., 2020a, Loboda et al., 2013).
628 Other remotely sensed products have shown promise in tundra (e.g., Chen et al., 2020b), but the applicability of
629 these results to other tundra systems remains to be explored. Within low severity areas, there were likely patches of
630 unburned tundra, potentially leading us to overestimate organic matter and carbon loss measurements. We also used
631 a relatively simple method for extrapolating emissions based on fire severity. More involved techniques such as
632 relating mechanism-based geospatial predictors to field plots using statistical techniques and machine learning,
633 which has been employed for boreal forests in Alaska and Canada (Dieleman et al., 2020; Walker et al., 2018b;

634 Veraverbeke et al., 2015b; Rogers et al., 2014), would likely yield more robust estimates for regional emissions. In
635 this context, we strongly recommend increasing the number of tundra fire carbon emission observations in different
636 regions to facilitate synthesis and biome-wide modeling, as has been done for boreal forests (Walker et al., 2020c;
637 Walker et al., 2020b; Walker et al., 2020a).

638 Our radiative forcings model uses data and algorithms from multiple previous studies, including for
639 emissions factors (Akagi et al., 2011), RCP scenarios (Meinshausen et al., 2011), GWPs (Myhre et al., 2013), ozone
640 and CO concentration ratios (Jaffe and Widger, 2012), and aerosol direct and indirect effects (Ward et al., 2012), all
641 of which may not be geographically, biologically, or temporally specific to the YKD fires. These factors are also
642 known to be variable depending on fuel types, fire severity and lifetime, and atmospheric dynamics at the time of
643 and following fire (e.g., Wiggins et al., 2016; Jaffe and Widger, 2012; Chen et al., 2009). Since emissions factors
644 for tundra burning were not available, we used emissions factors for burning boreal vegetation. Using boreal
645 emissions factors may overestimate emissions from woody vegetation in tundra and thereby increase the mass of
646 certain gasses released. Future research could also integrate the range of variation associated with emission factors
647 to quantify the uncertainty they introduce into radiative forcing estimates. Furthermore, our model does not include
648 the potential mitigating or exacerbating effects of post-fire ecosystem changes on gas concentrations, such as
649 changes in post-fire vegetation (Frost et al., 2020; Zhou et al., 2019; Barrett et al., 2012), increased soil respiration
650 (Rocha and Shaver, 2011a), and increased active layer depths and permafrost degradation (Holloway et al., 2020;
651 Jafarov et al., 2013; Rocha et al., 2012). With reparameterizations specific to individual fires, our model could be
652 made more accurate for future work.

653 **5 Conclusions**

654 To our knowledge, our study is the first to account for both carbon loss and radiative forcing from tundra
655 wildfires. We develop a method that pairs *in situ* measurements of combustion levels from local pre-fire reference
656 points with remotely sensed burn severity data to scale organic matter and carbon loss to the entire fire area. Our
657 estimate of the radiative forcing of gaseous and aerosol emissions from the fire event suggests that tundra wildfires
658 positively reinforce climate warming; however, the role of post-fire vegetative regeneration in mitigating these
659 carbon emissions remains unknown. Our results stress the importance of considering tundra wildfires in assessing
660 climate feedbacks and the need for future research that more explicitly discerns the warming effect of fires across
661 the tundra biome.

Figure A10. The radiative forcing of CO₂ emitted from the 2015 YKD fire season for RCP 4.5 (a) and 8.5 (b) when (i) holding the emission constant (red lines) so that no emitted CO₂ is sequestered, (ii) holding the background atmospheric concentration constant (green lines), and (iii) the combination of these, resulting in our main CO₂ radiative forcing equation (blue lines; Eq. 7). In the case of (i, red lines), increasing atmospheric CO₂ concentrations dampen the radiative impact of fire-emitted CO₂. In the case of (ii, green lines), the only time-varying impact on CO₂ radiative forcing is ocean and land sinks, which become less effective and even reverse with more extreme climate change according to model results presented in Joos et al. (2013). These lines are similar to the impulse response function of CO₂ for their respective scenarios in Joos et al. (2013).

741 **Code and Data Availability**

742 The radiative forcings calculation code is available on GitHub and Zenodo via DOI: 10.5281/zenodo.6617455
743 (Moubarak, 2022). All field and lab raw data used in this study, including vegetative reference point height
744 measurements and soil and vegetation core metrics, and combustion data products derived from our calculations are
745 publicly available in the NSF Arctic Data Center via DOI:10.18739/A2PR7MV5P (Moubarak et al., 2020).

746 **Author Contributions**

747 MM, BR, SS, and SN were involved with conceptualization, funding acquisition, and methodology. SP completed
748 investigation of burn severity data and jointly completed visualization with MM. MM, SS, and BR did investigation
749 of burn depth measurements and soil and vegetation characteristics. MM analyzed data and developed the radiative
750 forcings model. SS and SN did project administration for the field sampling. MM curated data and wrote the
751 original manuscript draft. MM, BR, SS, SP, and SN reviewed and edited the final published work.

752 **Competing Interests**

753 The authors declare that they have no conflict of interest.

754 **Acknowledgements**

755 This work was funded by the National Science Foundation (NSF-1915307 to SMN, NSF-1915307 to SS),
756 Casstevens Family Fund (to MM), and the National Aeronautics and Space Administration (NASA) Arctic-Boreal
757 Vulnerability Experiment (ABoVE; NNX15AU56A to BR) and the Gordon and Betty Moore Foundation (8414 to
758 SMN and BR). The authors would like to thank Dr. William Pfitsch for his helpful mentorship in the synthesis of
759 this project and creation of the written work. Also, the authors would like to thank Dr. Catherine Beck for offering
760 her knowledge about radiocarbon sample preparation and analysis.
